## Dedication

*With love and thanks to my family,  
and especially my father Goodman  
Tasman, for your inspiration and  
support.*

**Allan**

*To Rena, Jonathan, Rachel, and  
Sarah with appreciation for all that  
you have given me.*

**Jerry**

# Table of Contents

---

Preface ix

Acknowledgements xi

**Part One Approaches to the Patient 1**

Chapter 1 Listening to the Patient 3

Chapter 2 The Cultural Context of Clinical Assessment 20

Chapter 3 The Psychiatric Interview: Settings and Techniques 30

Chapter 4 Physician–Patient Relationship 51

Chapter 5 Professional Ethics and Boundaries 60

Chapter 6 Law, Ethics and Psychiatry 73

**Part Two A Developmental Perspective on Normal Domains of Mental and Behavioral Function 91**

Chapter 7 A Psychiatric Perspective on Human Development 93

Chapter 8 Psychopathology Across the Life-Cycle 109

**Part Three Scientific Foundations of Psychiatry 119**

Chapter 9 Psychiatric Epidemiology 121

Chapter 10 Psychiatric Pathophysiology: Schizophrenia 131

Chapter 11 Psychiatric Pathophysiology: Mood Disorders 136

Chapter 12 Psychiatric Pathophysiology: Anxiety Disorders 143

Chapter 13 Psychiatric Pathophysiology: Addiction 149

Chapter 14 Psychiatric Pathophysiology: Dementia 154

Chapter 15 Cognitive Neuroscience and Neuropsychology 159

Chapter 16 Cognitive Psychology: Basic Theory and Clinical Implications 174

Chapter 17 Social Psychology 182

Chapter 18 Psychoanalytic Theories 199

**Part Four Manifestations and Assessments of Psychiatric Illness 213**

Chapter 19 Clinical Evaluation and Treatment Planning: A Multimodal Approach 215

Chapter 20 Behavior and Adaptive Functioning 240

Chapter 21 Cultural Aspects of Psychiatric Disorders 250

**Part Five Disorders 261**

Chapter 22 Psychiatric Classification 263

Chapter 23 Diagnostic Classification in Infancy and Early Childhood 278

Chapter 24 Childhood Disorders: Mental Retardation 285

Chapter 25 Childhood Disorders: Learning and Motor Skills Disorders 294

Chapter 26 Childhood Disorders: Communication Disorders 300

Chapter 27 Childhood Disorders: The Autism Spectrum Disorders 308

Chapter 28 Childhood Disorders: Attention-deficit and Disruptive Behavior Disorders 321

Chapter 29 Childhood Disorders: Feeding and Other Disorders of Infancy or Early Childhood 331

Chapter 30 Childhood Disorders: Tic Disorders 341

Chapter 31 Childhood Disorders: Elimination Disorders and Childhood Anxiety Disorders 353

Chapter 32 Delirium and Dementia 365

Chapter 33 Mental Disorders Due to a General Medical Condition 392

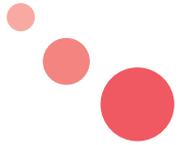

Chapter 34 General Approaches to Substance and Polydrug Use Disorders 409

Chapter 35 Substance Abuse: Alcohol Use Disorders 414

Chapter 36 Substance Abuse: Caffeine Use Disorders 431

Chapter 37 Substance Abuse: Cannabis-related Disorders 438

Chapter 38	Substance Abuse: Cocaine Use Disorders	451	Chapter 64	Medication-induced Movement Disorders	823
Chapter 39	Substance Abuse: Phencycline Use Disorders	458	Chapter 65	Relational Problems	838
Chapter 40	Substance Abuse: Hallucinogen- and MDMA-Related Disorders	462	<b>Part Six</b>	<b>Therapeutics</b>	<b>843</b>
Chapter 41	Substance Abuse: Inhalant-related Disorders	468	Chapter 66	Individual Psychoanalytic Psychotherapy	845
Chapter 42	Substance Abuse: Nicotine Dependence	471	Chapter 67	Group Psychotherapy	855
Chapter 43	Substance Abuse: Opioid Use Disorders	478	Chapter 68	Time-limited Psychotherapy(Including Interpersonal Therapy)	863
Chapter 44	Substance Abuse: Sedative, Hypnotic, or Anxiolytic Use Disorders	487	Chapter 69	Cognitive and Behavioral Therapies	872
Chapter 45	Schizophrenia and Other Psychoses	495	Chapter 70	Family Therapy	886
Chapter 46	Mood Disorders: Depression	533	Chapter 71	Couples Therapy	894
Chapter 47	Mood Disorders: Bipolar (Manic–Depressive) Disorders	556	Chapter 72	Hypnosis	903
Chapter 48	Mood Disorders: Premenstrual Dysphoric Disorder	573	Chapter 73	Psychosocial Rehabilitation	916
Chapter 49	Anxiety Disorders: Panic Disorder With and Without Agoraphobia	578	Chapter 74	Electroconvulsive Therapy, Transcranial Magnetic Stimulation, and Vagal Nerve Stimulation	922
Chapter 50	Anxiety Disorders: Social and Specific Phobias	588	Chapter 75	Neurosurgery for Treatment-Refractory Psychiatric Disorders: Obsessive–Compulsive Disorder and Major Depressive Disorder	931
Chapter 51	Obsessive–Compulsive Disorder	607	Chapter 76	Ethnic and Cultural Perspectives in Psychopharmacology	937
Chapter 52	Anxiety Disorders: Traumatic Stress Disorders	627	Chapter 77	Antipsychotic Drugs	944
Chapter 53	Anxiety Disorders: Generalized Anxiety Disorder	639	Chapter 78	Mood Stabilizers	957
Chapter 54	Somatoform Disorders	654	Chapter 79	Antidepressants	964
Chapter 55	Factitious Disorders	679	Chapter 80	Anxiolytic Drugs	983
Chapter 56	Dissociative Disorders	685	Chapter 81	Sedative–Hypnotic Agents	989

# Preface

---

*Essentials of Psychiatry* is a synopsis of the 2400 page *Psychiatry Second Edition* also published by John Wiley and Sons. *Psychiatry* has received exceptional reviews in the leading medical and psychiatric journals within the United States and abroad. *Essentials of Psychiatry* provides a broad overview to clinical psychiatry for beginning psychiatry residents, nonpsychiatric physicians, medical students, and people working in related mental health disciplines such as psychology, social work, psychiatric nursing and counseling. We hope that family members of patients may find this abbreviated text accessible and helpful as well. *Essentials of Psychiatry* differs from the comprehensive two-volume text in that it does not include such an extensive discussion of the neural and social sciences that underlie the practice of psychiatry.

The 112 chapters by more than 270 authors of the *Psychiatry Second Edition* have been condensed by approximately 50% for this new book. All chapters have been updated to include the latest advances in psychopharmacology, psychopathology and psychosocial treatment. Clinical vignettes, as well as DSM-IV™

and ICD 10 related material, have been retained from the original book to preserve an international scope. As indicated in the initial chapters of the *Essentials*, we have also maintained the focus on the centrality of the doctor–patient relationship.

The challenge of condensing a text as large as *Psychiatry Second Edition* was daunting. We are indebted to all of our colleagues who wrote for the original work. We pay homage to these authors at the start of this book. Since the two of us reviewed all 112 chapters, we accept responsibility for any omissions. We are also indebted to those who provided strong support for this effort. At Wiley, this included our editor Deborah Russell and her associate Andrea Baier. In Dr Kay's and Dr Tasman's offices, Edward Depp and Joan Lucas, respectively, were invaluable to the completion of this project.

JERALD KAY, MD

ALLAN TASMAN, MD

# Approaches to the Patient

---

# Listening to the Patient

## Listening: The Key Skill in Psychiatry

It was Freud who raised the psychiatric technique of examination – listening – to a level of expertise unexplored in earlier eras. As Binswanger (1963) has said of the period prior to Freudian influence: psychiatric “auscultation” and “percussion” of the patient was performed as if through the patient’s shirt with so much of his essence remaining covered or muffled that layers of meaning remained unpeeled away or unexamined.

This metaphor and parallel to the cardiac examination is one worth considering as we first ask if listening will remain as central a part of psychiatric examination as in the past. The explosion of biomedical knowledge has radically altered our evolving view and practice of the doctor–patient relationship. Physicians of an earlier generation were taught that the diagnosis is made at the bedside – that is, the history and physical examination are paramount. Laboratory and imaging (radiological, in those days) examinations were seen as confirmatory exercises. However, as our technologies have blossomed, the bedside and/or consultation room examinations have evolved into the method whereby the physician determines what tests to run, and the tests are often viewed as making the diagnosis. A cardiologist colleague expresses the opinion that, given the growing availability of non-invasive tests – echocardiograms, for example – he is not sure this is a bad thing (Hillis, 2001, personal communication).

So can one imagine a time in the not-too-distant future when the psychiatrist’s task will be to identify that the patient is psychotic and then order some benign brain imaging study which will identify the patient’s exact disorder?

Perhaps so, but will that obviate the need for the psychiatrist’s special kind of listening? Indeed, there are those who claim that psychiatrists should no longer be considered experts in the doctor–patient relationship (where expertise is derived from their unique training in listening skills) but experts in the brain (Nestler, 1999, personal communication). As we come truly to understand the relationship between brain states and subtle cognitive, emotional, and interpersonal states, one could also ask if this is a distinction that really makes a difference. On the other hand, the psychiatrist will always be charged with finding a way to relate effectively to those who cannot effectively relate to themselves or to others. There is something in the treatment of individuals whose illnesses express themselves through disturbances of thinking, feeling, perceiving and behaving that will always demand special expertise in establishing a therapeutic relationship – and that is dependent on special expertise in listening.

### Clinical Vignette 1

A 28-year-old white married man suffering from paranoid schizophrenia and obsessive–compulsive disorder did extremely well in the hospital, where his medication had been changed to clozapine with good effects. But he rapidly deteriorated on his return home. It was clear that the ward milieu had been a crucial part of his improvement, so partial hospitalization was recommended. The patient demurred, saying he didn’t want to be a “burden”. The psychiatrist explored this with the patient and his wife. Beyond the obvious “burdens” of cost and travel arrangements, the psychiatrist detected the patient’s striving to be autonomously responsible for handling his illness. By conveying a deep respect for that wish, and then educating the already insightful patient about the realities of “bearing schizophrenia”, the psychiatrist was able to help the patient accept the needed level of care.

Traditionally, this kind of listening has been called “listening with the third ear” (Reik, 1954). Other efforts to label this difficult-to-describe process have developed other terms: the interpretive stance, interpersonal sensitivity, the narrative perspective (McHugh and Slavney, 1986). All psychiatrists, regardless of theoretical stance, must learn this skill and struggle with how it is to be defined and taught. The biological or phenomenological psychiatrist listens for subtle expressions of symptomatology; the cognitive–behavioral psychiatrist listens for hidden distortions, irrational assumptions, or global inferences; the psychodynamic psychiatrist listens for hints at unconscious conflicts; the behaviorist listens for covert patterns of anxiety and stimulus associations; the family systems psychiatrist listens for hidden family myths and structures.

This requires sensitivity to the storyteller, which integrates a patient orientation complementing a disease orientation. The listener’s intent is to uncover what is wrong and to put a label on it. At the same time, the listener is on a journey to discover who the patient is, employing tools of asking, looking, testing and clarifying. The patient is invited to collaborate as an active informer. Listening work takes time, concentration, imagination, a sense of humor, and an attitude that places the patient as the hero of his or her own life story. Key listening skills are listed in Table 1.1.

The enduring art of psychiatry involves guiding the depressed patient, for example, to tell his or her story of loss in addition to having him or her name, describe, and quantify symptoms

**Table 1.1 Key Listening Skills**

Hearing	Connotative meanings of words Idiosyncratic uses of language Figures of speech that tell a deeper story Voice tones and modulation (e.g., hard edge, voice cracking) Stream of associations
Seeing	Posture Gestures Facial expressions (e.g., eyes watering, jaw clenched) Other outward expressions of emotion
Comparing	Noting what is omitted Dissonances between modes of expression
Intuiting	Attending to one's own internal reactions
Reflecting	Thinking it all through outside the immediate pressure to respond during the interview

of depression. The listener, in hearing the story, experiences the world and the patient from the patient's point of view and helps carry the burden of loss, lightening and transforming the load. In hearing the sufferer, the depression itself is lifted and relieved. The listening is healing as well as diagnostic. If done well, the listener becomes a better disease diagnostician. The best listeners hear both the patient and the disease clearly, and regard every encounter as potentially therapeutic.

### The Primary Tools: Words, Analogies, Metaphors, Similes and Symbols

To listen and understand requires that the language used between the speaker and the hearer be shared – that the meanings of words and phrases are commonly held. Common language is the predominant factor in the social organization of humanity (Chomsky, 1972) and is probably the single most important key to the establishment of an active listener/engaged storyteller dyad which the helping alliance represents. Indeed, the Sapir-Whorf hypothesis suggests that what we are able to think is limited/determined by the language with which we are working (Carroll and Whorf, 1956; Sapir, 2000). Patients are storytellers who have the hope of being heard and understood (Edelson, 1993). Their hearers are physicians who expect to listen actively and to be with the patient in a new level of understanding. Because all human beings listen to so many different people every day, we tend to think of listening as an automatic ongoing process, yet this sort of active listening remains one of the central skills in clinical psychiatry. It underpins all other skills in diagnosis, alliance building and communication. In all medical examinations, the patient is telling a story only she or he has experienced. The physician must glean the salient information and then use it in appropriate ways. Inevitably, even when language is common, there are subtle differences in meanings, based upon differences in gender, age, culture, religion, socioeconomic class, race, region of upbringing, nationality and original language, as well as the idiosyncrasies of individual history. These differences are particularly important to keep in mind in the use of analogies,

similes and metaphors. Figures of speech, in which one thing is held representational of another by comparison, are very important windows to the inner world of the patient. Differences in meanings attached to these figures of speech can complicate their use. In psychodynamic assessment and psychotherapeutic treatment, the need to regard these subtleties of language becomes the self-conscious focus of the psychiatrist, yet failure to hear and heed such idiosyncratic distinctions can affect simple medical diagnosis as well.

#### Clinical Vignette 2

A psychiatric consultant was asked to see a 48-year-old man on a coronary care unit for chest pain deemed “functional” by the cardiologist who had asked the patient if his chest pain was “crushing”. The patient said no. A variety of other routine tests were also negative. The psychiatrist asked the patient to describe his pain. He said, “It’s like a truck sitting on my chest, squeezing it down”. The psychiatrist promptly recommended additional tests which confirmed the diagnosis of myocardial infarction. The cardiologist may have been tempted to label the patient a “bad historian”, but the most likely culprit of this potentially fatal misunderstanding lies in the connotative meanings each ascribed to the word “crushing” or to other variances in metaphorical communication.

In psychotherapy, the special meanings of words become the central focus of the treatment.

#### Clinical Vignette 3

A psychiatrist had been treating a 35-year-old man with a narcissistic personality and dysthymic disorder for 2 years. Given the brutality and deprivation of the patient's childhood, the clinician was persistently puzzled by the patient's remarkable psychological strengths. He possessed capacities for empathy, self-observation, and modulation of intense rage that were unusual, given his background. During a session the patient, in telling a childhood story, began, “When I was a little fella...”. It struck the psychiatrist that the patient always said “little fella” when referring to himself as a boy, and that this was fairly distinctive phraseology. Almost all other patients will say, “When I was young/a kid/a girl (boy)/in school”, designate an age, etc. On inquiry about this, the patient immediately identified “The Andy Griffith Show” as the source. This revealed a secret identification with the characters of the TV show, and a model that said to a young boy, “There are other ways to be a man than what you see around you”. Making this long-standing covert identification fully conscious was transformative for the patient.

### How Does One Hear Words in This Way?

The preceding clinical vignettes, once described, sound straightforward and easy. Yet, to listen in this way the clinician must acquire specific yet difficult-to-learn skills and attitudes. It is extremely difficult to put into words the listening processes

embodied in these examples and those to follow, yet that is what this chapter must attempt to do.

Students, when observing experienced psychiatrists interviewing patients, often express a sense of wonder such as: “How did she know to ask that?” “Why did the patient open up with him but not with me?” “What made the diagnosis so clear in that interview and not in all the others?” The student may respond with a sense of awe, a feeling of ineptitude and doubt at ever achieving such facility, or even a reaction of disparagement that the process seems so indefinable and inexact. The key is the clinician’s ability to listen. Without a refined capacity to hear deeply, the chapters on other aspects of interviewing in this textbook are of little use. But it is neither mystical nor magical nor indefinable (though it is very difficult to articulate); such skills are the product of hard work, much thought, intense supervision, and extensive in-depth exposure to many different kinds of patients.

Psychiatrists, more than any other physicians, must simultaneously listen symptomatically and narratively/experientially. They must also have access to a variety of theoretical perspectives that effectively inform their listening. These include behavioral, interpersonal, cognitive, sociocultural and systems theories. Symptomatic listening is what we think of as traditional medical history taking, in which the focus is on the presence or absence of a particular symptom, the most overt content level of an interview. Narrative–experiential listening is based on the idea that all humans are constantly interpreting their experiences, attributing meaning to them, and weaving a story of their lives with themselves as the central character. This process goes on continuously, both consciously and unconsciously, as a running conversation within each of us. The conversation is between parts of ourselves and between ourselves and what Freud called “internalized objects”, important people in our lives whose images, sayings, and attitudes become permanently laid down in our memories. This conversation and commentary on our lives includes personal history, repetitive behaviors, learned assumptions about the world and interpersonal roles. These are, in turn, the products of individual background, cultural norms and values, national identifications, spiritual meanings and family system forces.

#### Clinical Vignette 4

A 46-year-old man was referred to a psychiatrist from a drug study. The patient had both major depression and dysthymic disorder since a business failure 2 years earlier. His primary symptoms were increased sleep, decreased mood, libido, energy and interests. After no improvement during the “blind” portion of the study, he had continued to show little response once the code was broken, and he was treated with two different active antidepressant medications. He was referred for psychotherapy and further antidepressant trials. The therapy progressed slowly with only episodic improvement. One day, the patient reported that his wife had been teasing him about how, during his afternoon nap, his snoring could be heard over the noise of a vacuum cleaner. The psychiatrist immediately asked additional questions, eventually obtained sleep polysomnography and, after appropriate treatment for sleep apnea, the patient’s depression improved dramatically.

It seems that three factors were present that enabled the psychiatrist in the above vignette to listen well and identify an unusual diagnosis that had been missed by at least three other excellent clinicians who had all been using detailed structured interviews that were extremely inclusive in their symptom reviews. First, the psychiatrist had to have readily available in mind all sorts of symptoms and syndromes. Secondly, he had to be in a curious mode. In fact, this clinician had a gnawing sense that something was missing in his understanding of the patient. There is a saying in American medicine designed to focus students on the need to consider common illnesses first, while not totally ignoring rarer diseases: when you hear hoofbeats in the road, don’t look first for zebras. We would say that this psychiatrist’s mind was open to seeing a “zebra” despite the ongoing assumption that the weekly “hoofbeats” he had been hearing represented the everyday “horse” of clinical depression. Finally, he had to hear the patient’s story in multiple, flexible ways, including the possibility that a symptom may be embedded in it, so that a match could be noticed between a detail of the story and a symptom. Eureka! The zebra could then be seen although it had been standing there every week for months.

Looking back at Clinical Vignette 3, we see the same phenomenon of a detail leaping out as a significant piece of missing information that dramatically influences the treatment process. To accomplish this requires a cognitive template (symptoms and syndromes; developmental, systemic and personality theories; awareness of cultural perspectives), a searching curious stance, and flexible processing of the data presented. If one is able to internalize the skills listed in Table 1.1, the listener begins automatically to hear the meanings in the words.

### Listening as More Than Hearing

Listening and hearing are often equated in many people’s minds. However, listening involves not only hearing and understanding the speaker’s words, but attending to inflection, metaphor, imagery, sequence of associations and interesting linguistic selections. It also involves seeing – movement, gestures, facial expressions, subtle changes in these – and constantly comparing what is said with what is seen, looking for dissonances, and comparing what is being said and seen with what was previously communicated and observed. Further, it is essential to be aware of what might have been said but was not, or how things might have been expressed but were not. This is where clues to idiosyncratic meanings and associations are often discovered. Sometimes, the most important meanings are embedded in what is conspicuous by its absence.

It was Darwin (1955) who first observed that there appears to be a biogrammar of primary emotions that all humans share and express in predictable, fixed action patterns. The meaning of a smile or nod of the head is universal across disparate cultures. This insight was lost until the late 1960s when several researchers from different fields (Tiger and Fox, 1971; Tomkins and McCarter, 1964) returned to it and demonstrated empirically the cross-cultural consistency of emotional expression. LeDoux (1996) has been a leader in identifying the neurobiological substrate for these primary emotions. Leslie Brothers (1989), using this work and her own experiments with primates, developed a hypothesis about the biology of empathy based on seeing as well as hearing. Both she and Damasio (1994) have identified the amygdala and the inferior temporal lobe gyrus as the neurobiological

substrate for recognition of and empathy for others and their emotional states. Further research has identified that these parts of the brain are, on the one hand, predicated to recognizing certain gestures, facial expressions, and so on, but require effective maternal–infant interaction in order to do so (Schore, 2001). The “gleam in the mother’s eye” of Mahler and colleagues (1975) is literally translated into the reflection of the mother’s fovea as she gazes at her infant, stimulating the nondominant orbital frontal cortex which, in turn, completes the key temporal circuits.

All of this is synthesized in the listener as a “sense” or intuition as to what the speaker is saying at multiple levels. The availability of useful cognitive templates and theories enables the listener to articulate what is heard.

#### Clinical Vignette 5

A 38-year-old Hispanic construction worker presented himself to a small-town emergency department in the Southwest, complaining of pain on walking, actually described in Spanish-accented English as “a little pain”. His voice was tight, his face was drawn, and his physical demeanor was burdened and hesitant. His response to the invitation to walk was met by a labored attempt to walk without favor to his painful limb. A physician could have discharged him from the emergency department with a small prescription of ibuprofen. The careful physician in the emergency department responded to the powerful visual message that he was in pain, was beaten down by it, and had suffered long before coming in. This recognition came first to the physician as an intuition that this man was somehow more sick than he made himself sound. A radiograph of the femur revealed a lytic lesion that later proved to be metastatic renal cell carcinoma. To hear the unspoken, one had to be keenly aware of the patient’s tone and how he looked, and to keep in mind, too, the cultural taboos forbidding him to give in to pain or to appear to need help.

As has been implied, not only must one affirmatively “hear” all that a patient is communicating, one must overcome a variety of potential blocks to effective listening.

### Common Blocks to Effective Listening

Many factors influence the ability to listen. Psychiatrists come to the patient as the product of their own life experiences. Does the listener tune in to what he or she hears in a more attentive way if the listener and the patient share characteristics? What blocks to listening (Table 1.2) are posed by differences in sex, age, religion, socioeconomic class, race, culture, or nationality (Kleinman, 2001; Comas-Diaz and Jacobsen, 1991; Kochman, 1991)? What blind spots may be induced by superficial similarities in different personal meanings attributed to the same cultural symbol? Separate and apart from the differences in the development of empathy when the dyad holds in common certain features, the act of listening is inevitably influenced by similarities and differences between the psychiatrist and the patient.

Would a woman have reported the snoring in Clinical Vignette 4 or would she have been too embarrassed? Would she have reported it more readily to a woman psychiatrist? What about the image in Clinical Vignette 2 of a truck sitting on someone’s chest? How gender and culture bound is it? Would “The

**Table 1.2** Blocks to Effective Listening

Superficial similarities	May lead to incorrect assumptions of shared meanings
Countertransference	Psychiatrist fails to hear or reacts inappropriately to content reminiscent of own unresolved conflicts
External forces	Managed care setting Emergency department Control-oriented inpatient unit
Attitudes	Need for control Psychiatrist having a bad day

Andy Griffith Show”, important in Clinical Vignette 3, have had the same impact on a young African-American boy that it did on a Caucasian one? In how many countries is “The Andy Griffith Show” even available, and in which cultures would that model of a family structure seem relevant? Suppose the psychiatrist in that vignette was not a television viewer or had come from another country to the USA long after the show had come and gone? (Roughly 50% of current residents in psychiatry in the USA are foreign born and trained [American Psychiatric Association, 2001].) Consider these additional examples.

#### Clinical Vignette 6

A female patient came to see her male psychiatrist for their biweekly session. Having just been given new duties on her job, she came in excitedly and began sharing with her therapist how happy she was to have been chosen by her male supervisor to help him with a very important project at their office. The session continued with the theme of the patient’s pride in having been recognized for her attributes, talents and hard work. At the next session, she said that she had become embarrassed after the previous session at the thought that she had been “strutting her stuff”. The therapist reflected back to her the thought that she sounded like a rooster strutting his stuff, connecting her embarrassment at having revealed that she strove for the recognition and power of men in her company, and that she, in fact, envied the position of her supervisor. The patient objected to the comparison of a rooster, and likened it more to feeling like a woman of the streets strutting her stuff. She stated that she felt like a prostitute being used by her supervisor. The psychiatrist was off the mark by missing the opportunity to point out in the analogous way that the patient’s source of embarrassment was in being used, not so much in being envious of the male position.

It is likely that different life experiences based on gender fostered this misunderstanding. How many women easily

identify with the stereotyped role of the barnyard rooster? How many men readily identify with the role of a prostitute? These are but two examples of the myriad different meanings our specific gender may incline us towards. Although metaphor is a powerful tool in listening to the patient, cross-cultural barriers pose potential blocks to understanding.

---

#### Clinical Vignette 7

A 36-year-old black woman complained to her therapist (of the same language, race, and socioeconomic class) that her husband was a snake, meaning that he was no good, treacherous, a hidden danger. The therapist, understanding this commonly held definition of a snake, reflected back to the patient pertinent, supportive feedback concerning the care and caution the patient was exercising in divorce dealings with the husband.

In contrast, a 36-year-old Chinese woman, fluent in English, living in her adopted country for 15 years and assimilated to Western culture, represented her husband to her Caucasian, native-born psychiatrist as being like a dragon. The therapist, without checking on the meaning of the word “dragon” with her patient, assumed it connoted danger, one of malicious intent and oppression. The patient, however, was using “dragon” as a metaphor for her husband – the fierce, watchful guardian of the family – in keeping with the ancient Chinese folklore in which the dragon is stationed at the gates of the lord’s castle to guard and protect it from evil and danger.

Even more subtle regional variations may produce similar problems in listening and understanding.

---

#### Clinical Vignette 8

In a family session, a psychiatrist from the South referred to the mother of her patient as “your mama”, intending a meaning of warmth and respect. The patient instantly became enraged at the use of such an offensive term toward her mother. Although being treated in Texas, the patient and her family had recently moved from a large city in New Jersey. The use of the term “mama” among working class Italians in that area was looked upon with derision among people of Irish descent, the group to which the patient was ethnically connected. The patient had used the term “mother” to refer to her mother, a term the psychiatrist had heard with a degree of coolness attached. What she knew of her patient’s relationship with her mother did not fit in with a word like mother, hence almost out of awareness she switched terms leading to a response of indignation and outrage from the patient.

Psychiatrists discern meaning in that which they hear through filters of their own – cultural backgrounds, life experiences, feelings, the day’s events, their own physical sense of themselves, nationality, sex roles, religious meaning systems and intrapsychic conflicts. The filters can serve as blocks or as magnifiers if certain elements of what is being said resonate with something within the psychiatrist. When the filters block, we call it countertransference or insensitivity. When they magnify, we

call it empathy or sensitivity. One may observe a theme for a long time repeated with a different tone, embellishment, inflection, or context before the idea of what is meant comes to mind. The “little fella” example in Clinical Vignette 3 illustrates a message that had been communicated in many ways and times in exactly the same language before the psychiatrist “got it”. On discovering a significant meaning that had been signaled before in many ways, the psychiatrist often has the experience, “How could I have been so stupid? It’s been staring me in the face for months!”

Managed care and the manner in which national health systems are administered can alter our attitudes toward the patient and our abilities to be transforming listeners. The requirement for authorization for minimal visits, time on the phone with utilization review nurses attempting to justify continuing therapy, and forms tediously filled out can be blocks to listening to the patient. Limitations on the kinds and length of treatment can lull the psychiatrist into not listening in the same way or as intently. With these time limits and other “third party payer” considerations (i.e., need for a billable diagnostic code from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition [DSM-IV-TR] or the *International Classification of Diseases*, 10th Revision [ICD-10]), the psychiatrist, as careful listener, must heed the external pressures influencing the approach to the patient. Many health benefits packages will provide coverage in any therapeutic setting only for relief of symptoms, restoration of minimal function, acute problem solving, and shoring up of defenses. In various countries, health care systems have come up with a variety of constraints in their efforts to deal with the costs of care. Unless these pressures are attended to, listening will be accomplished with a different purpose in mind, more closely

---

#### Clinical Vignette 9

An army private was brought to the emergency room in Germany by his friends, having threatened to commit suicide while holding a gun to his head. He was desperate, disorganized, impulsive, enraged, pacing and talking almost incoherently. Gradually, primarily through his friends, the story emerged that his first sergeant had recently made a decision for the entire unit that had a particularly adverse effect on the patient. He was a fairly primitive character who relied on his wife for a sense of stability and coherence in his life. The sergeant’s decision was to send the entire unit into the field for over a month just at the time the patient’s wife was about to arrive, after a long delay, from the USA. After piecing together this story, the psychiatrist said to the patient, “It’s not yourself you want to kill, it’s your first sergeant!” The patient at first giggled a little, then gradually broke out into a belly laugh that echoed throughout the emergency room. It was clear that, having recognized the true object of his anger, a coherence was restored that enabled him to feel his rage without the impulse to act on it. The psychiatrist then enlisted the friends in a plan to support the patient through the month and to arrange regular phone contact with the wife as she set up their new home in Germany. No medication was necessary. Hospitalization was averted, and a request for humanitarian dispensation, which would have compromised the patient in the eyes of both his peers and superiors, was avoided as well. And, with luck, the young man had an opportunity to grow emotionally as well.

approximating the crisis intervention model of the emergency room or the medical model for either inpatient or outpatient care. In these settings, the thoughtful psychiatrist will arm himself or herself with checklists, inventories, and scales for objectifying the severity of illness and response to treatment: the ear is tuned only to measurable and observable signs of responses to therapy and biologic intervention.

With emphasis on learning here and now symptoms that can bombard the dyad with foreground static and noise, will the patient be lost in the encounter? The same approach to listening occurs in the setting of the emergency department for crisis intervention. Emphasis is on symptom relief, assurance of capacities to keep oneself safe, restoration of minimal function, acute problem solving and shoring up of defenses. Special attention is paid to identifying particular stressors. What can be done quickly to change stressors that threw the patient's world into a state of disequilibrium? The difference in the emergency room is that the careful listener may have 3 to 6 hours, as opposed to three to six sessions for the patient with a health maintenance organization or preferred provider contract, or other limitations on benefits. If one is fortunate and good at being an active listener–bargainer, the seeds of change can be planted in the hope of allowing them time to grow between visits to the emergency department. If one could hope for another change, it would be for a decrease in the chaos in the patient's inner world and outer world.

### Crucial Attitudes that Enable Effective Listening

The first step in developing good listening skills involves coming to grips with the importance of inner experience in psychiatric treatment and diagnosis. The *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (American Psychiatric Association, 1994) and *International Classification of Diseases*, 10th Revision (World Health Organization, 1992) have been enormous advances in reliability and accuracy of diagnosis, but their emphasis on seemingly observable phenomena has allowed the willing user to forget the importance of inner experience even in such basic diagnoses as major depressive disorder. Consider the symptom “depressed mood most of the day” or “markedly diminished interest or pleasure” or even “decrease or increase in appetite”. These are entirely subjective symptoms. Simply reporting depression is usually not sufficient to convince a psychiatrist that a diagnosis of depression is warranted. In fact, the vast majority of psychiatric patients are so demoralized by their illnesses that they often announce depression as their first complaint. Further, there are a significant number of patients who do not acknowledge depression yet are so diagnosed. The clinician might well comment, “Sitting with him makes me feel very sad”.

The psychiatrist must listen to much more than the patient's overt behavior. There are qualities in the communication, including the inner experiences induced in the listener, that should be attended to. The experienced clinician listens to the words, watches the behavior, engages in and notices the ongoing interaction, allows himself/herself to experience his/her own inner reactions to the process, and *never forgets that depression and almost all other psychiatric symptoms are exclusively private experiences*. The behavior and interactions are useful insofar as they assist the psychiatrist in inferring the patient's inner experience.

Therefore, to convince a clinician that a patient is depressed, not only must the patient say she/he is depressed, but the observable behavior must convey it (sad-looking face, sighing, unexpressive intonations, etc.); the interaction with the interviewer must convey depressive qualities (sense of neediness, sadness induced in the interviewer, beseeching qualities expressed, etc.). In the absence of both of these, other diagnoses should be considered, but in the presence of such qualities, depression needs to remain in the differential diagnosis.

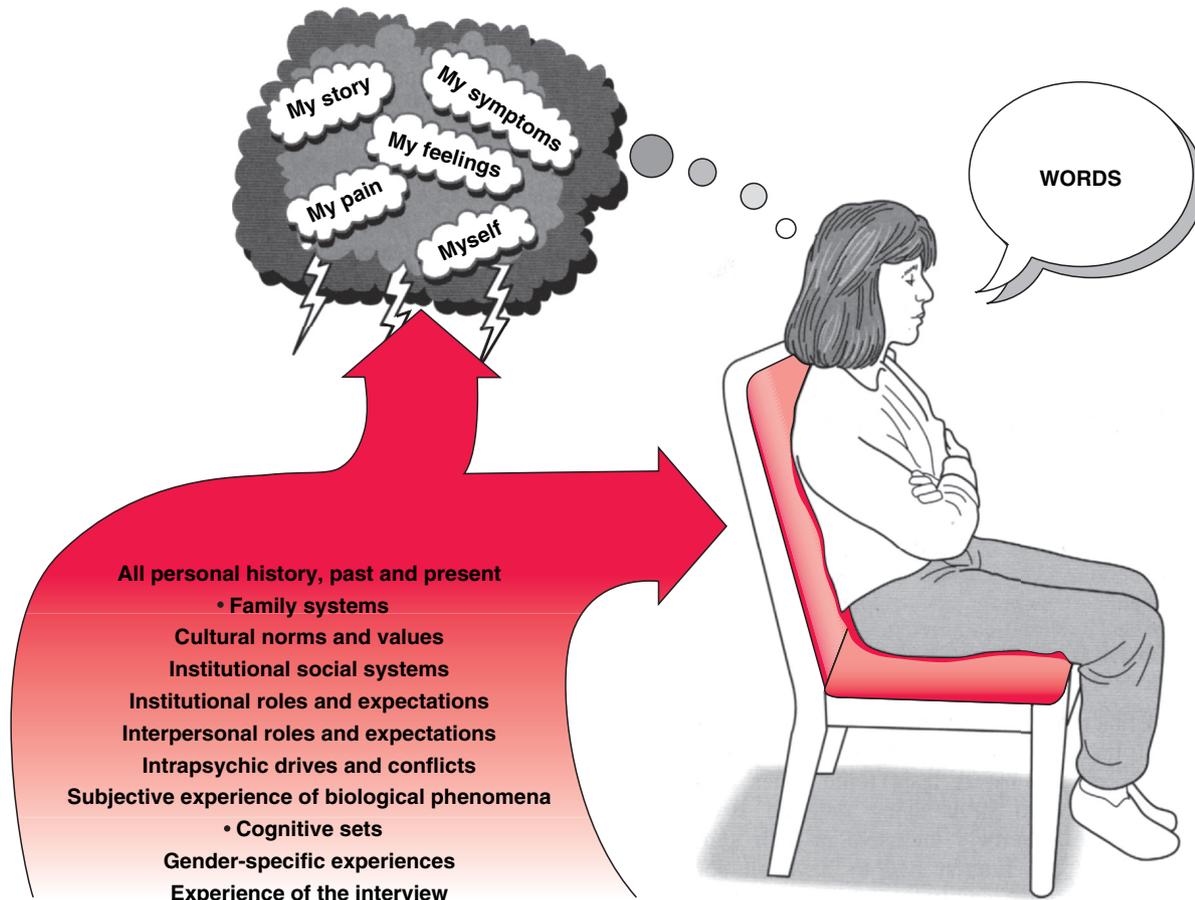

Even when we make statements about brain function with regard to a particular patient, we use this kind of listening, generally, by making at least two inferences. We first listen to and observe the patient and then infer some aspect of the patient's private experience. Then, if we possess sufficient scientific knowledge, we make a second inference to a disturbance in neurochemistry, neurophysiology, or neuroanatomy. When psychiatrists prescribe antidepressant medication, they have inferred from words, moved into inner experiences, and come to a conclusion that there is likely a dysregulation of serotonin or norepinephrine in the patient's brain.

As one moves towards treatment from diagnosis, the content of inner experience inferred may change to more varied states of feelings, needs, and conflicts, but the fundamental process of listening remains the same. The psychiatrist listens for the meaning of all behavior, to the ongoing interpersonal relationship the patient attempts to establish, and to inner experiences as well.

Despite all of the technological advances in medicine in general and their growing presence in psychiatry, securing or eliciting a history remains the first and central skill for all physicians. Even in the most basic of medical situations, the patient is trying to communicate a set of private experiences (how does one describe the qualities of pain or discomfort?) that the physician may infer and sort into possible syndromes and diagnoses. In psychiatry, this process is multiplied, as indicated in Figure 1.1. William Styron (1990), a prizewinning novelist, had to go to extraordinary lengths in his eloquent attempt to convey the “searing internal mental pain” that he experienced when suffering from a major depression.

The qualitative aspects of private experience remain, to this day, a major problem in philosophy. It was the basis of Rene Descartes' (1991) philosophical doubting that became the fundamental intellectual underpinning of Western thought for so long. Edmund Husserl (1977) used it as the basis for an entire philosophical system, phenomenology, which was a forerunner of existentialism, which was so influential in both American and European psychiatry in the 1950s and 1960s (May *et al.*, 1958; Binswanger, 1963).

Silvano Arieti (1967) hypothesized that cognitive development produces changes over time in the inner experience of various affects. Does a person with borderline personality disorder experience “anxiety” in the same qualitative and quantitative manner in which a neurotic person does? What is the relationship between sadness and guilt and the empty experiences of depression? This perspective underlies the principle articulated in text after text on interviewing that emphasizes the importance of establishing rapport in the process of history taking. It is incredibly easy for the psychiatrist to attribute to the patient what she/he would have meant and what most people might have meant in using a particular word or phrase. The sense in the narrator that the listener is truly present, connected, and with the patient enormously enhances the accuracy of the story reported.

**Figure 1.1** *Finding the patient.*

Words that have been used to describe this process of constant attention to and inference of inner experience by the listener include interest, empathy (Rogers, 1951; Kohut, 1991; Truax, 1963), attentiveness and noncontingent positive regard (Truax, 1963). However, these are words that may say less than they seem to. It is the constant curious awareness on the listener's part, that she/he is trying to grasp the private inner experience of the patient, and the storyteller's sense of this stance by the psychiatrist that impels the ever more revealing process of history taking. This quality of listening produces what we call rapport, without which psychiatric histories become spotty, superficial and even suspect. There are no bad historians, only patients who have not yet found the right listener.

In treatment, we even find empirical data to support this perspective. The two most powerful predictors of outcome in any form of psychotherapy are empathy and the therapeutic alliance (Horvath and Luborsky, 1993; Greenson, 1978). This has been shown again and again in study after study for dynamic therapy, cognitive therapy, behavior therapy and even medication management (Elkin *et al.*, 1989). This led some researchers and theorists to propose that the power of psychotherapy can be understood solely as a remoralization phenomenon based on support and empathy (Frank, 1973; Omer and London, 1989). The truth of this can be seen in the remarkable therapeutic success of the "clinical management" cell of the National Institutes of Mental Health Collaborative Study on the Treatment of Major Depression. Although the Clinical Management Cell was not

as effective as the cells that included specific drugs or specific psychotherapeutic interventions, 35% of patients with moderate to severe major depressive disorder improved significantly with carefully structured supportive clinical management alone (Elkin *et al.*, 1989).

Helpful psychiatric listening requires a complicated attitude toward control and power in the interview (see Table 1.3). The psychiatrist invites the patient/storyteller to collaborate as an active informer. He is invited, too, to question and observe himself. This method of history taking remains the principal tool of general clinical medicine. However, as Freud pointed out, these methods of active uncovering are more complex in the psychic

**Table 1.3** *Attitudes Important to Listening*

<p>The centrality of <b>inner experience</b></p> <p>There are no bad historians</p> <p>The answer is always inside the patient</p> <p>Control and power are shared in the interview</p> <p>It is OK to feel confused and uncertain</p> <p>Objective truth is never as simple as it seems</p> <p>Listen to yourself, too</p> <p>Everything you hear is modified by the patient's filters</p> <p>Everything you hear is modified by your own filters</p> <p>There will always be another opportunity to hear more clearly</p>
---

realm. The use of the patient as a voluntary reporter requires that the investigator keep in mind the unconscious and its power over the patient and listener. Can the patient be a reliable objective witness of himself or his symptoms? Can the listener hold in mind his own set of filters, meanings, and distortions as he hears? The listener translates for himself and his patient the patient's articulation of his experience of himself and his inner world into our definition of symptoms, syndromes, and differential diagnoses which make-up the concept of the medical model.

Objective–descriptive examiners are like detectives closing in on disease. The psychiatric detective enters the inquiry with an attitude of unknowing and suspends prior opinion. The techniques of listening invoke a wondering and a wandering with the patient. Periods of head scratching and exclamations of “I’m confused”, or “I don’t understand”, or “That’s awful!” or “Tell me more”, allow the listener to follow or to point the way for the dyad. Finally, clear and precise descriptions are held up for scrutiny, with the hope that a diagnostic label or new information about the patient’s suffering and emotional pain is revealed.

It is embarking on the history taking journey together – free of judgments, opinions, criticism, or preconceived notions – that underpins rapport. Good listening requires a complex understanding of what objective truth is and how it may be found. The effective psychiatrist must eschew the traditional medical role in interviewing and tolerate a collaborative, at times meandering, direction in which control is at best shared and sometimes wholly with the patient. The psychiatrist constantly asks: What is being said? Why is it being said at this moment? What is the meaning of what is being said? In what context is all this emerging? What does that tell me about the meaning and what does it reflect about the doctor–patient relationship?

### Theoretical Perspectives on Listening

Listening is the effort or work of placing the therapist where the patient is (“lives”). Greenson (1978) would call it “going along with”; Rogers (1951) “centering on the client”. The ear of the empathic listener is the organ of receptivity – gratifying and, at times, indulging the patient. Greenson would say that it is better to be deceived going along with the patient than to reject him/her prematurely and have the door slammed to the patient’s inner world. That is what is meant by the suspension of beliefs for the discovery of the true self. Harry Stack Sullivan, the father of interpersonal psychiatry, would remind us to heed those shrewd, small questions: “What is he up to?” “Where is he taking us?” Every human being has a preferred interpersonal stance, a set of relationships and transactions with which she or he is most comfortable and feels most gratified. The problem is that for most psychiatric patients they do not work well. This is the wisdom that Sullivan (1953) was articulating.

Beyond attitudes that enable or prevent listening there is a role for specific knowledge. It is important to achieve the cognitive structure or theoretical framework and use it with rigor and discipline in the service of patients so that psychiatrists can employ more than global “feelings” or “hunches”. In striving to grasp the inner experience of any other human being, one must know what it is to be human; one must have an idea of what is inside any person. This provides a framework for understanding what the patient – who would not be a patient if he fully understood what was inside of him – is struggling to communicate. Personality theory is absolutely crucial to this process.

Whether we acknowledge it or not, every one of us has a theory of human personality (in this day and age of porous boundaries between psychology and biology, we should really speak of a psychobiological theory of human experience) which we apply in various situations, social or clinical. These theories become part of the template alluded to earlier that allow certain words, stories, actions, and cues from the patient to jump out with profound meaning to the psychiatrist. There is no substitute for a thorough knowledge of many theories of human functioning and a well disciplined synthesis and internal set of rules to decide which theories to use in which situations.

Different theoretical positions offer slightly different and often complementary perspectives on listening (Table 1.4). The basic tools of therapeutic power and diagnostic acumen spring from the following:

1. Freud’s associative methods (Brill, 1938) and ego psychology (Freud, 1946), in which one listens for the associative trends and conflicts.
2. Melanie Klein’s (1975) and Harry Stack Sullivan’s (1953) object relations theory. The former discovered the story through inner world exploration and recognized the introjected

**Table 1.4 Theoretical Perspectives on Listening**

Theory	Focus of Attention	Listening Stance
Ego psychology	Stream of associations	Neutral, hovering attention
Object relations	Introjects (internalized images of others within the patient)	Neutral, hovering attention
Interpersonal	What relationship is the patient attempting to construct?	Participant observer
Existential	Feelings, affect	Empathic identification with the patient
Self-psychology	Sense of self from others	Empathic mirroring and affirmation
Patient centered	Content control by patient	Noncontingent positive regard, empathy
Cognitive	Hidden assumptions and distortions	Benign expert
Behavioral	Behavioral contingencies	Benign expert
Family systems	Complex forces maneuvering each member	Neutral intruder who forces imbalance in the system

persons of the past who live within the patient's mind, comprising the person's psychic structure; the latter discovered the knowing through the interpersonal experience of the therapeutic dyad (Greenberg and Mitchell, 1983).

3. Binswanger's (1963) understanding of the condition of empathy, in which the listener gives up his or her own position for that of the storyteller.
4. Kohut's (1991) self-psychology, which emphasizes the use of vicarious introspection to reflect (mirror) back to the patient what is being understood. This mirroring engenders in the storyteller a special sense of being "found", that is, of being known, recognized, affirmed, and heard. This feeling of being heard helps to undo the sense of aloneness so common in psychiatric patients.

Each of the great schools of psychotherapy places the psychiatrist in a somewhat different relationship to the patient. This may even be reflected in the physical placement of the therapist in relation to the patient. In a classical psychoanalytic stance, the therapist, traditionally unseen behind the patient, assumes an active, hovering attention. Existential analysts seek to experience the patient's position and place themselves close to and facing the patient. The interpersonal psychiatrist stresses a collaborative dialogue with shared control. One can almost imagine the two side by side as the clinician strives to sense what the storyteller is doing to and with the listener. Interpersonal theory stresses the need for each participant to act within that interpersonal social field.

In the object relations stance, the listener keeps in mind the "other people in the room" with him and the storyteller, that is, the patient's introjects who are constantly part of the internal conversation of the patient and thus influence the dialogue within the therapeutic dyad. In connecting with the patient, the listener is also tuned in to the fact that parts and fragments of him or her are being internalized by the patient. The listener becomes another person in the room of the patient's life experience, within and outside the therapeutic hour. Cognitive and behavioral psychiatrists are kindly experts, listening attentively and subtly for hidden assumptions, distortions, and connections. The family systems psychiatrist sits midway among the pressures and forces emanating from each individual, seeking to affect the system so that all must adapt differently.

Referring again to Clinical Vignette 3, we can see the different theoretical models of the listening process in the discovery of the meaning of "little fella". Freud's model is that the psychiatrist had listened repeatedly to a specific association and inquired of its meaning. Object relations theorists would note that the clinician had discovered a previously unidentified, powerful introject within the therapeutic dyad. The interpersonal psychiatrist would see the shared exploration of this idiosyncratic manner of describing one's youth; the patient had been continually trying to take the therapist to "The Andy Griffith Show". That is, the patient was attempting to induce the clinician to share the experience of imagining and fantasizing about having Andy Griffith as a father.

Existentialists would note how the psychiatrist was changed dramatically by the patient's repeated use of this phrase and then altered even more profoundly by the memory of Andy Griffith, "the consummate good father" in the patient's words. The therapist could never see the patient in quite the same way again, and the patient sensed it immediately. And Kohut would

note the mirroring quality of the psychiatrist's interpreting the meaning of this important memory. This would be mirroring at its most powerful, affirming the patient's important differences from his family, helping him to consolidate the memories. The behavioral psychiatrist would note the reciprocal inhibition that had gone on, with Andy Griffith soothing the phobic anxieties in a brutal family.

A cognitive psychiatrist would wonder whether the patient's depression resulted from a hidden assumption that anything less than the idyllic images of television was not good enough. The family systems psychiatrist would help the patient see that he had manipulated the forces at work on him and actually changed the definition of his family.

The ways and tools of listening also change, according to the purpose, the nature of the therapeutic dyad. The ways of listening also change depending upon whether or not the psychiatrist is preoccupied or inattentive. The medical model psychiatrist listens for signs and symptoms. The analyst listens for the truth often clothed in fantasy and metaphor. The existentialist listens for feeling, and the interpersonal theorist listens for the shared experiences engendered by the interaction. Regardless of the theoretical stance and regardless of the mental tension between the medical model's need to know symptoms and signs and the humanistic psychiatrist's listening to know the sufferer, the essence of therapeutic listening is the suspension of judgment before any presentation of the story and the storyteller. The listener is asked to clarify and classify the inner world of the storyteller at the same time he is experiencing it – no small feat!

## Using Oneself in Listening

Understanding transference and countertransference is crucial to effective listening. Tomkins, LeDoux, Damasio and Brothers have given us a basic science, biological perspective on this process. However one defines these terms, whatever one's theoretical stance about these issues, Harry Stack Sullivan (1969) had it right when he said that schizophrenics are more human than anything else. To know ourselves is to begin to know our patients more deeply. There are many ways to achieve this. Personal therapy is one. Ongoing life experience is another. Supervision that emphasizes one's emotional reactions to patients is still a third. Once we have started on the road to achieving this understanding by therapy, supervision, or life experience, continued listening to our patients, who teach us about ourselves and others, becomes a lifelong method of growth.

To know oneself is to be aware that there are certain common human needs, wishes, fears, feelings and reactions. Every person must deal in some way with attachment, dependence, authority, autonomy, selfhood, values and ideals, remembered others, work, love, hate and loss. It is unlikely that the psychiatrist can comprehend the patient without his own self-awareness. Thus, Figure 1.1 should really look like Figure 1.2. The most psychotic patient in the world is still struggling with these universal human functions.

In this case, the psychiatrist was able to connect with a patient's inner experience in a manner that had a fairly dramatic impact on the clinical course. That is the goal of listening. The art is hearing the patient's inner experience and then addressing it empathically, enabling the patient to feel heard and affirmed. There are no rules about this, and at any given point in a clinical encounter there are many ways to accomplish it.

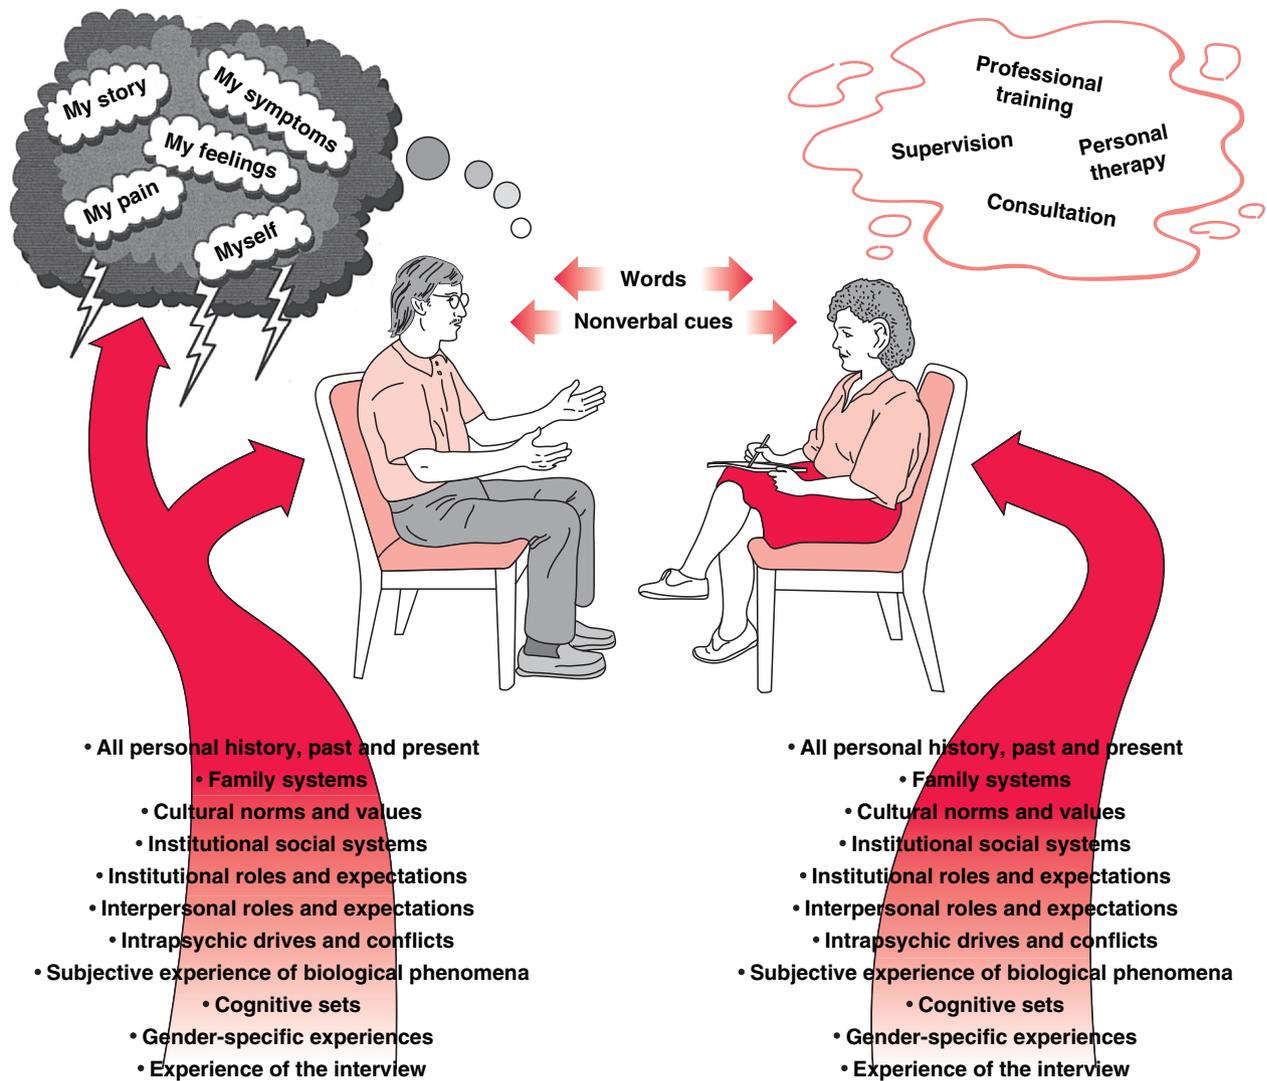

Figure 1.2 The therapeutic dyad.

**Clinical Vignette 10**

A young man with paranoid schizophrenia had been admitted in 1979 to the hospital following a near lethal attack on his father. When asked about this incident, he became frankly delusional, speaking of the Arab-Israeli conflict, the preciousness of Jerusalem, how the Israelis must defend it at all costs. Unspoken was his conviction that he was like the Israelis, with the entire world attacking and threatening him. He believed his father had threatened and attacked him when, in fact, his father had done little more than seek to be closer, more comforting and advising with the patient. The psychiatrist understood the patient to be speaking of that core of selfhood that we all possess, which, when threatened, creates a sense of vulnerability and panic, a disintegrating anxiety unlike any other. The psychiatrist spoke to the patient of Anwar Sadat's visit to Jerusalem and engaged him in a discussion of how that had gone, what the outcome had been, had the threat been lessened or increased? The patient, although still delusional, visibly relaxed and began to speak much more directly about

his own sense of vulnerability and uncertainty over his personal integrity and its ability to withstand any closeness. He still required neuroleptic medication for his illness; however, his violent thoughts and behaviors reduced dramatically. He was able to begin interacting with his father, and his behavior on the ward changed as well.

There are also many ways to respond that are unhelpful and even retraumatizing. The skilled psychiatrist, just as she/he never forgets that it is the patient's inner experience that is to be heard, also never stops struggling to find just the right words, gestures, expressions and inflections that say to a patient, "you have been understood". The most clever diagnostician or insightful interpreter who cannot "connect" with the patient in this manner will miss valuable information. This issue has been addressed by writers who have pointed out how little understood are the concepts of support and empathy (Peteet, 1982).

Being human is also to be a creature of habit and pattern in linguistic, interpersonal, and emotional realms. The skilled psychiatrist listens with this ever in mind. What we see in the

interview, what we hear in interactions, may be presumed to be repetitions of many other events. The content may vary, but the form, motive, process and evolution are generally universal for any given individual. This, too, is part of listening. To know what is fundamentally human, to have a well-synthesized rigorous theory, and to hear the person's unique but repetitive ways of experiencing are the essence of listening. These skills “find” the patient in all his/her humanity, but then the psychiatrist must find the right communication that allows the patient to feel “found”.

### To Be Found: The Psychological Product of Being Heard

Psychiatric patients may be lonely, isolated, demoralized, and desperate, regardless of the specific diagnosis. They have lost themselves and their primary relationships, if they ever had any. Stanley Jackson (1992) makes the point that before anything else can happen, they must be found, and feel found. They can only be found within the context of their own specific histories, cultures, religions, genders, social contexts, and so on. There is nothing more healing than that experience of being found by another. The earliest expression of this need is in infancy and we refer to it as the need for attachment. Referring to middle childhood, Harry Stack Sullivan spoke of the importance of the pal or buddy. Kohut spoke of the lifelong need for **self-objects**. In lay terms, it is often subsumed under the need for love, security, and acceptance. Psychiatric patients have lost or never had this experience. However obnoxious or destructive or desperate their overt behavior, it is the psychiatrist's job to seek and find the patient. That is the purpose of listening.

If we look back to Clinical Vignette 3, wherein the phrase “little fella” bespoke such deep and important unverbally meaning, the patient's reaction to the memory and recognition by the psychiatrist was dramatic. He had always known he was different in some indefinable ways from his family. That difference had been both a source of pride and pain to him at various developmental stages. However, the recognition of the specific source, its meaning, and its constant presence in his life created a whole new sense of himself. He had been found by his psychiatrist, who echoed the discovery, and he had found an entire piece of himself that he had enacted for years, yet which had been disconnected from any integrated sense of himself.

Sometimes objectifying and defining the disease/disorder enables the person to feel found. One of the most challenging patients to hear and experience is the acting out, self-destructive, demanding person with borderline personality disorder. Even as the prior sentence conveys, psychiatrists often experience the diagnosis as who the patient is rather than what she suffers. The following case conveys how one third year resident was able to hear such a patient, and in his listening to her introduce the idea that the symptoms were not her but her disorder.

Gender can play a significant role in the experience of feeling found. Some individuals feel that it is easier to connect with a person of the same sex; others, with someone of the opposite sex. Clinical Vignette 6 is an excellent example of this. In these days of significant change in and sensitivity to sex roles, a misinterpretation such as that early in treatment could result in a permanent rupture in the alliance. Psychiatrists vary in their sensitivity to the different sexes. Some may do better with those who have chosen more traditional roles; others may be more sensitive to those who have adopted more modern roles.

### Clinical Vignette 11

He was working the midnight Friday to 11 AM Saturday shift in a Psychiatric Emergency Room. The patient was a 26-year-old woman brought in by ambulance after overdosing on sertraline following an argument with her boyfriend. She had been partying with him and became enraged at the attention he was paying to the date of a friend who was accompanying them. After being cleared medically, the patient was transferred to psychiatry for crisis intervention. It was about 4 AM when she arrived. She was crying and screaming for the psychiatric staff to release her. In the emergency department she had grabbed a suture scissors attached to the uniform of the charge nurse. The report was given to the psychiatric resident that she had been a “management problem” in the medicine ER.

The psychiatrist sat wearily and listened to the patient tell her story with tears, shouts, and expletives sputtered through clenched teeth. She stated that she did not remember ever being happy, that she frequently had thoughts of suicide, and that she had overdosed twice before, following a divorce from her first husband at the age of 19 and then 8 months prior to this episode when she had been fired from a job for arguing with her supervisor. Her parents had kept her 6-year-old and 7-year-old sons since her divorce. She was currently working as a file clerk and living with her boyfriend of 2 months. She stated that she felt like there was a cold ice cube stuck in her chest as she watched her boyfriend flirting with the other woman. She acknowledged that she felt empty and utterly alone even in the crowded bar. She created an unpleasant scene and they continued to argue until they got home. Then he had laughed at her and left, stating that he would come back when she had cooled down.

The resident sat quietly and listened. He looked dreary. The night had been a busy one. She looked at him and complained, “Don't let me and my problems bore you!” He looked at her and said, “Quite the contrary. I've been thinking as you speak that I know what disorder you suffer from”. With that statement, he pulled out the DSM-IV and read with her the description of the symptoms and signs of borderline personality disorder. She had been in therapy off and on since she was 16 years old. No one had ever shared with her the name of the diagnosis but instead had responded to her as if the disorder was the definition of who she was. In his listening, he was able to hear her symptoms as a disorder and not the person. And in his ability to separate the two, he was able to allow her to distance herself from the symptoms, too, and see herself in a new light with her first inkling of her own personhood.

We now know that just as there is a neurobiological basis for empathy and countertransference, there is a similar biological basis for the power of listening to heal, to lift psychological burdens, to remoralize and to provide emotional regulation to patients who feel out of control in their rage, despair, terror, or other feelings (Table 1.5). Attachment and social support are psychobiological processes that provide the necessary physiological regulation to human beings. This has been shown by the work of Hofer (1996), Cobb (1976), Meaney (2001), Nemeroff (Heim and Nemeroff, 2001), and many others. Additional work of Paul

**Table 1.5 The Basic Sciences of Listening**

Neurobiology of primary affects
Universality of certain affective expressions
Neurobiology of empathy
Biological need for interpersonal regulation
Psychobiology of attachment
Biological impact of social support
Environmental impact on central nervous system structure and function

Ekman (1992) supports the notion of the patient's capacity to perceive empathy through the powerful nonverbal, universally understood communication of facial expressions. His research in basic human emotions sets forth the idea of their understanding across cultures and ages. It further supports the provocative idea that facial expressions of the listener may generate autonomic and central nervous system changes not only within the listener but within the one being heard, and vice versa. Indeed, the evidence is growing that new experiences in clinical interactions create learning and new memories, which are associated with changes in both brain structure and function (Kandel, 1999; Gabbard, 2000; Mohl, 1987; Liggan and Kay, 1999). When we listen in this way, we are intervening not only in a psychological manner to connect, heal, and share burdens but also in a neurobiological fashion to regulate, modulate and restore functioning. When patients feel found, they are responding to this psychobiological process.

### Listening to Oneself to Listen Better

To hold in mind what has been said and heard after a session and between sessions is the most powerful and active tool of listening. It is a crucial step often overlooked by students and those new at listening. It is necessary to hear our patients in our thoughts during the in-between times in order to pull together repetitive patterns of thinking, behaving, and feeling, giving us the closest idea of how patients experience themselves and their world. In addition, many of our traumatized patients have not had the experience of being held in mind, of being remembered, and their needs being thought of by significant others. These key experiences of childhood affirm the young person's psychological being. It is important to distinguish this kind of "re-listening" to the patient – an important part of the psychiatrist's ongoing processing and reprocessing of what has been heard and experienced – from what some may leap to call countertransference. One way of identifying this distinction would be to differentiate listening to oneself as one reviews in one's mind the patient's story versus

#### Clinical Vignette 12

A second year resident, rotating through an inpatient unit which serves the psychiatric needs of very severely ill psychotic patients with multiple admissions, dual diagnoses, homelessness, criminal records, significant histories of medical noncompliance, and, in some, unremitting psychosis, was particularly struggling with a 33-year-old white woman admitted for the 11th time

since age 19. The patient invariably stopped medications shortly after discharge, never kept follow-up appointments, and ended up on the streets psychotic and high on crack cocaine. She would then be involuntarily committed for restabilization. And so the cycle would repeat itself. The resident would see the patient on daily rounds. The patient's litany was the same day after day: "I'm not sick. I don't need to be here. I don't need medicines". And regularly she refused doses.

The resident spoke often of her patient to other residents in her class and often found herself ruminating about the patient's abject lostness. She began her regular supervision hours either frustrated or feeling hopeless that anything would change with this patient because the patient flatly refused to acknowledge her disorder. The patient's level of denial was of psychotic proportions. Shortly after a particularly difficult encounter with the patient concerning her refusal to take an evening dose of haloperidol, the resident came to supervision with the report that she had awakened terrified by dreaming the night before that she had been diagnosed with schizophrenia. She had been intensely affected by overwhelming pain, confusion and despair as she heard the diagnosis in her dream. "IT CAN'T BE!" she screamed, waking herself with a shaking start. "I'M NOT SICK! I DON'T NEED TO BE HERE! I DON'T NEED MEDICINE!" The words of her patient echoed in her mind as her own echoed in her ears. She had taken the patient's story and words home with her and kept them in mind at an unconscious level to be brought up in her dream, the ultimate identification with the patient. How more intensely can one be empathic with her patient than to dream as if she is experiencing the same horrifying reality? The patient and resident continued to struggle, but after the dream the resident was able to approach the patient and her story from a position of understanding the patient's need to maintain a lack of awareness or absence of insight. To acknowledge the presence of the disorder was more than the patient's already fragmented ego could bear. And now the resident "heard" it.

becoming preoccupied and stuck with one's thoughts and feelings about a particular aspect of a patient.

As the verbal interaction with the patient occurs, psychiatrists may find themselves expressing thoughts and feeling in ways that may be quite different from their usual repertoire. The following case is an example.

#### Clinical Vignette 13

A 45-year-old divorced white woman, being followed for bipolar disorder and borderline personality traits and stable for several years on lithium, was in weekly psychotherapy. During the prior weekend she had moved into another apartment closer to her work. On the day of the move, she overslept and woke up with a start. The admonition to herself as she awoke was, "You lazy bitch! You can never manage on your own". She had earlier, as a child, experienced a mother who was needy, engulfing, punishing, hostile, critical and dependent upon the patient. Her therapist, having some knowledge of the patient and

her background, said, “Your mother is still with you. It was she in your head continuing to bombard you with derogatory statements”. The same patient was often 10 or 15 minutes late for sessions, and her therapist found herself irritated at the patient’s habitual tardiness. To her own surprise and enlightenment, the therapist also found herself thinking, “What a chaotic woman! She’ll never manage to be here on time”. She, too, had heard the voice of her patient’s mother. In the next session she wondered with her patient if she found herself wishing to place her therapist in the position of her mother, wanting at once to be engulfed and punished.

---

#### Clinical Vignette 14

A psychiatrist was treating a 40-year-old man who was in the process of recognizing his own primary homosexual orientation. In the course of treatment he became enraged, suicidal, and homicidal. After one session, the psychiatrist, while driving home, experienced the fantasy that when he got home he would find his patient already there, having taken the psychiatrist’s family hostage. The psychiatrist became increasingly terrified, even outright paranoid that this fantasy might actually come to pass. The patient was a computer expert who had indeed discovered the unlisted phone number and address of his therapist. But the psychiatrist realized that this fantasy was far out of keeping with his own usual way of feeling and the patient’s way of behaving and viewing him. On arriving home to discover his family quite safe, the psychiatrist called the patient and scheduled him as his first for appointment the following morning. When the patient arrived, the psychiatrist said, “You know, I think I’m only now beginning to appreciate just how terrified and desperate all of this makes you”. The patient slumped down into his chair, heaved a sigh, and said, “Thank God!”

This sort of listening to oneself in order to understand the patient requires a good working knowledge of projective identification (Ogden, 1979). Projective identification, first defined by Melanie Klein, describes a defense mechanism in which the patient, in an effort to master intolerably terrifying emotions, unconsciously seeks to engender them in the therapist and to identify with the psychiatrist’s ability to tolerate and handle the feelings.

## Listening in Special Clinical Situations

### Children

Listening to younger children often involves inviting them to play and then engaging them in describing what is happening in the play action. The psychiatrist pays careful attention to the child’s feelings. These feelings are usually attributed to a doll, puppet, or other humanized toy. So if a child describes a stuffed animal as being scared, the psychiatrist may say, “I wonder if you, too, are scared when...” or “That sounds like you when...”. The following case is an example.

---

#### Clinical Vignette 15

A 4-year-old boy was brought in for psychiatric evaluation. He and his father had come upon a very serious automobile accident. One person had been thrown from the car and was lying clearly visible on the pavement with arms and legs positioned in grotesque angles, gaping head wound, obviously dead. The child’s father was an off duty police officer who stopped to assist in the extraction of two other people trapped in the car. The father kept a careful eye on the youngster who was left in the car. The child observed the scene for about 30 minutes until others arrived on the scene and his dad was able to leave. That night and for days to come, the child preoccupied himself with his toy cars which he repetitiously rammed into each other. He was awakened by nightmares three times in the ensuing weeks. During his evaluation in the play therapy room he engaged in ramming toy cars together. In addition, he tossed dolls about and arranged their limbs haphazardly. As he was encouraged to put some words to his action, he spoke of being frightened of the dead body and of being afraid to be by himself. He was afraid of the possibility of being hurt himself. He came in for three more play sessions which went much the same way. His preoccupation with ramming cars at home diminished and disappeared as did the nightmares. The content of his play was used to help him put words and labels on his scare.

### Geriatric Patients

Working with the elderly poses its own special challenges. These challenges include not only the unique developmental issues they face but also the difficulty in verbalizing a lifetime of experience and feelings and, commonly, a disparity in age and life experience between the clinician and the patient.

---

#### Clinical Vignette 16

A psychiatrist was asked to examine an 87-year-old white man whom the family believed to be depressed. They stated that he was becoming increasingly detached and disinterested in the goings-on around him. When seen, he was cooperative and compliant, but he stated that he didn’t believe he needed to be evaluated. The patient had faced multiple losses over the past few years. After retiring at the age of 65, he had developed the habit of meeting male friends at a coffee shop each morning at 7 am. Now, all but he and one other were dead, and the other was in a nursing home with the cognitive deficits of primary dementia of the Alzheimer’s type, preventing his friend from recognizing him when visiting. The patient’s wife had died 15 years before after many years of marriage. He had missed her terribly at first but then after a year or so he got on with his life. Several years later, he suffered a retinal detachment that impaired his vision to the point that he was no longer able to drive himself to get about as he once had. What he missed most was the independence of going places when it suited him, rather than relying on his son or grandson to accommodate him within their busy schedules. He had taken to watching televised church services rather than trouble his son to drive him to church. His mind

**Clinical Vignette 16 *continued***

remained sharp, he said, but his body was wearing out, and all the people with whom he had shared a common history had died. His answers were “fine” and “all right” when questions of quality of sleep and mood were asked – despite the fact that he had experienced significant nocturia. When questioned about his ability to experience joy, he retorted, “Would you be?” His youngest sister had died the year prior to the evaluation. She was 76 years old and had been on home oxygen for the last 18 months of her life for end-stage chronic obstructive pulmonary disease. He had been particularly close to her because she had been only 3 years old when their mother had died. He had been her caretaker all her life.

Although he denied feelings of guilt, he said that it “wasn’t right” that he had outlived the youngest member of his family. His family said that he had taken her death especially hard and was tearful and angry. The focus of his anger during the final stages of her illness was at the young doctors whom he perceived as having given up on her. After her death, it fell to him to dispose of her accumulated possessions as she had no children and her husband had preceded her in death many years before. At first he said that he couldn’t face the task. Finally, some 2 months later, he was able to close her estate. During that period of time, he had significant sleep disturbance, reduced energy and his family often experienced him as crotchety and complaining. They and the patient attributed it to mourning her loss. However, recently he was emotionally detached, not very interested in life around him, and they found it particularly alarming that he had said to his son that he was “ready to die”. What did all this mean? Was he depressed? Was he physically ill, creating the sense of apathy and disinterest? Was he grieving? He was not suicidal. He did not suffer negative thoughts about his own personhood. He was not having thoughts that he had let anyone down. Together, he and the psychiatrist decided that he was indeed grieving. This time, he was grieving for his own decline and imminent death. He, in fact, was in the final acceptance phase of that process. In a family meeting, in the discussions about the feelings of each member of the family, it became apparent that he was facing the end of life, which evoked many emotions in those who loved him.

It is challenging to elicit the elements of a story especially when they span generations. The elderly are often stoic. In the face of losses that mark the closing years of life, denial often becomes a healthy tool allowing one to accept and cope with declining abilities and the loss of loved ones. The psychiatrist must appreciate that grief and depression can often be similar in some respects.

**Chronically Mentally Ill**

Listening to the chronically mentally ill can be especially challenging, too. The unique choice of words characteristic of many who have a thought disorder requires that the physician search for the meanings of certain words and phrases that may be peculiar and truly eccentric. Clinical Vignettes 1, 10 and 12 are examples of this important challenge for the psychiatric listener.

**Clinical Vignette 17**

A young man with schizotypal personality disorder and obsessive–compulsive disorder presented for months using adjectives describing himself as “broken and fragmented”. Only after listening carefully, not aided by the expected or normal affect of a depressed person, was the psychiatrist able to discern that his patient was clinically depressed but did not have the usual words to say it or was unable to discuss it.

**Clinical Vignette 18**

A 32-year-old black woman who had multiple hospitalizations for schizophrenia and lived with her mother was seen in the community psychiatric center for routine medication follow-up. Her psychiatrist found her to have an increase in the frequency of auditory hallucinations, especially ones of a derogatory nature. The voices were tormenting her with the ideas that she was not good, that she should die, that she was worthless and unloved. Her psychiatrist heard her say that she had wrecked her mother’s car 2 weeks previously. The streets had been wet and the tires worn. She had slid into the rear of a car that had come to an abrupt stop ahead of her on a freeway. Although her mother had not been critical or judgmental, the patient felt overwhelming guilt as she watched her mother struggle to arrange transportation for herself each day to and from work.

Chronically psychiatrically disabled patients may have a unique way of presenting their inner world experiences. Sometimes the link to the outer world is not so apparent. The psychiatrist is regularly challenged with making sense of the meanings of the content and changes in intensity or frequency of the psychotic symptoms.

**Physically Ill Patients**

In consultations with a colleague in a medical or surgical specialty one is evaluating a patient who has a chronic or acute physical illness. The psychiatrist must listen to the story of the patient but also keep in mind the story as reflected in the hospital records and medical and nursing staff. Then the psychiatrist serves as the liaison not only between psychiatry and other medical colleagues, but also between the patient and his caregivers.

**Clinical Vignette 19**

A 35-year-old woman was hospitalized for complications of a pancreas/kidney transplant that was completed 20 months previously. Prior to surgery she had been on dialysis for over a year awaiting a tissue match for transplantation. That year she had been forced to take a leave of absence from her job as a social worker with a local child and adolescent community center. At the time of this hospitalization, she had been back at work for only 8 months when she developed a urinary tract infection that did not respond to several antibiotics. Her renal function was deteriorating and her doctors found her to be paranoid,

hostile and labile. Her physicians dreaded going into her room each morning and began distancing themselves from her.

Psychiatric consultation was sought following a particularly difficult interaction between the patient and her charge nurse, the leader of the transplant team and the infectious disease expert. She was hostile, blaming, agitated, circumstantial, refused further medications and pulled out her intravenous lines. The consultation requested assistance in hospital management.

When interviewed, the patient was lying quietly in bed but visibly stiffened when the psychiatrist introduced herself. She very quickly exhibited the symptoms described in the consultation. This patient had struggled with juvenile onset diabetes since the age of nine. Despite the fact that she consistently complied with diet and insulin, control of blood sugars had always been difficult. As complication after complication occurred, she often developed the belief that her physicians thought that she was a “bad” patient. And now, the hope that her life would normalize to the point that she could carry on with her career was dashed. She felt misunderstood and alone in her struggle with long-term, chronic illness. The psychiatrist resonated with the story emotionally and listened for ways to address symptoms from a biological standpoint as well. The patient felt reassured that someone was there to appreciate the tragic turn that her life had taken.

### Growing and Maturing as a Listener

Transference/countertransference influence not only relationships in traditional psychotherapy but also interactions between all physicians and patients and is always present as a filter or reverberator to that which is heard. However, even the most experienced of listeners are not always aware of the ways in which their patients' stories are impacted by countertransference. Patients come, too, with tendencies and predispositions to experience the listener, the other person in the therapeutic dyad, in familiar but distorted fashion. The patient may idealize and adapt to interpretations. She/he may be hostile and distrustful, identifying the psychiatrist in an unconscious way with one who has been rejecting in the past. Listening to the “flow of consciousness”, the psychiatrist discerns a thread of continuity and purposefulness in the patient's communications. As the psychiatrist becomes more and more familiar with his patient, he will discover the connections between threads and the meaning will become apparent. This awareness may come as a sign and symptom, fantasy, feeling, or fact.

There is an increasing recognition that to be a healing listener one must be able to bear the burden of hearing what is told. Like the patient, we fear what might be said. A patient's story may be one of rage in response to early childhood attachment ruptures or abuse, of sadness as losses are remembered, or of terror in response to disorganization during the experience of perceptual abnormalities accompanying psychotic breaks. The patient's stories invariably invoke anger, shame, guilt, abject helplessness, or sexual feelings within the listener. These feelings, unless attended to, appreciated and understood will block the listening that is essential for healing to take place.

Every insight is colored by what the listener has known. It is impossible to know that which is not experienced. The psychiatrist comes with his own experiences and the experiences he has had with others. To listen in the manner we are describing here is another way of truly experiencing the world. The experiences include the imaginings of how it must be to be 87 years old as a patient when one is a 35-year-old doctor just finishing residency; to be female when one is male; to be a child again; to grow up African-American in a small white suburb of a large city; to be an immigrant in a new country; to be Middle Eastern when one is Western European, and so on. One comes to know by listening with imagination, allowing the words of the patient to resonate with one's own experiences or with what one has come to know through hearing with imagination the stories of other patients or listening to the thoughts or insights of supervisors.

The best psychiatrists continue all their professional lives to learn how to listen better. This may be thought of not only as a matter of mastering countertransference but of self-education. One must learn to recognize when there are impasses in the treatment and to seek education, from a colleague or, perhaps, even from the patient. Consider these two examples.

---

#### Clinical Vignette 20

A Jewish resident was treating an 8-year-old Catholic boy who came in one day and mentioned offhandedly that he was about to go to his first confession. The psychiatric resident made no particular note of the issue and kept on listening to the boy's play and its themes. He noted that guilt, which had been an ongoing theme, was prominent again. When he presented the session in supervision the supervisor wondered about the connection. It emerged that there was a large gulf between the therapist and the boy. Jewish concepts of sin and atonement are different from Christian ones, and the rituals surrounding them have rather different intentions and ideas of resolution. The resident had missed the opportunity to explore the young boy's first introduction, within his religious context, to the belief in a forgiving God, a potentially important step in helping the child to resolve his ongoing struggles with guilt over his own greedy impulses.

---

#### Clinical Vignette 21

A psychiatrist began treating a Nigerian native who was suffering from post traumatic stress disorder (PTSD) after being assaulted at work. After several sessions, the psychiatrist felt a sense of being at a loss in terms of what the patient was expecting out of their work and how the therapist was being seen by the patient. He then took several sessions to inquire of the patient about his tribe, its structure, family roles, definitions of healing, ideas of illness and wellness, etc. After this exploration, the psychiatrist adopted a different stance with the patient, heard the patient's communications very differently, and the therapy proceeded much more smoothly and comfortably to a successful conclusion.

How can the psychiatrist's demeanor convey to the patient that he is safe to tell his story, that the listener is one who can be trusted to be with him, to worry with him, and serve as a helper? Much is written about the demeanor of the psychiatrist. The air, deportment, manner, or bearing is one of quiet anticipation – to receive that which the patient has come to tell and share in the telling. Signals of anticipation and curiosity may be conveyed by such statements as “I’ve thought about what you said last time,” “How do you feel about...?” “What if...?”

Efforts of clarification often serve as bridges between sessions and communicate that the listener is committed to a fuller understanding of the patient. Patients have the need to experience the psychiatrist as empathic. Empathy describes the feeling one has in hearing a story which causes one to conjure up or imagine how it would have been to have actually had an experience oneself. How does one integrate all this so that it is automatic but not deadened by automaticity? How does the psychiatrist continue to hear the “same old thing” with freshness and renewal? How does one encourage the patient with consistency, clarity, and assurance in the face of uncertainty and occasional confusion? Not by assurance that everything will be all right when things might probably not be. Not by attempting to talk the patient into seeing things the clinician's way but rather by the psychiatrist's having the capacity to hear things his patient's way, from the patient's perspective.

Psychiatry is one of those rare disciplines where the experience of listening over and over again allows the listener to grow in their capacities to hear and to heal. Hopefully, we get better and better as the years advance, become smoother, and develop a style which blends with our personality and training. We are renewed by the shared experiences with our patients.

To hear stories of the human condition reminds the psychiatrist that he, too, is human. There is time to make discoveries in the patient's stories from previous times, and maybe in previous patients. Patients will always endeavor to tell their stories. The psychiatrist continues to grow by being the perpetual student, always with the ear for the lesson, the remarkable life stories of his patients.

# The Cultural Context of Clinical Assessment

---

## Introduction: The Cultural Matrix of Psychiatry

Although it has long been recognized that the mode of expressing psychological distress and behavioral disturbances varies with cultural beliefs and practices, a growing body of evidence shows that the effects of culture are more far-reaching. Research has clearly demonstrated that the causes, course and outcome of major psychiatric disorders are influenced by cultural factors (Kleinman, 1988; Kirmayer, 2001; Leff, 2001; Lopez and Guarnaccia, 2000). Wide variations in the prevalence of many psychiatric disorders across geographic regions and ethnocultural groups have been documented with current standardized epidemiological survey methods (Canino *et al.*, 1997; Kirmayer and Groleau, 2001). In addition, social and cultural factors are major determinants of the use of health care services and alternative sources of help (Rogler and Cortes, 1993).

For all of these reasons, careful assessment of the cultural context of psychiatric problems must form a central part of any clinical evaluation (GAP, 2002). Beyond this, culturally based attitudes and assumptions govern the perspectives that both patient and clinician bring to the clinical encounter. Lack of awareness of important differences can undermine the development of a therapeutic alliance and the negotiation and delivery of effective treatment.

The changing demography of North America and around the world has made the recognition and response to cultural diversity increasingly important in psychiatric practice (GAP, 2002). The overarching ideology took for granted that newcomers would gradually become just like all others through a process of cultural assimilation (Portes and Rumbaut, 1996; Susser and Patterson, 2001). However, sociological research has shown a high degree of retention of ethnic culture with the persistence of religious practices, family life-cycle rituals and ethnic enclaves in many cities. Added to this is the recognition of the importance of maintaining and renewing ethnocultural identity to combat the legacy of racial discrimination. This has led to rethinking the notion of assimilation to take into account other modes of acculturation including the development of multiple cultural identities. More recent waves of global migration from south to north and east to west have brought together new mixes of peoples with greater differences in their cultural assumptions, with corresponding challenges for intercultural clinical work.

These changes, along with larger forces of globalization, have encouraged a fresh look at culture in every area of psychiatry. In clinical practice, “cultural competence” has become the rubric under which to advance a broad range of skills and perspectives pertinent to working with a culturally diverse clinical population (GAP, 2002). In

the sections that follow, we will summarize some of the concepts and approaches that can inform culturally competent clinical practice.

## What Is Culture?

There is a famous saying to the effect that we do not know who discovered water but it was not the fish. So it is with culture: we are immersed in our own cultural worlds from birth, and consequently our culture is largely implicit and unexamined. Just as we are unconscious of many of our own motivations and patterns of thought and behavior until they are reflected back to us by others, so too are we unconscious of our cultural background knowledge and assumptions. Bringing the cultural unconscious to light may be more difficult than facing the individual unconscious because institutions and others around us may reinforce our assumptions and resist any attempt to question them. Our explicit appreciation of culture usually comes from intercultural encounters, which make us suddenly aware of culture through difference. More formally, anthropological research comparing different cultures allows us to see the tacit assumptions of our own worldviews. There is no substitute for this sort of systematic reflection on cultural difference, which should extend to the critical analysis of the construction of psychiatric knowledge (Lock and Gordon, 1988; Young, 1995).

Older views of culture were based on ethnographic studies of relatively isolated small-scale societies. Many accounts tended to assume that cultures were finely balanced systems and that, as a result, everything was for a purpose and had an adaptive function for the group (if not always for the individual). The outsider was thus cautioned not to pass judgment on cultural differences or to see pathology where there was simply difference. This is still wise advice. However, it is clear that cultures are not homeostatic systems in a steady state or equilibrium but are constantly shifting and evolving systems. They may be riven by conflict and create maladaptive circumstances not only for disadvantaged individuals but for specific groups or even the society as a whole. Thus, while refraining from prejudging specific cultural values or practices, the clinician must nevertheless consider that every culture encompasses practices that may help or hinder patients, and aggravate or ameliorate any given type of psychopathology. Each society tends to cultivate blind spots around the specific forms of social suffering that it produces (Kleinman *et al.*, 1997). Openness, respect and capacity for collective self-criticism are thus key elements of any transcultural clinical encounter.

At the same time, anthropologists have come to recognize the high level of individual variability within even small cultural groups and the active ways in which individuals and groups make use of a variety of forms of knowledge to fashion an identity and a viable way of living. In urban settings where many cultures meet, individuals have a wide range of options available and can position themselves both within and against any given ethnocultural identity or way of living. This has led anthropologists to rethink the notion of culture or even to suggest that it has outlived its usefulness.

Indeed, the modern world includes forms of electronic communication and rapid transportation that have begun to weave the whole globe together in new ways. This results in the intermixing of cultural worlds and the creation of new ethnocultural groups and individuals with multiple or hybrid identities. Many people now see themselves as transnational, with networks of affiliation and support that span great distances. The mental health implications of these new forms of identity and community have been little explored and will be an increasingly important issue for psychiatry in the years to come (Bibeau, 1997; Kirmayer and Minas, 2000).

As this brief discussion makes clear, the notion of culture covers a broad territory. It is useful precisely because of this breadth, but to apply it to clinical practice we need to make some further specifications and distinctions. In the North American context, it is useful to distinguish notions of race, ethnicity and social class from culture.

Race is a term used to mark off groups within and between societies. Racial distinctions generally reflect a few superficial physical characteristics and hence have little correlation with clinically relevant genetic variation. The boundaries of any racial group are socially defined and have no biological reality (Graves, 2001). Race is usually ascribed by others and cannot readily be changed or discarded unless larger social criteria change. Race is significant as a social category that is employed in racist and discriminatory practices. Racism is clinically important because of its effects on mental and physical health and the challenge it presents to both individual and collective self-esteem.

Ethnicity refers to the collective identity of a group based on common heritage, which may include language, religion, geographic origin and specific cultural practices. Ethnic identity is often constructed *vis-à-vis* others and a dominant society. Hence, it is sometimes assumed that “foreigners” or minorities have ethnicity while the dominant group (e.g., Americans of British or northern European extraction) does not. This obscures the fact that everyone may become aware of an ethnic identity in the right context (in China, an American clearly has a distinct ethnicity). Ethnicity may be chosen or ascribed by others. For example, the US census defined five ethnoracial blocs: White, African-American, Hispanic, Asian-American and Pacific Islander, and American Indian and Alaska Native. These are heterogeneous categories variously based on race, language, geographic origin and ethnicity. Although the categories are fictive, they have acquired practical and political reality because they have been used to present epidemiological findings and define health service needs (Hollinger, 1995). Nevertheless, the clinician must recognize that to meet the patient on a common ground requires a much more fine-grained notion of ethnocultural identity than afforded by these crude categories.

Finally, social class reflects the fact that most societies are economically stratified and individuals’ opportunities, mobility, lifestyle and response to illness are heavily constrained

by their economic position. Issues of poverty, unemployment, powerlessness and marginalization may overshadow cultural factors as causes of illness and influences on identity and help-seeking behavior. Violence is a particularly striking example in North American society of the overlap of exclusion, poverty, discrimination and intergenerational transmission of trauma.

The notion of culture is sometimes extended to speak of various subcultures or the cultures of professions. In this sense, we can speak of the cultures of biomedicine and of psychiatry. Each of these systems of knowledge includes a wide range of behavioral norms and institutional practices that may be familiar to clinicians but novel and confusing to patients. However, familiar cultural notions of self and personhood underwrite these technical domains, which therefore serve to reinforce larger cultural ideologies (Lock and Gordon, 1988). This becomes clear when we consider alternative systems of medicine such as traditional Chinese medicine or Indian Ayurveda, which are based on different notions of the person (ethnopsychology), the body (ethnophysiology), different roles for patient and healer, and, indeed, different epistemologies (Leslie and Young, 1992). Even the understanding and practice of biomedicine may differ across countries, so the clinician should not assume that familiar terms always refer to the same practice.

## Culture and Gender

Gender refers to the ways in which cultures differentiate and define roles based on biological sex or reproductive functions. Because of this link with physical aspects of sex, there is a tendency to view gender differences as biological givens. However, while some distinctions may be closely related to the physiological differences between males and females, most are assigned to the sexes on the basis of specific cultural beliefs and social organization (Comas-Diaz and Greene, 1994).

Men and women do have some fundamentally different experiences of their bodies, of their social worlds and of their life course. It has been suggested that women are more in touch with their bodies because of the experiences of menstruation, child-bearing, childbirth, breast-feeding and menopause. These differences may be as substantial as any between disparate cultures. At the same time, there is much evidence that these bodily grounded experiences vary substantially across cultures. For example, the anthropologist Margaret Lock (1993) has shown that Japanese women report fewer bodily symptoms of menopause and do not think of the end of menstruation as a distinctive “change of life” in the same terms as many women in North America.

There are also important gender differences in styles of emotional expression, symptom experience, and help-seeking. In epidemiological surveys in the USA, women tend to report more somatic symptoms as well as more emotional distress and they are more likely to seek help for psychological or interpersonal problems. However, the gender difference in symptom reporting varies significantly cross-nationally (Piccinelli and Simon, 1997).

In North America, important differences have been documented in male and female styles of conversation that are relevant to the clinical context (Tannen, 1994). In general, women tend to give more frequent acknowledgments that they are listening to a speaker. They may give signs of assent simply to indicate they are following the conversation. Men tend to be more taciturn and, if they signal assent, it usually means they actually agree with the speaker. These differences in communication style may lead to systematic misunderstandings between men and women

that are further aggravated by cultural differences in gender roles and etiquette.

#### Clinical Vignette 1

When an ultra-orthodox Jewish family arrives for their consultation, the female psychiatrist, who is dressed in a short skirt, welcomes them offering her hand to the father in greeting. He is confused and offended, avoiding eye contact and reluctant to proceed with the session. The female doctor's style of dress and friendly handshake were viewed as disrespectful or as indicating her lack of familiarity with norms of conduct with observant orthodox families.

In many societies, gender is associated with marked differences in power and social status. For example, in patriarchal societies, men have specific power and privileges that give them a measure of control over the lives of women. This is often coupled with responsibilities for maintaining family honor and well-being. In recent years, North American society has espoused social and political equality in gender roles. From this egalitarian point of view, patriarchal families may seem oppressive to women. However, women may accept and participate in cultural definitions of their roles that appear restrictive by North American cultural norms but that make family life meaningful. Any judgment as to whether a given family's relationships are oppressive or pathological must not only take into account social norms and practices but also explore the meaning of issues and events for the individuals involved.

#### Clinical Vignette 2

A 29-year-old East Indian woman, in the US for 6 months, presents with symptoms of depression and PTSD. Throughout the initial evaluation, the patient looks away from the male psychiatrist, never making eye contact. The interviewer is concerned that he may have offended the woman in some way. The female interpreter explains that the patient is showing respect by not looking directly at a male in authority.

Differences in cultural definitions of gender roles may become sources of conflict after migration. Culturally prescribed patterns of marriage and child bearing may be central to the social status, identity and self-esteem of men and women even when they are not given the same importance in the dominant culture.

#### Clinical Vignette 3

A 28-year-old woman from South Asia has an arranged marriage with an older man from the same religious community, who has lived all of his life in the USA. The couple has been unable to conceive for 5 years and is in the midst of extensive infertility treatments. The husband complains that she is paranoid and does not want to work or go out of the house. The woman tearfully relates that she feels depressed and ashamed because of her predicament and fears that her marriage will end if she cannot bear children.

### The Cultural Formulation

In an effort to address the cultural dimensions of clinical assessment, DSM-IV-TR introduced an outline for a cultural formulation (Table 2.1). This outline covers major areas that a clinician should explore in a comprehensive evaluation. These are integrated in a formulation that helps to account for symptomatology, diagnosis, prognosis and appropriate treatment (Lewis-Fernandez, 1996; see also Chapter 21). The formulation may go well beyond the DSM-IV-TR categories to consider many sorts of problems and predicaments relevant to the patient's well-being.

The cultural formulation is merely intended as a checklist or reminder to encourage the clinician to perform the needed exploration and integration of a broad range of relevant social and cultural information. Clearly, cultural considerations may apply to every aspect of the clinical assessment and interview and must not be used only as an afterthought to the standard psychiatric interview.

### Ethnocultural Identity

The first dimension of the cultural formulation involves ethnocultural identity. This includes the individual's ethnic or cultural reference groups and the position of these groups *vis-à-vis* the larger society. Certain groups have a specific ethnocultural identity ascribed to them by others; this may have an impact on individuals' everyday experience and narratives of identity whether or not they are explicitly aware of it.

In a world of mass migration and intermingling of peoples over generations, identity is very often hybrid, multiple and fluid (Bibeau, 1997). For immigrant and ethnic minorities it is important to understand the degree of involvement with both the culture of origin and the host culture. Ethnic identity may be situational and shift with social context. The ethnocultural and religious groups with which the patient most identifies may depend on who asks the question and in what context. For example, whether someone self-identifies as Canadian, West Indian or Trinidadian may depend on the perceived identity of the interviewer and the setting where the interview takes place.

Language is central to identity for many people and has a profound effect on clinical encounters. Individuals who speak multiple languages, learned at different stages in their life, may have different memories, affect and interpersonal schemas associated with the use of each language. Languages may be associated with developmentally important relationships and tied to specific areas of conflict or mastery. Personal and political allegiances within the family and community may be expressed through choice of language.

Language is the medium through which experience is articulated; hence, the assessment of higher cognitive functions, complex emotions and experiential symptoms of pathology all depend on the clinician's access to the patient's language. Patients who are hobbled in a second language may be misjudged as less intelligent or competent than they are in fact; wishing to avoid such bias, clinicians may be overly generous in their assessment and miss significant problems or pathology.

Even where patients have a moderate level of facility in the clinician's preferred language, they may not express themselves fully in a second language so that important details are not conveyed. The use of a second language not only affects doctor-patient communication, it also influences individuals' ability to reflect about themselves. When patients are forced to formulate their problems in a language in which they are not proficient, they may be less creative and effective as problem solvers. When patients are able to use their own best language, their accounts of experience become much richer, more complex and nuanced; their thinking is subtler; they can express a wider range of affect and engage in playful therapeutic exchanges.

Multilingual people sometimes report that they feel and think differently when using a second language. In part, this is due to the cognitive effort of having to find words in a language in which one is not totally fluent. Since each language favors certain modes of expression and ways of thinking, bilingual speakers may report that they feel like a different person in their other language. It follows that aspects of the history and experience of a patient can be less accessible in a clinical evaluation if patients are not able to express themselves in the appropriate language. Of course, use of a second language may also afford the patient some distance from intense emotions and painful memories, and so assist in coping and affect regulation. Careful attention to spontaneous or strategic shifts in use of language in a multilingual assessment can provide the clinician with important information about areas of conflict and strengths. Often this requires the use of a trained interpreter, as discussed later in this chapter.

Religion is another key marker of identity. For many individuals and communities, it may structure the moral world more strongly than ethnic or national identity. The term "spirituality" has gained currency to acknowledge the fact that many individuals maintain deeply held personal beliefs about God, the meaning of life and what happens after death, without being formally affiliated with one religion or another. Religious affiliation is also a frequent source of discrimination.

Despite the ubiquity of religious and spiritual experience, it is frequently neglected during routine psychiatric evaluation. A thorough cultural formulation requires consideration of the patient's religion and spirituality. Areas to cover include religious identity, the role of religion in the family of origin, current religious practices (attendance at services, public and private rituals), motivation for religious behavior (i.e., religious orientation), and specific beliefs of individuals and of their family and community.

### Illness Explanations and Help-seeking

The second major dimension of the cultural formulation concerns cultural explanations of symptoms and illness. Cultures provide systems of diagnosis and treatment of illness and affliction that may influence patients' experience of illness and help-seeking behavior. People label and interpret their distress based on these systems of knowledge, which they share with others around them. Much

**Table 2.2 Explanatory Model Interview**

1. What do you call your problem?
2. What causes your problem?
3. Why do you think it started when it did?
4. How does it work?
5. What is going on in your body?
6. What kind of treatment do you think would be best for this problem?
7. How has this problem affected your life?
8. What frightens or concerns you most about this problem or treatment?

*Source:* Kleinman A, Eisenberg L and Good B (1978) Culture, illness, and care: Clinical lessons from anthropologic and cross-cultural research. *Ann Intern Med* 88, 251–258. Reproduced by permission of American College of Physicians.

research in medical anthropology has developed the idea of explanatory models, which may include accounts of causality, mechanism or process, course, appropriate treatment, expected outcome and consequences. Not all of this knowledge is related directly to personal experience – much of it resides in cultural knowledge and practices carried by others. Hence, understanding the cultural meanings of symptoms and behavior may require interviews with other people in the patient's family, entourage, or community.

Table 2.2 provides questions for eliciting patients' explanatory models. These questions should be modified based on the patient's responses. For example, the origins of problems may be located not in the body but in the workings of the mind, the family, the community, the realms of ancestors or spirits, or in mythological accounts that explain the social and moral order.

In many cases, particularly with acute illness, patients may not have well-developed explanatory models. Instead, they reason by analogy on the basis of past experiences of their own or other prominent prototypes encountered in family, friends, or mass media. Once an explanatory model is evoked in conversation, however, patients may give formulaic accounts that accord with that cultural model or script. Therefore, to obtain more complete information about the cognitive and social factors that are actually influencing the patients' illness experience and behavior, it is useful to begin with an open-ended interview that simply aims to reconstruct the events surrounding symptoms and the illness experience. This will reveal idiosyncratic temporal patterns of contiguity and association that may not fit any explicit cultural model. Following this, the clinician can ask about prototypes (Have you ever had anything like this before? Has anyone you know ever had anything like this before?) This will uncover salient models of illness that may shape illness experience and be used to reason analogically about the current episode. Finally, it is important to inquire into explicit cultural models using the sorts of questions devised for the explanatory model interview.

The ethnomedical systems described in anthropological texts often are idealized and complex portraits pieced together by working with cultural experts. In clinical practice, patients usually have only partial or fragmentary knowledge of the traditional explanations and treatment for their problem. Depending on the knowledge and attitudes of family and kin, and on the availability of practitioners of traditional medical systems, patients may be influenced by larger cultural systems to which they themselves do not fully subscribe.

---

**Clinical Vignette 4**

A family from Nigeria consults for developmental delay in their 4-year-old son. Problems had become evident when they attempted to integrate the child into a preschool program. The child presents a classical profile of pervasive developmental disorder. The parents comment that their family doctor raised the possibility of autism but that they did not consider that what he described applied to their son. They explain that the migration process, when the child was two, had hindered his acquisition of speech and social activities. After a few sessions it becomes apparent that the child's difficulties had already been recognized in Nigeria but were attributed by both the maternal and the paternal lineage to sorcery on the other side of the family because they were in conflict.

In everyday life, people use culturally prescribed idioms to discuss their problems. These cultural idioms of distress cut across specific diagnostic categories. They may be used to talk about ordinary problems as well as to shape the expression of distress associated with major psychiatric disorders. For example, many cultures have notions of “nerves” (in Spanish, *nervios*), which signal emotional distress that may range from mild upset with life events to disabling anxiety or psychosis. Appendix I of DSM-IV-TR provides a list of some common idioms of distress. The same appendix also lists some well-described culture bound syndromes, culturally distinctive clusters of symptoms that may be of pathological significance. Many culture-specific terms, however, do not refer to syndromes or idioms of distress but are actually symptoms or illness attributions that reference folk models of causality. For example, *susto*, a term used in Central and South America, attributes a wide range of bodily symptoms and diseases (including infectious diseases and congenital malformations) to the damaging effects of sudden fright.

Many cultural idioms of distress use bodily metaphors for experience. In seeking medical help, patients usually try to present the sort of problems they believe the clinician is competent to treat. Consequently, in biomedical settings patients tend to emphasize physical symptoms. This pattern of clinical presentation combined with the wide currency of somatic idioms of distress has led to a characterization of many ethnocultural groups as prone to somatize their distress (Kirmayer, 2001). The social stigma commonly associated with psychiatric symptoms and disorders, as well as with substance abuse, antisocial behavior and various other behaviors also may prevent patients from acknowledging such problems and events. However, with clear communication and a respectful stance, the clinician may be able to build sufficient trust over time for patients to disclose shameful or potentially stigmatizing information.

Similarly, people commonly use multiple remedies or consult various healers for their symptoms, and may be reluctant to disclose treatments they think the clinician will not understand or accept. They may also omit mention of preparations they view as “natural” or as foods and hence not included under the rubric of medications or drugs. Commonly used remedies like ginseng, St John's Wort and *Gingko biloba* have significant effects on pharmacokinetics and drug metabolism (see Chapter 76) and are, therefore, important for their potential impact on physiology as well as their role in patients' belief systems and sense of control over their illness. A nonjudgmental inquiry by the clinician will

enable patients more freely to discuss their use of traditional and alternative treatments.

## Psychosocial Environment and Levels of Functioning

Cultural factors have a dual influence on the psychosocial environment: they determine life circumstances and, at the same time, provide interpretations of their meaning and significance for the individual. This dual effect of culture means that the clinician must explore both events and their personal and cultural meanings to understand the impact of the social environment.

There are wide cultural variations in the composition and functioning of families including the variety of people living together in a household (not always identical to the family or kin); who is considered close or distant kin; hierarchy, power structure and economic arrangements; age and gender roles; organization of household activities and routines; styles of expression of emotion and distress; body practices (arrangements and procedures for sleeping, eating, washing, dressing, recreation and use of physical remedies for ailments); conflict management strategies; and the relationship of family to larger social networks and communities.

Social support must be assessed with attention to cultural configurations of the family and community. Extended multigenerational families, tightly knit religious and ethnocultural communities, and transnational networks all may provide specific forms of instrumental and emotional support. Often these supports are inextricably intertwined with interpersonal obligations and demands that may constitute burdens for the individual. This complex relationship of burden and support may have crucial implications for clinical interventions.

---

**Clinical Vignette 5**

A woman from South Asia appears to have a severe depression with vegetative symptoms and persistent suicidal ideation. She does not respond to trials of several antidepressant medications. On reassessment with a clinician who speaks her language, she reveals that her husband has an unpaid debt of honor to her daughter's husband's family, and she is suffering from the ongoing feud, which has barred her from seeing her daughter and grandchildren. When this is addressed in a series of family therapy sessions, her “depression” lifts dramatically.

Similarly, levels of functioning and disability must be assessed against culturally determined notions of social roles and values. It is important to recognize that the clinician's priority may not be the most important issue for patients or their families.

In addition to these general cultural considerations, certain social situations present specific stressors with which the clinician must become familiar. All immigrants and refugees have arrived in the host country after a migration experience. For some, migration is a personal choice taken in the hope of bettering personal and family prospects; for others the experience is borne of extreme difficulty and is only taken under threat of harm or death. Many new arrivals face bleak job prospects, are isolated from family and cultural institutions, and have an uphill battle as they adapt to a new language and unfamiliar social rules

and obligations. Furthermore, the path that some immigrants take prior to arriving at their final destination is often lengthy, circuitous and costly, in addition to being dangerous. It is crucial, therefore, to take into account the migration experience when evaluating immigrants and refugees. Questions must be carefully phrased and asked in a judicious manner, as not all patients will be ready to discuss their reasons for leaving their homeland. Important points to cover include the premigration lifestyle of the patient, the context of migration, the experience of migration, the postmigration experience, and the “aftermath” of migration, or the long-term adjustment and acculturation to the host society (Beiser, 1999).

The stresses experienced by refugees may include the confusion and disorientation of unplanned flight and exile; loss of social status, wealth, security and community; and worry about the safety of family left behind and still in peril. Refugee claimants or asylum seekers usually face a stressful period of uncertainty while waiting to have their status determined. The refugee review process itself may be traumatic because it often occurs in an adversarial atmosphere that questions the veracity of the refugee’s story even as it foregrounds traumatic memory (Silove *et al.*, 2000). Individuals who have endured war-related trauma, torture, or other forms of organized violence have special needs to insure the safety of the clinical setting and relationship (Silove, 1999).

#### Clinical Vignette 6

A 35-year-old professional from Peru visited the emergency room because of high fever caused by pneumonia. While waiting to be seen, he suddenly became agitated and fled the hospital, breaking through the parking lot barrier. After his arrest the judge ordered a psychiatric assessment. The patient explained that on seeing the medical instruments in the ER he was reminded of his torture in Peru and felt convinced that he was back there and that his life was in danger. The combined effects of fever and reminders of the trauma had triggered a dissociative episode.

The growing number of undocumented people around the world also presents ethical and pragmatic challenges to the medical profession. These illegal immigrants and families may have particular mental health needs, which are largely unrecognized because there is almost no funded research or services to address them.

### Clinician–Patient Relationship

The roles of healer, helper and physician differ across cultural contexts, and patients may have correspondingly different expectations of their relationship with clinicians, including the duration, level of disclosure, formality and emphasis on technical competence. These expectations often need to be explored, with opportunities for patients and clinicians to negotiate or explain limits to the roles they are able and willing to adopt. Once these differing perspectives are made explicit, a culturally appropriate and professionally acceptable relationship and working alliance can be negotiated.

Clinicians must become aware of their own ethnocultural background and identity and reflect on how it is perceived by patients from their own and different backgrounds. The terms

“cultural transference” and “cultural countertransference” have been used to acknowledge that both patient and clinician may have fantasies and responses to the other that are based on earlier relationships with others from that culture or on culturally rooted associations to the other, rather than to strictly personal characteristics (Adams, 1996; Comas-Diaz and Jacobsen, 1991).

#### Clinical Vignette 7

Sent by her 8-year-old son’s school, a university-educated woman from Somalia consults for his conduct problems which are not responding to stimulant medication prescribed by a pediatrician for attention deficit hyperactivity disorder. She is obviously reticent about the assessment process. The white clinician explicitly addresses the difficulty of being a black, veiled woman in North America because of the strong prejudices against both Islam and Africa. The woman visibly relaxes and begins to explain that she feels that she is being treated as though she is intellectually handicapped or as a child by the school. They use a loud voice and simplistic formulations when they speak to her, and she finds this very humiliating. Later in the interview, after further strengthening of the alliance with the clinician, she discloses the war trauma to which the boy was exposed.

### Overall Assessment

The aim of the cultural assessment is to integrate all of the pertinent elements of the cultural context of the patient’s identity, illness and social context in a formulation that can guide diagnosis and treatment (Hays, 2001; Tseng and Streltzer, 1997). Factors associated with one aspect of the formulation may have an impact that cuts across many dimensions of illness experience and behavior. The salient aspects of culture vary across cases and may reflect issues in the dominant society as much as any intrinsic characteristics of the patient’s ethnocultural group.

For example, cultural notions of race and racism may profoundly affect every aspect of the cultural formulation (Pinderhughes, 1989; Patel *et al.*, 2000; GAP, 2002). Racial categories may impose a disvalued identity on the patient; this may be resisted by reconstructing identity in a fashion that imbues one’s background with dignity and “cultural capital” (Comas-Diaz and Greene, 1994; Kareem and Littlewood, 1992). Race may figure in explanations of the nature of illness. For example, some Native peoples have come to view alcoholism, diabetes and other conditions as “white man’s illnesses”, which they suffer in large numbers precisely because of the history of colonization and racist practices. High blood pressure among African-Americans has been linked to the stresses of racial prejudice and related economic and educational disparities (Dressler *et al.*, 1998). Institutionalized racism may have a powerful impact on the level of stress and social support for individuals, families and communities, which may fracture or unite around this issue. The legacy of racism may define the clinician–patient relationship, where it may influence the transference and undermine rapport.

### Cultural Competence

Recent years have seen the development of professional standards for training and quality assurance in cultural competence (Lopez, 1997; Sue, 1998). This term stands for a range of

**Table 2.3 Strategies to Elicit Cultural Information**

- Present an open, friendly face of the institution (have the diversity of the community represented within the diversity of the institution, with attention to not simply reproducing the class structure of the society in the institutional hierarchy).
- Make explicit the clinician's position and identity, explain goals and methods, use self-disclosure appropriately.
- Ask for clarification of unfamiliar terms or key terms that may be mistakenly assumed to be familiar.
- Ask for detailed description of practices related to health, illness and coping.
- Have the patient compare situation with previous events or experiences of others from similar background.
- Interview other family members and patient's entourage to obtain normative framework and identify consensus and conflicting perspectives.
- Consult knowledgeable clinicians, culture-brokers, interpreters, anthropologists and ethnographic literature.

approaches aimed at improving the delivery of appropriate services to a culturally diverse population. Cultural competence may involve both culture-specific and generic strategies to address a range of practical issues in intercultural work (Okpaku, 1998). This includes the clinician's ability to elicit cultural information during the clinical encounter (Table 2.3), to understand how different cultural worlds of patients and their families influence the course of the illness, and to develop a treatment plan that empowers the patient by acknowledging cultural knowledge and resources while allowing appropriate psychiatric intervention.

### Clinical Vignette 8

A 16-year-old girl from Haiti presents with disorganized schizophrenia, which began around age 14 years. Her family has not been compliant with treatment and this has led to several hospitalizations of the patient in a dehydrated state. During the third hospitalization, the clinical team decide to explore the family's interpretation of the illness. A grand-aunt insists on sending the girl to Haiti for a traditional diagnosis. The traditional healer indicates that the problem is due to an ancestor's spirit in the mother's family and that for this reason it will be a prolonged illness. This explanation helps to restore cohesion in the extended family by rallying people around the patient, and her family receives much support. The traditional interpretation and treatment has broken the family sense of shame and isolation and promoted an alliance with the medical team and the acceptance of antipsychotic medication.

Specific cultural competence has to do with knowledge and skills pertaining to a single cultural group, which may include history, language, etiquette, styles of child-rearing, emotional expression and interpersonal interaction as well as cultural explanations of illness and specific modalities of healing. Often, it is assumed that specific cultural competence is assured when there is an ethnic match between clinician and patient (e.g., a

Hispanic clinician treating a client from the same background). However, ethnic matching without explicit training in models of culture and intercultural interaction may not be sufficient to ensure that clinicians become aware of their tacit cultural knowledge or biases and apply their cultural skills in a clinically effective manner.

Ethnic matching can occur at the level of the individual, the technique, the institution, or any combination of these levels (Weinfeld, 1999). At the level of the individual, it may be easier to establish rapport when clinician and patient share a common background. However, there is a risk that some issues may be left unexplored because they are taken for granted, or are taboo and awkward to approach. There is also difficulty when the patient's expectations of a fellow community member are not met because the clinician applies the rules and limits dictated by professional training. This may include expectations of receiving special treatment, of being cured quickly, of becoming friends, or intervening inappropriately on behalf of other family or community members.

In many cases, however, ethnic matching is only crude or approximate. For example, the term **Hispanic** covers a broad territory with many cultural, educational and social class differences that transcend language. Indeed, there is enormous intracultural variation and no one person carries comprehensive knowledge of his or her own cultural background, so there is always the need to explore local meanings with patients.

In the course of professional training, clinicians may distance themselves from their own culture of origin and become reluctant or unable to use (or understand the impact of) their tacit cultural knowledge in their clinical work. Clinicians from ethnic minority backgrounds may resent being pigeon-holed and expected to work predominately with a specific ethnocultural group. Patients may have complex reactions to meeting a clinician from the same background. These issues require attention and sensitive exploration just as much as the feelings evoked by meeting someone from a different background.

At the level of technique, the clinician familiar with a specific ethnocultural group learns to modify his or her approach to take advantage of culturally supported coping strategies. For example, religious practices, family and community supports, and appeals to specific cultural values may all provide useful strategies for symptom management and improved functioning. Traditional diagnostic and treatment methods may be used in concert with conventional psychiatric treatments. The clinician may use his or her own person differently in recognition of cultural notions of healing relationships, adopting a more authoritative stance, making selective use self-disclosure, or participating in symbolic social exchanges with patients and their extended families to establish trust and credibility.

At the level of institutions, ethnic match is represented in the organization of the clinical service, which should reflect the composition of the communities it serves (Kareem and Littlewood, 1992). This is not merely a matter of hiring practices but also involves creating structures that allow a measure of community feedback and control of the service institution. When people feel a sense of ownership in an institution, they will evince a higher level of trust and utilization. It is important, therefore, for clinicians to understand how the institutional setting in which they are working is seen by specific ethnocultural communities.

Increasingly, clinicians work in settings where there is great cultural diversity that precludes reaching a high level of

specific competence for any one group. Changes in migration patterns and new waves of immigrants and refugees lead to corresponding changes in patient populations. For all of these reasons, it is crucial to supplement specific cultural competence with more generic competence that is based on a broad theoretical understanding of culture and ethnicity. Generic cultural competence abstracts general principles from specific examples of cultural differences. The core of generic competence resides in clinicians' understanding of their own cultural background and assumptions, some of which are related to ethnicity and religion and many of which derive from professional training and the context of practice. Appreciating the wide range of cultural variation in gender roles, family structures, developmental trajectories, explanations of health and illness, and responses to adversity allows the clinician to ask appropriate questions about areas that would otherwise be taken for granted. The culturally competent clinician has a keen sense of what he or she does not know and a solid respect for difference. While empathy and respectful interest allow the clinician gradually to come to know another's world, the clinician must tolerate the ambiguity and uncertainty that comes with not knowing. In the end, patients are the experts on their own experiential worlds and cultural context must be reconstructed simultaneously from the inside out (through the patient's experience) and from the outside in (through an appreciation of the social matrix in which the patient is embedded).

The wide range of specific and generic skills needed for competent intercultural work means that most clinicians will find it helpful to work in multidisciplinary teams that contain cultural diversity that reflects the patient population. A variety of models for such teamwork have been developed (Kareem and Littlewood, 1992; Kirmayer *et al.*, 2003).

### Working with Interpreters and Culture-brokers

A key skill which has not been addressed in many training programs concerns how to work with interpreters (Table 2.4). In the absence of familiarity with this technique and quality assurance standards insisting on appropriate use of interpreters, many clinicians simply try to avoid the situation, relying on patients' sometimes limited command of the clinician's language. This is unfortunate and may lead to errors in diagnosis and management as well as the failure to engage and help many patients.

There are several models of working with interpreters (Westermeyer, 1989). Medical interpreters have adopted a code of ethics and model of working that owes much to forensic and political interpreting. Their goal is to provide accurate, complete and literal translation of the statements of patient and physician. This model tends to portray the interpreter as providing a transparent window or conduit of communication between clinician and patient. In this approach, the clinician addresses the patient directly as though the interpreter is not present. The interpreter may speak in the first person for the patient and for the clinician alternately. The model assumes that it is possible to achieve complete and accurate translation of message in both directions and treats the interpersonal triad of doctor–interpreter–patient as if it was a dyad. To do so assumes that the interpreter does not have an independent relationship with patient or clinician. Of course, this is certainly not the case in any clinical encounter that goes on for a time or involves repeated meetings. Indeed, at the level of transference it is never the case because the mere presence of another person immediately evokes distinctive thoughts, feelings

**Table 2.4** Guidelines for Working with Interpreters and Culture-Brokers

Before the Interview
<ul style="list-style-type: none"> <li>• Explain the goals of the interview to the interpreter</li> <li>• Clarify the roles of interpreter and clinician, and the conduct of the interview</li> <li>• Discuss the interpreter's social position in country of origin and local community as it may influence the relationship with the patient</li> <li>• Explain the need for literal translation in the Mental Status Examination (e.g., to ascertain thought disorder, emotional range and appropriateness, and suicidality)</li> <li>• Ask for feedback when something is hard to translate</li> <li>• Discuss etiquette and cultural expectations</li> </ul>
After the Interview
<ul style="list-style-type: none"> <li>• Debrief the interpreter to address any of their own emotional reactions and concerns</li> <li>• Discuss the process of the interview, any significant communication that was not translated, including paralinguage</li> <li>• Assess the patient's degree of openness or disclosure</li> <li>• Consider translation difficulties, misunderstandings</li> <li>• Plan future interviews</li> <li>• Work with same interpreter/culture-broker for the same case whenever possible</li> </ul>

and fantasies. Then too, the presence of the interpreter inevitably changes a dyad into a triadic social system with its own complex interpersonal dynamics. These dynamics are complicated by the ethnocultural background of the interpreter and his or her own cultural assumptions.

The very idea of literal translation is also problematic. Across languages, words and phrases with similar denotation often have different sets of connotations. Every translation, therefore, is an interpretation that emphasizes some potential meanings while muting or eliding others. Interpreters tend to smoothe out fragmentary, incomplete, or incoherent statements and so may mask thought disorder or other idiosyncrasies of speech with diagnostic relevance. The clinician needs to understand the choice of alternatives made by the interpreter in order to appreciate the connotations of the patient's words and to convey his or her own nuanced meanings. These requirements place much higher demands on interpreting in mental health setting than in other medical or legal settings.

A slightly different model views the interpreter as a “go-between”. In this approach, the interpreter takes turns interacting with clinician and patient to clarify what is being said and to find a means of conveying it. This model acknowledges the interpreter as an active intermediary and allows the interpreter some autonomy. The sequential dyadic interaction puts greater time and distance between clinician and patient. This demands that the interpreter have a high degree of clinical knowledge and interpersonal skill, which is possible when the interpreter has been trained as a clinician. Taking this autonomy further, the interpreter may be viewed as a cotherapist. In this approach, the interpreter with clinical skills develops his or her own working alliance with the patient. The interpreter may respond independently to the patient and initiate interventions. This sometimes

happens because of language barriers, when patients may contact the interpreter to ask for help with practical issues.

Given the complexities of interpreting, we prefer to view the interpreter as a culture-broker who works to provide both the patient and the clinician with the cultural context needed to understand each other's meanings. To do this, the interpreter must understand something of the perspectives, cultural background and social positions of both patient and clinician and appreciate the goals of the clinical task. Based on this knowledge, the culture-broker can enhance patient and clinician understanding of each other and can help negotiate compromises when there are widely divergent understandings of a problem and its solutions.

Despite increasing recognition of the importance of adequate interpretation, many clinicians or institutions use lay interpreters who are directly available at no cost, usually family members (even children) or other workers within the institution. Except in emergency situations, this practice should be avoided because it exerts a strong censorship on what may be disclosed in the encounter and because it may damage relationships that are very important to the patient by transgressing certain social and familial taboos.

Both interpreters and culture brokers need training to perform competently, and clinicians need training, in turn, to work with these allied professionals. The clinician must take a systemic approach, understanding the other people in the room as part of an interactional system. Clinicians must also understand the interpreter's position in the larger community. Some of this training can go on when clinicians have an opportunity to work repeatedly with the same interpreters, who thus become part of a treatment team.

---

### Clinical Vignette 9

A 42-year-old man from the Congo is referred for psychiatric consultation because of concern that he is depressed following chemotherapy for leukemia. The patient lies in bed staring out the window and complaining of poor appetite, headache and fatigue. At first he says little to the Euro-Canadian interviewer. After a few minutes of stilted conversation, the culture-broker, a psychologist from central Africa, stands at the foot of the bed and delivers a lecture full of exhortations to the patient. He explains that the doctor has come to help, urges the patient to cooperate with the doctor and insists that he must try to get better. After this intervention, the patient speaks more openly, clarifying that his fatigue and poor appetite are not due to depression or the lingering effects of chemotherapy but stem from the absence of appropriate African foods in his diet and the fear that he will die an improper death, far from home. His symptoms improve markedly once suitable food is arranged by contacting supportive members of his cultural community.

### Conclusion: The Limits of Culture

The cultural formulation and the basic strategies of cultural competence represent useful initial approaches to exploring clinically relevant dimensions of patients' cultural backgrounds. However, to apply these tools successfully, the clinician must avoid some biases implicit in psychiatric assessment and in the concept of culture itself.

Psychiatric diagnosis tends to be individual-centered, locating problems inside the individual, in their psychology, or neurophysiology. Cultural psychiatry, in agreement with family theory and therapy, recognizes that many problems are systemic and reside in interpersonal interactions or social contexts.

In the cultural formulation, culture tends to appear as something distinctive of patients who come from ethnocultural minorities, migrants, or indigenous peoples. The clinician too has a culture that is distinctive from the patients' point of view. Indeed, culture also constitutes the larger social matrix in which the clinical encounter is embedded. The cultural critique of psychiatric theory and practice are important correctives to this view of culture as something only possessed by the "other".

Talk of culture tends to reify and essentialize it as a fixed set of traits or characteristics shared by all members of a group. However, there is enormous diversity and individual variation within any cultural group, and many divergent perspectives. The integrated whole of culture then appears to be a fiction or idealization. Contemporary anthropologists have argued for entirely dispensing with the notion of culture or else viewing it as an abstraction for a shifting set of perspectives, discourses and resources used by individuals and groups to construct and position socially viable selves. This perspective recognizes that cultures are flexible frameworks that provide both opportunities and constraints but do not wholly determine the trajectories of individual lives.

With these caveats in mind, the clinician can apply the cultural formulation by approaching each case as unique, with a focus on the social and cultural context of the behavior and experience of the identified patient and his or her family. Cultural competence involves using one's knowledge of culture, language and etiquette as modes of inquiry rather than as *a priori* answers to the dilemmas of a specific case. With the help of cultural experts, the clinician can appreciate the range of variation in a cultural group and its significance for individuals and the community. In this way, it is possible to recognize when culture is a camouflage for problems at other levels and when it is constitutive of problems itself. In assessment the aim is to formulate cultural dynamics as part of a comprehensive process model of pathology. This can then be used to design interventions to address the most flexible or accessible level of the individual, family, or social system. Whenever possible, clinical interventions should mobilize and work with the family and ethnocultural community, who will have their own strategies and resources for problem solving and coping with adversity.

Cultural competence is based on respect for and interest in difference. It requires that clinicians become familiar with and comfortable talking about cultural differences rather than attempting to "treat everyone the same" in a misguided sense of "colorblindness" or "neutrality"; lack of recognition of important differences results in ethnocentrism, seeing the world strictly from one's own cultural point of view. Instead, the clinician must learn to de-center, to encounter the other on a more equal footing that allows some questioning of cultural assumptions relevant to psychiatric practice.

Mainstream care cannot respond adequately to the needs of a diverse population unless it gives explicit attention to cultural issues. The ethnocultural diversity of mental health professionals represents an invaluable resource. Training programs must recognize this and make it safe for clinicians to explore their own ethnocultural background and assumptions as a path to more sensitive and responsive work with others.

# The Psychiatric Interview: Settings and Techniques

The interview is the principal means of assessment in clinical psychiatry. Despite major advances in neuroimaging and neurochemistry, there are no laboratory procedures as informative as observing, listening to, and interacting with the patient, and none as yet are more than supplementary to the information gathered by the psychiatric interview. This chapter deals with the interview as a means of assessing the patient and developing an initial treatment plan in clinical situations.

Psychiatric interviews are analogous to the history and physical in a general medical assessment, and they share the major features of other types of medical interviews (Mackinnon and Yudofsky, 1986); they systematically survey subjective and objective aspects of illness, and generate a differential diagnosis and plan for further evaluation and treatment. They differ from other medical interviews in the wide range of biological and psychosocial data which they must take into account, and in their attention to the emotional reactions of the patient and the process of interaction between the patient and interviewer. The nature of the interaction is informative diagnostically and is a means of building rapport and eliciting the patient's cooperation, which is especially important in psychiatry (Reiser and Schroder, 1980). The style and content of a psychiatric interview are necessarily shaped by the interviewer's theory of psychopathology (Lazare, 1973). Thus, a biological theory of illness leads to an emphasis on signs, symptoms and course of illness; a psychodynamic theory dictates a focus on motivations, attitudes, feelings and personal interactions; a behavioral viewpoint looks at antecedents and consequences of symptoms or maladaptive behaviors. In past times, when these and other theories competed for theoretical primacy, an interviewer might have viewed exploration from a particular single perspective as adequate. However, modern psychiatry views these perspectives as complementary rather than mutually exclusive, and recognizes the contributions of biological, intrapsychic, social and environmental factors to human behavior and its disorders (Leigh and Reiser, 1992b). The interviewer, therefore, faces the task of understanding each of these dimensions, adequately surveying them in the interview, and making informed judgments about their relative importance and treatment implications (Shea, 1990).

The written psychiatric database, the mental organization which the interviewer maintains during the interview, and the structure of the interview itself may differ considerably from one another. The written psychiatric database is an orderly exposition of information gathered in the interview, presented in a relatively

fixed format. The mental organization of the interviewer consists of questions and tentative hypotheses. It evolves flexibly over the course of the interview, and is determined by the goals of the interview and emerging information which indicates needed areas of focus (Lazare, 1976).

The third structure is that of the interview itself. While guided by general principles of interviewing, this structure is the most flexible of the three, being determined not only by the purpose of the interview and the type of problem which the patient presents, but also by the patient's mode of communication and style of interaction with the interviewer. Thus, the interviewer must hold his/her own structure in mind while responding flexibly to the patient.

## Goals of the Psychiatric Interview

The interviewer may be thought of as seeking the answers to several basic questions about the patient and the presenting problems. These questions provide the mental framework of the interview (although not its explicit form). They begin with triaging of patients into broad categories of type and severity and progress to inquiry about details in each salient area. Table 3.1 lists the questions which the interview addresses and the implications of each for understanding and treating the patient. The answers to the questions in Table 3.1 are presented here in greater detail.

### Does the Patient Have a Psychiatric Disorder?

This is the most basic question which the psychiatrist is called upon to answer, and determines whether or not there is any need for further psychiatric assessment or treatment.

### How Severe Is the Illness?

The answer to this question determines the necessary level of treatment, ranging from hospitalization with close observation to infrequent outpatient visits. The main determinants of severity are dangerousness to self and others and impairment in ability to care for oneself and function in social and occupational roles.

### What Is the Diagnosis?

In psychiatry, as in the rest of medicine, descriptive information about signs, symptoms and course over time is used to assign a diagnosis to the presenting problem. Not all psychiatric diagnoses have well-established validity, but most convey knowl-

**Table 3.1** Issues to be Addressed in a Psychiatric Assessment

Question	Implications
Does the patient have a psychiatric disorder?	Need for treatment
How severe is the disorder?	Need for hospitalization Need for structure or assistance in daily life Ability to function in major life roles
Are there abnormalities of brain function?	Degree of dysfunction of major mental processes such as perception, cognition, communication, regulation of mood and affect Responsivity of symptoms to environmental and motivation features Responsivity of symptoms to biological treatment
What is the diagnosis?	Description of the illness Prognosis and treatment response
What is the patient's baseline level of functioning?	Determination of onset of illness State vs. trait pathology Goals for treatment Capacity for treatment
What environmental issues contribute to the disorder?	Prediction of conditions which may trigger future episodes of illness Need for focus on precipitating stressors Prevention of future episodes through amelioration of environmental stressors and/or increased environmental/social support
What biological factors contribute to the disorder?	Need for biological therapy Place of biological factors in explanation of illness presented to the patient Focus on biological factors as part of ongoing therapy
What psychological factors contribute to the disorder?	Responsivity of the symptoms to motivational, interpersonal, reinforcement factors Need to deal with psychological or interpersonal issues in therapy
What is the patient's motivation and capacity for treatment?	Decision to treat Choice of treatment

edge of prognosis, comorbidity, treatment response, occurrence in family members, or associated biological or psychological findings (Tischler, 1987). Even in the case of poorly understood entities, our present system of diagnosis using specific criteria maximizes uniformity in the description and naming of psychiatric disorders.

One important implication of diagnoses is whether there may be reduced plasticity of brain functioning due to anatomical or physiological abnormalities. Symptoms, deficits and behaviors which stem from such abnormalities vary less in response to environmental and motivational factors than those behaviors which arise in the context of normal brain function. For example, mood swings in a patient with bipolar disorder, a condition for which there is strong evidence of a biological–genetic etiology, typically recur at regular time intervals, often independently of the patient's life situation. By contrast, mood swings in a patient with narcissistic personality disorder are much more likely to be triggered by interactions with other people. Furthermore, when brain function is impaired, biological treatments are more likely to be necessary, and verbal, interpersonal, or environmental interventions are less likely to be sufficient. Thus, the likelihood of altered brain function has major implications for understanding and treating the patient's problems.

Although the question of brain abnormalities is basic to psychiatric triaging, we do not yet have a clearcut biological

etiology for any disorder outside of those historically classified as “organic”. Standard laboratory studies (such as brain imaging or electroencephalography) are not generally diagnostic of psychopathology; however, there is research-based evidence of altered brain function in many psychiatric disorders. Table 3.2 presents an overview of the current state of knowledge of brain abnormalities in psychiatric disorders, along with known responses to biological and psychosocial treatments.

### What Is the Patient's Baseline Level of Functioning?

Determining what the patient has been like in his/her best or most usual state is a vital part of the assessment. This information allows the interviewer to gauge when the patient became ill, and how he/she is different when ill versus well. Environmental, biological and psychological factors that contribute to low baseline levels of functioning may also predispose a patient to the development of psychiatric disorders. Thus, information about baseline functioning provides clues about the patient's areas of vulnerability to future illness as well as his/her capacity to benefit from treatment. It is also an important guide to realistic goals and expectations for such treatment. Table 3.3 lists major components of functioning with examples of elements of each.

**Table 3.2 Brain Dysfunction in Psychiatric Disorders**

Disorder	Evidence for Brain Dysfunction	Response to Biological Treatments	Response to Psychosocial Treatments
Delirium, dementia, amnesic and cognitive disorders (Popkin 1994; Lipowski 1984; Lishman 1978; Leigh and Reiser, 1992a)	Well established	Reversible causes respond to appropriate treatment, neuroleptics, anxiolytics, antidepressants, lithium and anticonvulsants. Beta-blockers may be helpful	Environmental support and supportive psychotherapy may be helpful
Schizophrenia (Carpenter and Buchanan, 1994; Kotrla and Weinberger, 1995; Davis, 1975; Bellack and Mueser, 1993; Sensky <i>et al.</i> , 2000)	Strong evidence	Most respond to antipsychotics; antidepressants, mood stabilizers, and anxiolytics may be helpful adjunctively	Environmental support, supportive psychotherapy, cognitive-behavioral therapy, family therapy, and skills training are helpful
Delusional disorder (Maber 1992; Manschreck, 1996)	Little evidence – few studies	Poor to fair response to psychotics	Poor response to psychotherapy
Schizoaffective disorder (Kendler, 1991; Winokur <i>et al.</i> , 1996; Keck <i>et al.</i> , 1996)	Evidence for relationship to schizophrenia and mood disorders	Most respond to combinations of antipsychotics, antidepressants, mood stabilizers, carbamazepine, ECT	Not well established. Similar range of treatments as for schizophrenia may be helpful
Brief psychotic disorder (Susser <i>et al.</i> , 1995; Jorgensen <i>et al.</i> , 1996)	Little evidence – few studies	Not well established	Environmental support and supportive psychotherapy helpful
Bipolar disorder (Goodwin and Jamison, 1990; Janowsky <i>et al.</i> , 1974; Tsuang and Faraone, 1990)	Strong evidence	Most respond to lithium, antidepressants, anticonvulsants, neuroleptics, or ECT	Supportive and educative psychotherapy and family therapy helpful
Major depressive disorder (Siever and Davis, 1985; Thase and Howland, 1995; Elkin <i>et al.</i> , 1989)	Evidence suggestive – considerable heterogeneity	Often responds to antidepressants or ECT	Less severe cases respond to cognitive, interpersonal and psychodynamic psychotherapy
Panic disorder (Barlow, 1988; Barlow <i>et al.</i> , 2000; Goddard and Charney, 1997; Milrod <i>et al.</i> , 2000)	Evidence suggestive	Most respond to anxiolytics or antidepressants	Variable. Cognitive – behavioral therapy more effective than psychodynamic
Generalized anxiety disorder (Blazer <i>et al.</i> , 1991)	Little evidence	Variable. Anxiolytics may be helpful	Variable. Psychodynamic, or cognitive-behavioral psychotherapies are often helpful
Simple phobia (Fyer <i>et al.</i> , 1990; Marks, 1987)	Little evidence	Medications not usually helpful	Most respond to behavioral therapy
Post traumatic stress disorder (Heim <i>et al.</i> , 2000; Marks <i>et al.</i> , 1998; Katz <i>et al.</i> , 1996)	Evidence suggestive	Variable. Antidepressants and mood stabilizers may be helpful	Psychotherapy with exploratory, supportive, and behavioral features usually helpful
Obsessive-compulsive disorder (Baxter <i>et al.</i> , 1992; Insel, 1992; Abramowitz, 1997)	Evidence suggestive	Most respond to selective serotonin reuptake inhibitors	Rituals but not obsessive thoughts respond to behavioral therapy
Somatization disorder (Cloninger <i>et al.</i> , 1986; Min and Lee, 1997)	Preliminary evidence	Poor. Medication for comorbid depression or anxiety may help	Poor. Supportive psychotherapy may help

Continues

**Table 3.2** Brain Dysfunction in Psychiatric Disorders *Continued*

Disorder	Evidence for Brain Dysfunction	Response to Biological Treatments	Response to Psychosocial Treatments
Conversion disorder (Lazare, 1981; Ford and Foulks, 1985)	None known	Amytal interview may help; otherwise not indicated	Most respond to psychotherapy with exploratory, expressive and behavioral features. May remit spontaneously
Hypochondriasis (Kellner, 1987; Ford, 1995)	None known	No direct response. Medications may help for treatment of comorbid depression and anxiety	Variable. Supportive–educative psychotherapy may be helpful
Dissociative disorders (Brenner and Marmer, 1998; Kluft and Fine, 1993)	None known	No direct response. Medications may help for treatment of comorbid depression and anxiety	Variable. Many respond to expressive–exploratory psychotherapy
Alcoholism (Prescott and Kendler, 1999; Merlett, 1998)	Strong evidence in subgroups	No well-demonstrated direct effects. Opiate antagonists may be helpful	Group and individual psychotherapies most common treatment modalities. Response variable, relapse high
Psychoactive substance use disorders (Banmohl and Jaffe, 1995; Nesse and Berridge, 1997)	Little evidence – some subgroups	No well-demonstrated direct effects	Group and individual psychotherapies most common treatment modalities. Response variable, relapse high
Sexual disorder (LoPiccolo, 1985; Marshall and Barbaree, 1990)	May be due to metabolic disorders; otherwise little evidence	Medications for underlying medical conditions may be necessary. Antiandrogens or serotonergic antidepressants may be helpful for paraphilias	Sexual dysfunctions often respond to behavior therapy. Couples therapy or exploratory therapy may also be helpful
Eating disorders (Johnson and Connors, 1987; Halmi, 1992)	Evidence suggestive	Antidepressants may help ameliorate symptoms	Expressive exploration, family and behavioral therapy often helpful
Adjustment disorders (Andreasen and Hoevk, 1982; Greenberg <i>et al.</i> , 1995)	None known	Medications may alleviate symptoms of anxiety or depression	Supportive psychotherapy often helpful
Personality disorders: Cluster A (Kendler <i>et al.</i> , 1984; Siever <i>et al.</i> , 1991)	Evidence for relationship of schizotypal personality to schizophrenia; otherwise none known	Schizotypal patients may improve on antipsychotic medication; otherwise not indicated	Poor. Supportive psychotherapy may help
Personality disorders: Cluster B (Coccaro and Kavoussi, 1997; Tarnepolsky and Berlowitz, 1987; Bateman and Fonagy, 2001; Zuckerman, 1996)	Evidence suggestive for antisocial and borderline personalities; otherwise none known	Antidepressants, antipsychotics, mood stabilizers may help for borderline personality; otherwise not indicated	Poor in antisocial personality. Variable in borderline, narcissistic and histrionic personalities
Personality disorders: Cluster C (Cloninger <i>et al.</i> , 1993; Cloninger, 1987; Millon, 1996)	None known	No direct response. Medications may help with comorbid anxiety, depression	Most common treatment for these disorders. Response variable

**Table 3.3** Assessment of Baseline Functioning

Component	Examples
Level of symptoms	Depression Anxiety Obsessions and compulsions Delusion Hallucinations
Interpersonal relations	Sexual relationships and marriage Quality and longevity of friendships Capacity for intimacy and commitment
Work adjustment	Employment history Level of responsibility Functioning in nonpaid roles, e.g., homemaker, parent Satisfaction with work life
Leisure activities	Hobbies and interests Group and social activities Travel
Ego functions	Ability to take pleasure in nonwork activities Talents, skills, intelligence Ability to cope; reality testing Control over affects and behaviors Ability to formulate and carry through plans Stable sense of self and others Capacity for self-observation

### What Environmental Factors Contribute to the Disorder?

Environmental contributions to the presenting problem are factors external to the patient. They may be acute events which precipitate illness, or longstanding factors which increase general vulnerability. Loss, change and traumatic events are very common acute precipitants (Paykel, 1978). Longstanding environmental stressors may predispose the patient to the development of illness and may also worsen the outlook for recovery.

It is important to identify adverse environmental influences which can be modified, and to help the patient or family make necessary changes. For example, a patient with recurrent paranoid psychosis needed yearly hospitalization as long as she worked in an office with many other people. However, she no longer suffered severe relapses when she was helped to find work which she could do in her own home. However, even irreversible precipitants, such as death of a loved one, must be identified and dealt with in the treatment plan.

### What Biological Factors Contribute to the Disorder?

Biological factors may contribute to psychiatric disorders directly by their effects on the central nervous system and indirectly through the effects of pain, disability, or social stigma. Thus, biological factors must be assessed through both the psychiatric history and diagnosis, and the general medical history.

Biological factors affecting the central nervous system may be genetic, prenatal, perinatal, or postnatal. There is strong evidence of genetic contributions to schizophrenia, bipolar disorder and alcoholism, among others (Carpenter and Buchanan, 1994; Jorgensen *et al.*, 1996; Kluft and Fine, 1993); conditions such as maternal substance abuse or intrauterine infections may

affect fetal brain development; birth complications may cause cerebral hypoxia with resultant brain damage. In postnatal life, the entire range of diseases which affect the brain may alter mental function and behavior, as may exposure to toxins at work, in the environment, and through substance abuse. In addition, medical conditions which do not directly affect brain functioning may have profound effects on the patient's state of mind and behavior.

Biological factors may both predispose to and precipitate episodes of illness. Thus, a patient with a genetic vulnerability to schizophrenic illness may have an episode of acute psychosis precipitated by heavy cocaine use. Similarly, a patient with borderline low intellectual capacity due to hypoxia at birth may have marginal ability to care for herself. An accident resulting in a fractured arm might overwhelm this person's coping capacity and precipitate a severe adjustment disorder.

### What Psychological Factors Contribute to the Disorder?

Psychological factors are mental traits which the patient brings to life situations. While they interact with social and environmental factors, they are intrinsic to the individual, and not readily changed by outside influences.

Psychological factors predisposing to illness include both general and focal deficits in coping adaptability. General deficits encompass the entire range of ego functioning, including poor reality testing, rigid or maladaptive psychological defense mechanisms, low ability to tolerate and contain affects, impulsivity, poorly formed or unstable sense of self, low self-esteem and hostile, distant, or dependent relationships with others (Valliant, 1977). Patients with such deficits generally meet diagnostic criteria for one or more personality disorders and are at increased risk for episodes of acute psychiatric illness. An example of general

deficits in psychological functioning is illustrated by the following case.

#### Clinical Vignette 1

A 30-year-old married woman suffers from chronic low mood and lack of enjoyment of life. She is highly dependent on her husband for practical and emotional support, although she frequently flies into rages at him, feeling that he is cold and uncaring. She has had a series of secretarial jobs which she begins enthusiastically, but soon comes to feel that her employers are highly critical and belittling, whereupon she resigns. Her friendships are limited to people with whom she can have very special, exclusive relationships. She deals poorly with change or loss, which frequently trigger episodes of acute dysfunction. When a friend is not sufficiently available to her, she feels betrayed and worthless, her mood plummets, she becomes lethargic, has eating binges, and is unable to work or pursue her usual routine for up to weeks at a time.

Focal psychological issues may also contribute to mental disorders. These issues, which typically involve conflicts between opposing motivations, may affect the patient in certain specific areas of function or life situations, leaving other broad areas of function intact (Nemiah, 1961a). Such conflicts are most likely to cause maladaptive behaviors or symptoms when the patient is not clearly aware of them.

#### Clinical Vignette 2

A patient functions well in a responsible job and has had a long-standing, stable marriage. However, he is driven by the need to be liked and accepted by all who know him, and has a deep-seated, but not conscious, belief that he must continually fulfil the wishes of others in order to accomplish this. At the same time, he has a chronic feeling of powerlessness and an unarticulated wish to be able to say no. At times of increased demands by family members or coworkers, he develops flu-like symptoms and stays home from work “recuperating”, relieved of responsibility for fulfilling the expectations of others.

The meaning of an event in the context of the patient’s life course is another focal issue which may contribute to illness.

#### Clinical Vignette 3

A young woman became acutely depressed upon receiving her acceptance to medical school. She was the oldest of four children and had been expected to assume a major caretaking role with her younger siblings. Her mother, a busy physician, wished for her daughter to have a similar career. To the patient, entering medical school meant accepting a lifelong role as a caretaker and forever relinquishing her own wishes to be taken care of.

## What Is the Patient’s Motivation and Capacity for Treatment?

Whatever the physician’s view of the presenting problem, the patient’s wishes and capacities are a major determinant of treatment choice (Lazare *et al.*, 1975). Some patients seek relief of symptoms; some wish to change their behavior or the nature of their relationships; some want to understand themselves better. Patients may wish to talk or to receive medication or instructions.

The patient’s capacity for treatment must also be considered in the treatment plan. For example, a patient with schizophrenia may agree to medication but be too disorganized to take it reliably without help. Suitability for exploratory psychotherapy depends upon such factors as the ability to observe oneself, tolerate unpleasant affects, and establish and maintain a working relationship with the treater (Strupp and Binder, 1984). Such factors must be evaluated in the interview.

## The Psychiatric Database

The body of information to be gathered from the interview may be termed the psychiatric database (Tables 3.2 to 3.4). It is a variable set of data: either very specific or general, mainly limited to the present state or focused on early life, dominated by neurological questions or inquiry into relationships. To avoid setting the impossible task of learning everything about every patient, one must consider certain factors which modify the required database.

Whose questions are to be answered – the patient’s concern about himself, a family or friend’s concern about him, another physician’s diagnostic dilemma, a civil authority’s need to safeguard the public, or a research protocol requirement? Who will have access to the data gathered and under what circumstances? What is the setting of the interview? Priorities in an emergency room differ from those in an office setting (Meyers and Stein, 2000). Is the interview to be the first session of a psychotherapy regimen, or is it a one time only evaluation? What is the nature of the pathology? For example, negative responses regarding the presence of major psychotic symptoms, coupled with a history of good occupational function, will generally preclude a detailed inventory of psychotic features. A missed orientation or memory question will require careful cognitive testing. Patients with personality disorder symptoms warrant careful attention to the history of significant relationships (Nurnberg *et al.*, 1991), work history and the feelings evoked in the interviewer during the evaluation process. The database should be expanded in areas of diagnostic concern to support or rule out particular syndromes. The amount and nature of the data obtained is also, of necessity limited, by the patient’s ability to communicate and his cooperativeness.

## Database Components

### Identifying Data

This information establishes the patient’s identity, especially for the purpose of obtaining past history from other contacts, when necessary, as well as to fix his/her position in society. The patient’s name should be recorded, along with any nickname or alternative names he/she may have been known by in the past. This

**Table 3.4 Core Database**

Identifying Data	Chief Complaint	History of Present Illness
<b>Name</b>	<b>Reason for consultation</b>	<b>Major symptoms</b>
<b>Age/date of birth</b> <b>Next of kin</b>		<b>Time course</b> Stressors Change in functioning Current medical problems and treatment
Past Psychiatric History	Past Medical History	Family History
Any previous psychiatric treatment	Ever hospitalized Surgery Medications	Psychiatric illness
History of suicide attempts		
Functioning problems secondary to psychiatric symptoms		
Alcohol/drug abuse		
Personal History	Mental Status	
Educational level	Appearance	
Ever married/committed relationship	Attitude Affect Behavior	
Work history	Speech	
Means of support	Thought process	
Living situation	Thought content Perception Cognition Insight Judgment	

is important for women who might have been treated previously under a maiden name, or a patient who has had legal entanglements and so has adopted aliases.

Date of birth, or at least age, and race are other essential parts of every person's database. A number of different classifications for race exist, as well as different terms and controversies (Porter, 1993). In the USA and Canada, the categories of white, black (or African-American), Asian, Native American, and others are generally accepted. The additional modifier of ethnicity, especially Hispanic/nonHispanic, is becoming more widely used. If a patient is a member of a particular subculture based on ethnicity, country of origin, or religious affiliation, it may be noted here.

A traditional part of the identifying data is a reference to the patient's civil status: single, married, separated, divorced, or widowed. The evolution of relationship patterns over the last two decades, with less frequent formalization of relationships, has made classification more difficult (Ishii-Kuntz and Tallman, 1991), especially in the case of homosexual patients, whose relationships are not legally recognized in most jurisdictions.

The patient's social security number (or other national ID number) can be a very useful bit of data when seeking information from other institutions.

In most cases, it is assumed that the informant (supplier of the history) is the patient. If other sources are used, and espe-

cially if the patient is not the primary informant, this should be noted at the beginning of the database.

### Chief Complaint

The chief complaint is the patient's responses to the question, "What brings you to see me/to the hospital today?" or some variant. It is usually quoted verbatim, placed within quotation marks, and should be no more than one or two sentences.

Even if the patient is very disorganized or hostile, quoting his response can give an immediate sense of where the patient is as the interview begins. If the patient responds with an expletive, or a totally irrelevant remark, the reader of the database is immediately informed about how the rest of the information may be distorted. In such cases, or if the patient gives no response, a brief statement of how the patient came to be evaluated should be made and enclosed in parentheses.

### History of the Present Illness

#### Minimum Essential Database

The present illness history should begin with a brief description of the major symptoms which brought the patient to psychiatric attention. The most troubling symptoms should be detailed initially; later a more thorough review will be stated. As a minimum, the approximate time since the patient was last at his baseline

level of functioning, and in what way he is different from that now, should be described, and any known stressors, the sequence of symptom development, and the beneficial or deleterious effects of interventions included.

How far back in a patient's history to go, especially when he has chronic psychiatric illness, is sometimes problematic. In patients who have required repeated hospitalization, a summary of events since last discharge (if within 6 months) or last stable baseline is indicated. It is rare that more than 6 months of history be included in the history of the present illness, and detailed history is more commonly given on the past month.

### Expanded Database

A more expanded description of the history of the present illness would include events in a patient's life at the onset of symptoms, as well as exactly how the symptoms have affected the patient's occupational functioning and important relationships. Any concurrent medical illness symptoms, medication usage (and particularly changes), alterations in the sleep-wake cycle, appetite disturbances and eating patterns should be noted; significant negative findings should also be remarked upon.

### Past Psychiatric History

#### Minimum Essential Database

Most of the major psychiatric illnesses are chronic in nature. For this reason, often patients have had previous episodes of illness with or without treatment. New onset of symptoms, without any previous psychiatric history, becomes increasingly important with advancing age in terms of diagnostic categories to be considered. At a minimum, the presence or absence of past psychiatric symptomatology should be recorded, along with psychiatric interventions taken and the result of such interventions. An explicit statement about past suicide and homicide attempts should be included.

#### Expanded Database

A more detailed history would include names and places of psychiatric treatment, dosages of medications used, and time course of response. The type of psychotherapy, the patient's feelings about former therapists, his compliance with treatment as well as circumstances of termination are also important. Note what the patient has learned about the biological and psychological factors predisposing him/her to illness, and whether there were precipitating events.

### Past Medical History

#### Minimum Essential Database

In any clinical assessment, it is important to know how a patient's general health status has been. In particular, any current medical illness and treatment should be noted (Slaby and Andrew, 1987), along with any major past illness requiring hospitalization. Previous endocrine or neurological illness are of particular pertinence (Flomenbaum and Altman, 1985).

#### Expanded Database

An expanded database could well include significant childhood illnesses, how these were handled by the patient and his fam-

ily, and therefore the degree to which the patient was able to develop a sense of comfort and security about his physical well-being. Illnesses later in life should be assessed for the degree of regression produced. The amount of time a patient has had to take off work, how well he/she was able to follow a regimen of medical care, his/her relationship with the family physician or treating specialist can all be useful in predicting future response to treatment. A careful past medical history can also at times bring to light a suicide attempt, substance abuse, or dangerously careless behavior, which might not be obtained any other way.

### Family History

#### Minimum Essential Database

Given the evidence for familial, genetic factors in so many psychiatric conditions, noting the presence of mental illness in biological relatives of the patient is a necessary part of any database (Hammen *et al.*, 1987). It is important to specify during questioning the degree of family to be considered – usually to the second degree: aunts, uncles, cousins and grandparents, as well as parents, siblings and children.

#### Expanded Database

A history of familial medical illness is a useful part of an expanded database. A genogram (pedigree), including known family members with dates and causes of death and other known chronic illnesses is helpful. Questioning about causes of death will also occasionally bring out hidden psychiatric illness, for example, sudden, unexpected deaths which were likely suicides or illness secondary to substance abuse.

### Personal History

#### Minimum Essential Database

Recording the story of a person's life can be a daunting undertaking and is often where a database can expand dramatically. As a minimum, this part of the history should include where a patient was born and raised, and in what circumstances – intact family, number of siblings and degree of material comfort. Note how far the patient went in school, how he/she did there, and what his/her occupational functioning has been. If he/she is not working, why not? Has the patient ever been involved in criminal activity, and with what consequences? Has the patient ever married or been involved in a committed relationship? Are there any children? What is his/her current source of support? Does he/she live alone or with someone? Has he/she ever used alcohol or other drugs to excess, and is there current use? Has he/she ever been physically or sexually abused or been the victim of some other trauma?

#### Expanded Database

An expanded database can include a great deal of material beginning even prior to the patient's conception. What follows is an outline of the kind of data which may be gathered, along with an organizational framework.

##### Family of Origin

Were parents married or in committed relationships?

Personality and significant events in life of mother, father, or other significant caregiver.

Siblings: how many? their ages, significant life events, personality, relationship to patient.

Who else shared the household with the family?

#### Prenatal and Perinatal

Was the pregnancy planned? Quality of prenatal care; mother's and father's response to pregnancy.

Illness, medication or substance abuse, smoking, trauma during pregnancy; labor – induced or spontaneous?

Weeks gestation, difficulty of delivery, vaginal or Caesarean section.

Presence of jaundice at birth, birth weight, Apgar score.

Baby went home with mother or stayed on in hospital.

#### Early Childhood

Developmental milestones: smiling, sitting, standing, walking, talking, type of feeding – food allergies or intolerance.

Consistency of caregiving: interruptions by illness, birth of siblings.

Reaction to weaning, toilet-training, maternal separation.

Earliest memories: problematic behavior (tantrums, bedwetting, hair-pulling or nail-biting).

Temperament (shy, overactive, outgoing, fussy).

Sleep problems: insomnia, nightmares, enuresis, parasomnias.

#### Later Childhood

Early school experiences: evidence of separation anxiety.

Behavioral problems at home or school: firesetting, bedwetting, aggressive toward others, cruelty to animals, nightmares.

Developmental milestones: learning to read, write.

Relationships with other children and family: any loss or trauma.

Reaction to illness.

#### Adolescence

School performance: ever in special classes?

Athletic abilities and participation in sports.

Evidence of gender identity concerns: overly “feminine” or “masculine” in appearance/behavior, or perception by peers.

Ever run away? Able to be left alone and assume responsibility.

Age onset of puberty (menarche or nocturnal emissions), reaction to puberty.

#### Identity

Sexual preference and gender identity, religious affiliation (same as parents?).

Career goals: ethnic identification.

#### Sexual History

Early sexual teaching: earliest sexual experiences, experience of being sexually abused, attitudes toward sexual behavior.

Dating history, precautions taken to prevent sexually transmitted diseases and/or pregnancy.

Episodes of impotence and reaction.

Masturbating patterns and fantasies.

Preoccupation with particular sexual practices, current sexual functioning, length of significant relationships, ages of partners.

#### Adulthood

Age at which left home, level of educational attainments.

Employment history, relationships with supervisors and peers at work, reasons for job change.

History of significant relationships including duration, typical roles in relationships, patterns of conflict: marital history, legal entanglements and criminal history, both covert and detected, ever victim or perpetrator of violence.

Major medical illness as adult.

Participation in community affairs.

Financial status: own or rent home, stability of living situation.

Ever on disability or public assistance?

Current family structure, reaction to losses of missing members (parents, siblings), if applicable.

Substance abuse history.

### Mental Status Examination

It can be helpful to conceptualize the recording of the Mental Status Examination as a progression. One begins with a snapshot: what can be gained from a cursory visual exam, without any movement or interaction – appearance and affect. Next, motion is added: behavior. Then comes sound: the patient's speech, though initially only as sound. The ideas being expressed come next: the thought process and content, perception, cognition, insight, and judgment. Table 3.5 gives a summary of areas to be commented on, along with common terms.

At every level of the Mental Status Examination, preference should be given for explicit description over jargon. Stating that a patient is delusional is less helpful than describing him as believing that his neighbors are pumping poisonous gases into his bedroom while he sleeps.

### Conduct of the Interview: Factors Which Affect the Interview

A skillful interview will not necessarily yield all the relevant information but will make the most of the opportunities in a clinical situation, given the limitations which both the patient and interviewer bring. Factors which influence the development of an alliance and the amount which can be learned in the interview include the following:

#### The Patient's Physical or Emotional Distress

Patients who are in acute distress either from physical discomfort or from emotional factors such as severe depression or anxiety will be limited in their motivation and ability to interact with the interviewer. The interviewer may be able to enhance communication by addressing the patient's discomfort in a supportive manner. However, he/she must also recognize times when the patient's discomfort necessitates a more limited interview.

#### The Cognitive Capacities of the Patient

Patients who are demented, retarded, disorganized, thought-disordered, amnesic, aphasic, or otherwise impaired in intellectual or cognitive capacity have biologically based deficits which limit the amount of information they can convey.

**Table 3.5 Mental Status Examination**

**Appearance**

---

Level of consciousness (alert, hypervigilant, somnolent, stuporous)  
Dress (casual, appropriate for weather, eccentric, careless, disheveled)  
Grooming (style of hair, degree of makeup, shaven/unshaven, clean, malodorous)  
Idiosyncracies – tattoos (professional or amateur), prominent scars, religious emblems

---

**Attitude**

---

Cooperative, hostile, evasive, threatening, obsequious

---

**Affect**

---

Range (restricted, expansive, blunted, flat)  
Appropriateness to items discussed  
Stability (labile, shallow)  
Quality (silly, anxious)

---

**Mood**

---

Response to question: “How are you feeling/How’s your mood been?”

---

**Behavior**

---

Psychomotor agitation or retardation

---

**Speech**

---

Rate (rapid, slowed, pressured, hard to interrupt)  
Volume (loud, soft, monotone, highly inflected or dramatic)  
Quality (neologisms, fluent, idiosyncratic)

---

**Thought Process**

---

Goal directed, disorganized, loose associations, tangential, circumstantial, flight of ideas

---

**Thought Content**

---

Major preoccupations, ideas of reference, delusions (grandiose, paranoid, bizarre, state exactly what it is the patient appears to believe)  
Thought broadcasting, insertion, or withdrawal  
Suicidal or homicidal ideation. Plan and intent to carry out ideas

---

**Perception**

---

Illusions and hallucinations – type (auditory, visual, olfactory, tactile, gustatory), evidence (patient spontaneous report, answer to interviewer question, observation of patient attending or responding to nonexistent external stimuli).  
Patient’s beliefs about hallucinatory phenomenon (do they seem to originate from the outside or inside, how many voices, what gender, talking to patient or to other voices, are they keeping up constant commentary on the patient.)

---

**Cognition**

---

Orientation: time, place, person, situation  
Memory: number of remembered objects, digit span, presidents backward, recent events  
Concentration: serial 7s, *world* spelled backwards  
Abstraction: proverb interpretation – what would someone mean by “The grass is always greener on the other side of the fence”, (“Get off my back”).  
Similarities: (How are these things alike – apple–orange, table–chair, eye–ear, praise–punishment?)  
Computation: number of digits successfully added or subtracted, ability to calculate change  
(How many quarters are in \$1.50? If you bought a loaf of bread for 89 cents and gave the cashier a dollar, what change would you get back?)

---

**Insight**

---

Knows something is wrong, that he/she is ill, that illness is psychiatric; understands ways in which illness disrupts function

---

**Judgment**

---

Response to standard questions (If you found a sealed, addressed, stamped letter, what would you do? If you smelled smoke in a crowded theater?)  
Evidence from behavior prior to and during interview (Was the patient caring for himself/herself properly, handling business affairs well? Does the behavior during the interview match his/her stated goals, e.g., if he/she wishes to be thought to be in control, is he/she keeping the voice down and movement in check?)

## The Emotionally Based Biases of the Patient

Patients bring to the interview a wide variety of preconceptions, expectations and tendencies toward distortion, which influence how they view and relate to the interviewer. Such biases are commonly referred to as **transference** because they frequently can be understood as arising from interactions with important figures in childhood, such as parents, which then color perceptions of others during adult life (Nemiah, 1961b). Transference biases may be positive or negative. Thus, even before the start of the interview, one patient may be primed to view the doctor as a wise and kindly healer, while another will be predisposed to see him/her as an exploitative charlatan. Clearly, such biases affect the amount of openness and trust which the patient brings to the interview and the quality of information he/she provides.

## The Emotionally Based Biases of the Interviewer

The interviewer, like the patient, may have feelings stirred up by the interaction. The interviewer's emotional reactions to the patient can be an invaluable asset in assessment if he/she can be conscious of them and reflect on their causes. For example, an interviewer finds himself becoming increasingly annoyed at a highly polite patient. On reflection, he realizes that the politeness serves to rebuff his attempts to establish a warmer, more spontaneous relationship and is a manifestation of the patient's underlying hostile attitude.

When the interviewer is unable to monitor and examine his/her emotional reactions, they are more likely to impede rather than enhance understanding of the patient. This is most likely to happen when emotional reactions are driven more by the interviewer's own biases than by the patient's behavior. Such reactions are referred to as the interviewer's **countertransference** (Mackinnon and Michels, 1971). In the example cited in the previous paragraph, the interviewer might inaccurately perceive a polite patient as rigid and hostile due to unconscious biases (countertransference) based on his relationship with his own rigidly polite parent. The entire range of countertransference interviewer attitudes toward the patient, from aversion to infatuation, might similarly bias judgment.

## Situational Factors

Patients' attitudes toward the interview will be strongly influenced by the situation in which the consultation arises. Some patients decide for themselves that they need treatment, while others come reluctantly, under pressure from others. Patients who are being evaluated for disability or in connection with a lawsuit may feel a need to prove that they are ill, while those being evaluated for civil commitment or at the insistence of family members may need to prove that they are well. Similarly, a patient's past history of relationships with psychiatrists or with health professionals in general is likely to color his/her attitude toward the interviewer.

The interviewer may also be affected by situational factors. For example, pressure of time in a busy emergency service may influence the interviewer to omit important areas of inquiry and reach premature closure; the experience of a recent patient suicide may bias the interviewer toward overestimation of risk in someone with suicidal thoughts. As with countertransference

reactions, it is important for the interviewer to minimize distortions due to situational factors by being as aware of them as possible.

## Racial, Ethnic and Cultural Factors

The degree of racial, ethnic, cultural, and socioeconomic similarity between the patient and interviewer can influence the course and outcome of the interview in many ways. (see also Chapters 2 and 21.) It may affect the level of rapport between patient and interviewer, the way both view the demands of the situation, the way they interpret each other's verbal and non-verbal communications, and the meaning the interviewer assigns to the patient's statements and behaviors (Gaw, 1993). Not only racial or cultural prejudice but also well-intentioned ignorance can interfere with communication and accurate assessment.

Some cultures, for example, place a higher value on politeness and respect for authority than does western culture. A patient from such a background might be reluctant to correct or disagree with the interviewer's statements even when they are erroneous. The interviewer might not suspect that he/she was hearing distorted information, or conversely, might see the patient as pathologically inhibited or unemotional. Many nonwestern cultures place a higher value on family solidarity than on individuality. Pressing a patient from such a culture to report angry feelings toward family members might raise his/her anxiety, decrease rapport with the interviewer and produce defensive distortions in the material.

## General Features of Psychiatric Interviews

### Setting

The ideal interview setting is one which provides a pleasant atmosphere and is reasonably comfortable, private and free from outside distractions. Such a setting not only provides the physical necessities for an interview but conveys to the patient that he/she will be well cared for and safe. Providing such a setting may pose special problems in certain interviewing situations. For example, it may be necessary to interview highly agitated patients in the presence of security personnel; interviewers on medical-surgical units must pay special attention to the patient's comfort and privacy.

### Verbal Communication

Verbal communication may be straightforward imparting of information: "Every year around November, I begin to lose interest in everything and my energy gets very low". However, patients may convey information indirectly through metaphor, or use words for noninformational purposes such as to express or contain emotions or to create an impact on the interviewer.

In metaphorical language, one idea is represented by another with which it shares some features. For example, when asked how she gets along with her daughter-in-law, a woman replies, "I can never visit their house because she always likes to keep the thermostat down. It's never as warm as I need". Such a reply suggests that the woman may not feel "warmly" accepted and welcomed by her son's wife. Metaphor may also use the body to represent ideas or feelings. A man who proved

to meet the diagnostic criteria for major depressive disorder described his mood as “OK” but complained that his life was being ruined by constant aching in his chest for which the doctors could find no cause. In this instance, the pain of depression was experienced and described metaphorically as a somatic symptom.

Language may be used to express emotions directly (“I’m afraid of you and I don’t want to talk to you”), but more often is used indirectly by influencing the process of the interview (Bernstein and Bernstein, 1985). Patients may shift topics, make off-hand remarks or jokes, ask questions, and compliment or belittle the interviewer as a way of expressing feelings. The process of the interview frequently expresses the patient’s feelings about his/her immediate situation or interaction with the interviewer (Malan, 1979). For example, a woman being evaluated for depression and anxiety suddenly said, “I was just wondering doctor, do you have any children?” The further course of the interview revealed that she was terrified of being committed to a hospital and abandoned. The question was an attempt to establish whether the interviewer was a good parent and therefore safe as a caretaker for her.

Language may also be used in the service of psychological defense mechanisms to contain rather than express emotions (Freud, 1946). For example, a young man with generalized anxiety was asked whether he was sexually active. He replied by talking at length about how all the women he knew at college were either unappealing or attached to other men. Further discussion revealed that he developed severe symptoms of anxiety whenever he was with a woman to whom he felt sexually attracted. His initial reply represented an automatic, verbal mechanism (in this case, a rationalization) for keeping the anxiety out of awareness.

Another form of process communication is the use of language to make an impact on the interviewer (Casement, 1985). A statement such as “If you can’t help me I’m going to kill myself”, might convey suicidal intent, but may also serve to stir up feelings of concern and involvement in the interviewer. Similarly, the patient who says, “Dr X really understood me, but he was much older and more experienced than you are”, may be feeling vulnerable and ashamed, and unconsciously trying to induce similar feelings in the interviewer. When language is used in this way, the interviewer’s subjective reaction may be the best clue to the underlying feelings and motivations of the patient.

## Nonverbal Communication

Emotions and attitudes are communicated nonverbally through facial expressions, gestures, body position, movements of the hands, arms, legs, and feet, interpersonal distance, dress and grooming, and speech prosody (Knapp, 1978). Some nonverbal communications such as gestures are almost always conscious and deliberate, while others often occur automatically outside one’s awareness. The latter type are particularly important to observe during an interview because they may convey messages entirely separate from or even contradictory to what is being said.

Facial expression, body position, tone of voice, and speech emphasis are universal in the way they convey meaning (Ekman *et al.*, 1972). The interviewer will automatically decode these signals but may ignore the message due to coun-

tertransference or social pressure from the patient. For example, a patient may say, “I feel very comfortable with you, doctor”, but sit stiffly upright and maintain a rigidly fixed smile, conveying a strong nonverbal message of tension and mistrust. The nonverbal message may be missed if, for example, the interviewer has a strong need to be liked by the patient. Another patient denies angry feelings while sitting with a tightly clenched fist. The interviewer may unconsciously collude with the patient’s need to avoid his anger by ignoring the body language.

As with any medical examination, observation of nonverbal behavior may provide important diagnostic information. For example, a leaden body posture may indicate depression, movements of the foot may arise from anxiety or tardive dyskinesia, and sudden turning of the head and eyes may suggest hallucinations.

Nonverbal communication proceeds in both directions, and the nonverbal messages of the interviewer are likely to have a considerable effect on the patient. Thus, the interviewer who sits back in his chair and looks down at his notes communicates less interest and involvement than one who sits upright and makes eye contact. Similarly, an interviewer who gives a weak handshake and sits behind a desk or far across the room from the patient will communicate a sense of distance which may interfere with establishing rapport. It is important that the interviewer be aware of his/her own nonverbal messages and adapt them to the needs of the patient.

## Listening and Observation

The complexity of communication in the psychiatric interview is mirrored by the complexity of listening (Luborsky, 1984). The interviewer must remain open to literal and metaphorical messages from the patient, to the impact the patient is trying to make, and to the degree to which nonverbal communication complements or contradicts what is being said. Doing this optimally requires that the interviewer also be able to listen to his/her own mental processes throughout the interview, including both thoughts and emotional reactions. Listening of this kind depends upon having a certain level of comfort, confidence and space to reflect, and may be very difficult when the patient is hostile, agitated, demanding, or putting pressure on the interviewer in any other way. With such patients, it may take many interviews to do enough good listening to gain an adequate understanding of the case.

Another important issue in listening is maintaining a proper balance between forming judgments and remaining open to new information and new hypotheses. On the one hand, one approaches the interview with knowledge of diagnostic classifications, psychological mechanisms, behavioral patterns, social forces and other factors which shape one’s understanding of the patient. The interviewer hears the material with an ear to fitting the information into these preformed patterns and categories. On the other hand, the interviewer must remain open to hearing and seeing things which extend or modify his/her judgments about the patient. At times the interviewer may listen narrowly to confirm a hypothesis, while at others he/she may listen more openly, with relatively little preconception. Thus, listening must be structured enough to generate a formulation but open enough to avoid premature judgments.

## Attitude and Behavior of the Interviewer

The optimal attitude of the interviewer is one of interest, concern and intention to help the patient. While the interviewer must be tactful and thoughtful about what he/she says, this should not preclude behaving with natural warmth and spontaneity. Indeed, these qualities may be needed to support patients through a stressful interview process. Similarly, the interviewer must try to use natural, commonly understood language and avoid jargon or technical terms. The interviewer must communicate his/her intention to keep the patient as safe as possible, whatever the circumstances. Thus, while one must at times set limits on the behavior of an agitated, threatening, or abusive patient, one should never be attacking or rejecting.

Empathy is an important quality in psychiatric interviewing. While sympathy is an expression of agreement or support for another, empathy entails putting oneself in another's place and experiencing his/her state of mind. Empathy comprises both one's experiencing of another person's mental state and the expression of that understanding to the other person (Barrett-Lennard, 1981). For example, in listening to a man talk about the death of his wife, the interviewer may allow himself to resonate empathetically with the patient's feelings of loneliness and desolation. Based on this resonance, he might respond, "After a loss like that, it feels as if the world is completely empty".

As a mode of listening, empathy is an important way of understanding the patient; as a mode of response, it is important in building rapport and alliance. Patients who feel great emotional distance from the interviewer may make empathic understanding difficult or impossible. Thus, the interviewer's inability to empathize may itself be a clue to the patient's state of mind.

## Structure of the Interview

The overall structure of the psychiatric interview is generally one of reconnaissance and detailed inquiry (Sullivan, 1970). In reconnaissance phases, the interviewer inquires about broad areas of symptomatology, functioning, or life course: "Have you ever had long periods when you felt very low in mood?" "How have you been getting along at work?" "Tell me what you did between high school and when you got married". In responding to such questions, patients give the interviewer leads which then must be pursued with more detailed questioning. Leads may include references to symptoms, difficulty in functioning, interpersonal problems, ideas, states of feeling, or stressful life events. Each such lead raises questions about the nature of the underlying problem, and the interviewer must attempt to gather enough detailed information to answer these questions. Reliance on yes or no "gate questions" to rule out areas of pathology has been shown to increase the risk of missing important information. This risk may be minimized by asking about important areas in several ways (Barber *et al.*, 2001).

In general, the initial reconnaissance consists of asking how the patient comes to treatment at this particular time. This is done by asking an open-ended question such as "What brings you to see me today?" or "How did you come to be in the hospital right now?" A well-organized and cooperative patient may spontaneously provide most of the needed information, with little intervention from the interviewer. However, the patient may reveal deficits in thought process, memory, or ability to com-

municate, which dictate more structured and narrowly focused questioning.

The patient's emotional state and attitude may also impede a smooth flow of information. For example, if the patient shows evidence of anxiety, hostility, suspiciousness, or indifference, the interviewer must first build a working alliance before trying to collect information. This usually requires acknowledging the emotions which the patient presents, helping the patient to express his/her feelings and related thoughts, and discussing these concerns in an accepting and empathic manner (Strean, 1985). As new areas of content open up, the interviewer must continue to attend to the patient's reactions, both verbal and nonverbal, and to identify and address resistance to open communication.

Setting an appropriate level of structure is an important aspect of psychiatric interviewing. Psychiatric patients may spontaneously report a low number of symptoms, and initial diagnostic impressions may be misleading (Herran *et al.*, 2001). Over the past two decades, a variety of structured interview formats have been developed for psychiatric assessment (Wiens, 1990; Spitzer *et al.*, 1978). In these interviews, the organization, content areas, and, to varying degrees, wording of the questions are standardized; vague, overly complex, leading or biased, and judgmental questions are eliminated, as is variability in the attention given to different areas of content. The major benefits of such interviews are that they ensure complete coverage of the specified areas and greatly increase the reliability of information gathered and diagnostic judgments. In addition, formats which completely specify the wording of questions can be administered by less highly trained interviewers or even as patient self-reports.

The disadvantages of highly structured interviews are that they diminish the ability to respond flexibly to the patient and preclude exploration of any areas not specified in the format (Groth-Marnat, 1990). They are therefore used to best advantage for interviews with focused goals. For example, such interviews may aim to survey certain DSM IV Axis I disorders, to assess the type and degree of substance abuse, or to delineate the psychological and behavioral consequences of a traumatic event. They are less useful in a general psychiatric assessment where the scope and focus of the interview cannot be preordained.

In the usual clinical situation, while the interviewer may have a standardized general plan of approach, he/she must adapt the degree of structure to the individual patient. Open-ended, nondirective questions derive from the psychoanalytic tradition. They are most useful for eliciting and following emotionally salient themes in the patient's life story and interpersonal history. Focused, highly structured questioning derives from the medical/descriptive tradition and is most useful for delineating the scope and evolution of pathological signs and symptoms. In general, one uses the least amount of structure needed to maintain a good flow of communication and cover the necessary topic areas.

## Phases of the Interview

The typical interview comprises an opening, middle and closing phase. In the opening phase, the interviewer and patient are introduced, and the purposes and procedures of the interview are set. It is generally useful for the interviewer to begin by summarizing what he/she already knows about the patient and

proceeding to the patient's own account of the situation. For example, the interviewer may say, "Dr Smith has told me that you have had several episodes of depression in the past, and now you may be going into another one", or "I understand that you were brought in by the police because you were threatening people on the street. What do you think is happening with you?" or "When we spoke on the phone you said you thought your marriage was in trouble. What has been going wrong?" Such an approach orients the patient and sets a collaborative tone.

The opening phase may also include clarification of what the patient hopes to gain from the consultation. Patients may sometimes state this explicitly, but often do not, and the interviewer should not assume that his/her goals are the same as the patient's (Lazare *et al.*, 1975). A question such as "How were you hoping I could help you with the problem you have told me about?" invites the patient to formulate and express his/her request and avoids situations in which the patient and interviewer work at cross-purposes. The interviewer must also be explicit about his/her own goals and the extent to which they fit with the patient's expectations. This is especially important when the interests of a third party, such as an employer, a family member, or a court of law is involved.

The middle phase of the interview consists of assessing the major issues in the case and filling in enough detail to answer the salient questions and construct a working formulation. Most of the work of determining the relative importance of biological, psychological, environmental and sociocultural contributions to the problem is done during this phase. The patient's attitudes and transference perceptions are also monitored during this phase so that the interviewer can recognize and address barriers to communication and collaboration.

When appropriate, formal aspects of the Mental Status Examination are performed during the middle phase of the interview. While most of the mental status evaluation is accomplished simply by observing the patient, certain components such as cognitive testing and review of psychotic symptoms may not fit smoothly into the rest of the interview. These are generally best covered toward the end of the interview, after the issues of greatest importance to the patient have been discussed and rapport has been established. A brief explanation that the interviewer has a few standard questions he/she needs to cover before the end of the interview serves as a bridge and minimizes the awkwardness of asking questions which may seem incongruous or pejorative.

In general, note-taking during an assessment interview is helpful to the interviewer and not disruptive of rapport with the patient. Notes should be limited to brief recording of factual material such as dates, durations, symptom lists, important events and past treatments, which might be difficult to keep in memory accurately. The interviewer must take care not to become so involved in taking notes as to lose touch with the patient. It is especially important to maintain a posture of attentive listening when the patient is talking about emotionally intense or meaningful issues. When done with interpersonal sensitivity, note-taking during an assessment interview may actually enhance rapport by communicating that what the patient says is important and worth remembering. This is to be distinguished from note-taking during psychotherapy sessions, which is more likely to diminish the treator's ability to listen and respond flexibly.

In the third or closing phase of the interview, the interviewer shares his/her conclusions with the patient, makes treatment recommendations and elicits reactions. In situations where the assessment runs longer than one session, the interviewer may sum up what has been covered in the interview and what needs to be done in subsequent sessions. Communications of this kind serve several purposes. They allow the patient to correct or add to the salient facts as understood by the interviewer. They contribute to the patient's feeling of having gained something from the interview. They are also the first step in initiating the treatment process because they present a provisional understanding of the problem and a plan for dealing with it. All treatment plans must be negotiated with the patient, including discussion of mutual goals, expected benefits, liabilities, limitations and alternatives, if any. In many cases, such negotiations extend beyond the initial interview and may constitute the first phase of treatment.

### Dimensions of Interviewing Techniques

Although many systems have been suggested for classifying interview techniques (Elliott *et al.*, 1987), it is convenient to think about four major dimensions of interviewing style: degree of directiveness, degree of emotional support, degree of fact versus feeling orientation and degree of feedback to the patient. The interviewer must seek a balance among these dimensions to best cover the needed topics, build rapport, and arrive at a plan of treatment.

#### Directiveness

Directiveness in the interview ensures that the necessary areas of information are covered and supplies whatever cognitive support the patient needs in discussing them. Table 3.6 lists interventions which are low, moderate and high in directiveness.

Low-directive interventions request information in the broadest, most open-ended way and do not go beyond the material supplied by the patient. Moderately directive interventions are narrower in focus and may extend beyond what the patient himself/herself has said. For example, confrontation makes the patient aware of paradoxes or inconsistencies in the material and requests him/her to resolve them; interpretation requests the patient to consider explanations or connections that had not previously occurred to him/her. Highly directive interventions aim to focus and restrict the patient's content or behavior. Such interventions include yes-no or symptom-checklist type questions and requests for the patient to modify behaviors that impede the progress of the interview.

#### Supportiveness

Patients vary considerably in the degree of emotional and cognitive support they need in the interview. Table 3.7 lists examples of emotionally supportive interventions. Each such intervention supports the patient's sense of security and self-esteem. While some patients may come to the interview feeling safe and confident, others have considerable anxiety about being criticized, ridiculed, rejected, taken advantage of, or attacked (literally so in the case of some psychotic patients).

Overt manifestations of insecurity range widely, from fearful demeanor and tremulousness to requests for reassurance to haughty contemptuousness. The interviewer's task is to identify such anxiety when it arises and respond in a manner

**Table 3.6** Degrees of Directiveness in the Interviewer

Directiveness	Intervention	Examples
Low	Open-ended questions	“What brings you to the hospital?” “Tell me about your current situation in life.”
Low	Repetition	<i>Patient:</i> “Last night I suddenly started to feel so terrible I was afraid I was going to die.” <i>Interviewer:</i> “You were afraid you were going to die.”
Low	Restatement	<i>P:</i> “Nobody is on my side anymore – even my family is out to get me.” <i>I:</i> “So it seems as if everyone has turned against you.”
Low	Summarization	“To review what we have been discussing, over the last month you’ve been very low in mood, you felt overwhelmed even by small chores, and you no longer want to see any of your friends.”
Low	Clarification	“You told me that it “upsets” you to have to say no. It seems that when you say no to your boss your feeling is fear, but when you say no to your children you feel guilty.”
Low	Nonverbal Acknowledgment	“Uh-huh”; nodding of head
Low	Attentive listening	In talking about the recent death of his wife, the patient became tearful and hesitant in speech. The interviewer remains silent, but attentive, allowing the patient time to express himself
Moderate	Broad-focus questions	“What do you notice about yourself lately that is different from usual?” “What is it about your job that you find stressful?”
Moderate	Use of examples	“Sometimes illness seems to be triggered by something that happens, like a change in finances or living situation, or losing someone who’s close to you. Has anything like that been happening to you?”
Moderate	Confrontation	“You told me you got a “terrible” evaluation at work, but in 9 of 10 categories your rating was actually excellent.” “You don’t feel the medicine does you Any good, but whenever you’ve stopped It you’ve had to go back into the hospital. How do you account for that?”
Moderate	Interpretation	“Part of the tension between you and your wife is that you forget things she tells you. Perhaps this is what you do when you are angry at her.”
High	Narrow-focus questions	“Do you have trouble getting to sleep or staying asleep? “How much alcohol do you drink in a week?”
High	Question repetition	<i>I:</i> “How has your daily routine changed in the last month?” <i>P:</i> “I used to like to read, but now I don’t anymore. My husband thinks I would feel better if I pushed myself to keep busy, but I tell him that this dizziness makes it impossible for me to do anything. I don’t know what to think anymore.” <i>I:</i> “How else has your routine changed lately?”
High	Redirection	<i>P:</i> “I’ve always thought that my father’s personality caused a lot of my troubles in life.” <i>I:</i> “I’d like to hear more of your thoughts about that, but first I need to get a clearer picture of what’s been happening with you lately. When did you decide to make the appointment with me?”
High	Change of topics	“You mentioned before that your brother had similar problems to yours. Can you tell me how many brothers and sisters you have, and if they’ve had any emotional problems?” “We’ve been talking about your marriage, but now I’d like to know something about your work.”
High	Limit-setting	“I’m going to have to interrupt you because there are a few more things we need to cover in the time left.” “I know you feel restless, but I have to ask you to try to stay in your chair and concentrate on what we’re talking about.”

**Table 3.7 Supportive Interventions**

Intervention	Examples
Encouragement	<i>Patient:</i> “I’m not sure I’m making any sense today doctor.” <i>Interviewer:</i> “You’re doing very well at describing the troubles you’ve been having.”
Approval	“You did the right thing by coming in for an appointment.” “You’ve been doing your best to keep going under very difficult circumstances.”
Reassurance	“What you are telling me about may seem very strange to you, but many people have had similar experiences.” “You feel like you will be sick forever, but with treatment you have a very good chance of feeling better soon.”
Acknowledgment of affect	“You look very sad when you talk about your brother.” “I have the impression that my question made you angry.”
Empathic statements	“When your boyfriend doesn’t call you, you feel completely helpless and unloved.” “It seems unfair for you to get sick so many times while others remain well.”
Nonverbal communication	Smiling, firm handshake, attentive body posture, gentle touch on shoulder.
Avoidance of affect-laden material	Interviewer elects to defer discussion or probing of topics that arouse intense feelings of anxiety, shame, or anger.

that conveys empathic understanding, acceptance and positive regard.

Obstructive interventions are one which (usually unintentionally) impede the flow of information and diminish rapport. Table 3.8 lists common examples of such interventions. Compound or vague questions are often confusing to the patient and may produce ambiguous or unclear answers. Biased or judgmental questions suggest what answer the interviewer wants to hear or that he/she does not approve of what the patient is saying. “Why” questions often sound critical or invite rationalizations. “How” questions better serve the purposes of the interview (“How did you come to change jobs?” rather than “Why did you change jobs?”). Other interventions are obstructive because they disregard the patient’s feeling state or what he/she is trying to say. Paradoxically, this may include premature reassurance or advice. When given before the interviewer has explored and understood the issue, this has the effect of cutting off feelings and coming to a premature closure.

### Fact Versus Feeling Orientation

Interviews differ in the degree to which they focus on factual—objective versus feeling—meaning oriented material. Tables 3.9 and 3.10 provide examples of interventions of both types. The interviewer must determine what the salient issues are in a given case and develop the focus accordingly. For example, at one extreme, the principal task in assessing a cyclically occurring mood disorder might be to delineate precisely the symptoms, time course and treatment response of the illness. At the other end of the spectrum might be a patient with a circumscribed difficulty in living, such as the inability to achieve an intimate, lasting love relationship. In such a case, the interviewer may focus not only on the facts of the patient’s interactions with others but also on the feelings, fantasies and thoughts associated with such relationships.

### Feedback

Interviews differ in how much the interviewer conveys to the patient of his/her own thoughts, feelings, conclusions and recommendations. Table 3.11 presents common types of feedback from the interviewer. Judicious statements about the interviewer’s ongoing thoughts and feelings can be used to pose questions or make clarifications or interpretations while enhancing rapport and trust. Communication of factual information, formulations of the problem and treatment recommendations are the foundations of joint treatment planning with the patient. Responding to questions and giving advice may serve an educational purpose as well as enhancing the alliance. When responding to requests for advice or information, the interviewer must first take care to be sure of what is being asked, and for what reason.

There is little systematic data on the superiority of one clinical interviewing style over another, but what there are suggest that many styles can be used effectively. Rutter and his colleagues have investigated this question in a series of naturalistic and experimental studies of interviews of parents in a child psychiatry clinic (Rutter *et al.*, 1981; Cox *et al.*, 1981, 1988). The major findings of these studies are:

1. Active, structured techniques are no better than nondirective styles in eliciting positive findings (i.e., areas of pathology). However, active techniques are better in eliciting more detailed and thorough information in areas where pathology is found and are also better at delineating areas without pathology.
2. An active, fact-gathering style does not prevent the interviewer from effectively eliciting emotional reactions from informants.
3. Use of open questions, direct requests for feelings, interpretations of feelings, and expressions of sympathy are associated with greater expression of emotions by informants.

**Table 3.8 Obstructive Interventions**

Intervention	Examples
Suggestive or biased questions	“You haven’t been feeling suicidal, have you?” “You’ve had six jobs in the last 2 yr I guess none of them held your interest.”
Judgmental questions or statements	“How long have you been behaving so selfishly?” “What you’ve told me is typical of delusional thinking.”
“Why” questions	“Why can’t you sit still?” “Why do you keep choosing men who can’t make a commitment to you?”
Ignoring the patient’s leads	<i>Patient:</i> “I’m afraid I’m going to fall apart”. <i>Interviewer:</i> “Have you had any odd experiences, such as hearing voices?” <i>P:</i> “No, but I just feel as though I can’t cope and I wanted to talk to someone about it.” <i>I:</i> “Has your sleep pattern or appetite changed?” <i>P:</i> “Well, I don’t sleep as well as I used to, but it’s getting through the days that’s the hardest.” <i>I:</i> Have you had any suicidal thought?”, etc.
Crowding the patient with questions	<i>P:</i> “I just can’t get it out of my mind that this cancer of mine is a punishment of some kind because I...” <i>I:</i> “Have you been in a low mood or been tearful?”
Compound questions	“Have you ever heard voices or thought that other people were out to harm you?”
Vague questions	“Do you feel socially self-conscious a lot?” “How much trouble do you have with your memory?”
Minimization or dismissal	<i>P:</i> “I don’t seem to be able to enjoy my life as much as I think I should”. <i>I:</i> “You’re doing well at your job and have a nice family – you’re probably just feeling some minor stress”.
Premature advice or reassurance	<i>P:</i> “I’ve been having terrible headaches and I forget a lot of things. There’s nothing wrong with my brain, is there?” <i>I:</i> “Headaches and forgetfulness are very common and are probably due to some minor cause in your case.” <i>P:</i> “I’ve started to have thoughts that I married the wrong man and I should leave my husband.” <i>I:</i> “Maybe the two of you ought to take some time away together.”
Nonverbal questions	Sitting at a distance, yawning, looking at watch, fidgeting, frowning, rolling of eyes.

**Table 3.9 Fact-oriented Interventions in the Psychiatric Interview**

Intervention	Examples
Questions about symptoms	“Do the voices seem to come from within your own head or from outside?” “When did you first begin to check your door lock many times before going out?”
Questions about behavior	“What do you do when you fly into a rage – do you yell, hit the furniture, or hit people?” “Since you’ve had your pain, how is your daily routine different than it used to be?”
Questions about events	“What was the next thing you did after you took the overdose of medication?” “What led up to your decision to move out of your parents’ home?”
Request for biographical data	“Who lived with you when you were growing up?” “How many times have you been in a psychiatric hospital?” “Tell me about your close relationships with women.”
Requests for medical data	“What medicines do you take?” “What conditions do you see a doctor for?”

**Table 3.10** Feeling-oriented Interventions in the Psychiatric Interview

Intervention	Examples
Questions about feelings in specific situations	<p>“Some people might have been angry in the situation you told me about. Did you feel that way?”</p> <p>“How did you feel when your doctor told you that you had a heart attack?”</p> <p>“I’ve noticed your voice got much quieter when you answered my last question. What were you feeling just then?”</p>
Questions or comments about emotional themes or patterns	<p>“Growing up, you never felt like you measured up to your mother’s expectations. Do you feel that same way in your marriage?”</p>
Questions or comments about the personal meaning of events	<p>“You are concerned about becoming enraged at your daughter. When she disregards your wishes, what do you feel that means about you as a parent?”</p>

**Table 3.11** Feedback in the Psychiatric Interview

Intervention	Examples
Sharing of ongoing thoughts	<p>“As you were talking I began to wonder if you had ever lost anyone very close to you.”</p> <p>“As I hear your story it occurs to me that you’ve been an outsider every place you’ve lived in.”</p>
Sharing of subjective reactions	<p>“What you are saying makes me feel quite sad.”</p> <p>“You’ve told me how you left treatment with your last psychiatrist, but I still feel a bit confused about what happened.”</p> <p>“I notice I’m feeling somewhat tense right now and I wonder if you might be feeling it too.”</p>
Imparting of information	<p>“About 75% of people with your condition respond well to medication.”</p> <p>“The tendency to develop the kind of symptoms you have described runs in families, and probably is inherited.”</p>
Proposing a formulation	<p>“I think the immediate cause of your depression and insomnia is your heavy drinking.”</p> <p>“When you are under stress you tend not to think clearly and to develop unrealistic fears. It seems as though your present stress comes from the way you and your family are getting along at home.”</p>
Making treatment recommendations	<p>“In order for you to keep safe and begin treatment I think it would be best to go into the hospital for a while.”</p> <p>“Medication should help you get out of your depression much faster. When you are feeling better, it would be a good idea for us to try to understand how you got so isolated from your friends and family.”</p>
Advice	<p>“It might be better not to decide about changing jobs until you’re feeling back to your regular self.”</p>
Response to questions	<p><i>Patient:</i> “What type of psychiatrist are you, doctor?”</p> <p><i>Interviewer:</i> “I’m a general psychiatrist who uses medication and psychotherapy. I also have a special interest in anxiety disorder.”</p> <p><i>P:</i> “Have you ever seen another patient like me?”</p> <p><i>I:</i> “I can answer your question better if you tell me what there is about you that I might have never seen before.”</p> <p><i>P:</i> “Do you think I’m a terrible person?”</p> <p><i>I:</i> “I don’t think you are terrible, but I wonder what you think about yourself that you would ask me that.”</p>

4. Less activity on the interviewer's part is associated with more informant talkativeness and spontaneous emotional expression. Less directive techniques also tend to produce more emotional responses at times when they are not specifically requested. Conversely, more active styles of asking about feelings may be more effective for informants who are low in spontaneous emotional expression.
5. In summary, techniques which actively elicit both facts and emotions are likely to produce the richest, most detailed database. When skillfully used, these do not impair the doctor-patient relationship.

# Physician–Patient Relationship

---

For centuries, healers had little understanding of disease and lacked the technologies we now know are necessary for the treatment and cure of many diseases. Physicians had few medications, and surgery was only a last resort. In fact, the most important tool for healing was the relationship between the physician and the patient. Interpersonal relationships have a powerful influence on both morbidity and mortality (House *et al.*, 1988). Social connectedness enhances health in both direct and indirect ways: directly regulating many biological functions, decreasing anxiety, providing opportunities for new information, and fostering alternative behaviors (Hofer, 1984). We know little about the basic mechanisms by which interpersonal relationships, and the physician–patient relationship in particular, operate (Ursano and Fullerton 1991). However, clinical wisdom holds that both the reality-based elements of the physician–patient relationship – in modern times referred to as the working alliance or the therapeutic alliance (Zetzel, 1956; Greenson, 1965) – and the fantasy-based elements of that relationship affect the patient’s pain, suffering and recovery from illness.

Physicians learned through trial and error to interact with their patients in ways that relieved pain and promoted health (Frank, 1971). Often the physician’s only interventions were reassuring patients, providing knowledge about the patient’s disease, accepting the patient’s feelings of distress as normal, and maximizing the patient’s hope for the future. Although these interventions, based on wisdom and intuition, are no longer the only tools available to the physician, they continue to be an important part of the physician’s and particularly the psychiatrist’s therapeutic armamentarium.

Such nonspecific aspects of cure are often thought to be mystical or mysterious. In fact, in biological studies they are recognized as the placebo effect. Oddly, these effects of interpersonal relationships are both one of the prized and one of the most denigrated aspects of all of medicine. Yet, as clinicians, we all strive to alleviate our patients’ pain and suffering and return them to health as soon as possible with whatever tools may help. Many well-designed studies show that 20 to 30% of subjects respond to the placebo condition. Recent studies show that analgesic placebo has similar neural mechanisms to opioid analgesia (Petrovic *et al.*, 2002). The problem with placebos is not whether they work but that we do not understand how they work and, therefore, we do not have control over their effects. As a physician, one strives to maximize one’s interpersonal healing effects and, in this way as well as with other healing tools, increase the chances of our patients’ relief from pain and of recovery.

The physician–patient relationship includes specific roles and motivations. These form the core ingredients of the healing

process. In its most generic form the physician–patient relationship is defined by the coming together of an expert and a help seeker to identify, understand and solve the problems of the help seeker. The help seeker (in modern terms, the patient) is motivated by the desire and hope for assistance and relief from pain (Sullivan, 1954). A physician is required to have a genuine interest in people and a desire to help (Lidz, 1983). Simply stated, “the secret of the care of the patient is in caring for the patient” (Peabody, 1927). Caring about and paying attention to a patient’s suffering can yield remarkable therapeutic dividends. More than one attending physician has been reminded of this when a patient deferred making a treatment decision until he or she was able to consult with “my doctor”, who turned out to be the medical student.

In today’s technology-driven medicine, the importance and complexity of the physician–patient interaction are often overlooked. The amount of information the medical student or resident must learn frequently takes precedence over learning the fine points of helping the patient relax sufficiently to provide a thorough history or to allow the physician to palpate a painful abdomen. Talking with patients and understanding the intricacies of the physician–patient relationship may be given little formal attention in the medical school curriculum. Even so, medical students, residents and staff physicians recognize, often with awe, the skill of the senior physician who uncovers the lost piece of history, motivates the patient who had given up hope, or is able to talk to the distressed family without increasing their sense of hopelessness or fear.

The relationship between the physician and the patient is essential to the healing of many patients, perhaps particularly so for many psychiatric patients. The physician who can skillfully recognize the patient’s half-hidden comment that he or she has not been taking the prescribed medication, perhaps hidden because of feelings of shame, anger, or denial, is better able to ensure long-term compliance with medication as well as to motivate the patient to stay in treatment. Regardless of the type of treatment – medication, biofeedback, hospitalization, psychotherapy, or the rearrangement of the demands and responsibilities in the patient’s life – the relationship with the physician is critical to therapeutic outcome.

Modern medicine emphasizes a specific role for the physician in the relationship with the patient. In many Western countries, the patient comes for help with a specific problem, the doctor’s office staff secures permission from a third party payer for the doctor to conduct a particular treatment, a prescribed intervention, which will take a specified amount of time. Decades ago, when the doctor was neighbor, advisor and friend to the patient and routinely invited to important family events in

the patient's life such as weddings of children, and when doctors routinely cared for more than one generation of the same family, the physician typically assumed that he or she would be a source of strength and assistance to the patient throughout the cycle of life. This meant more than curing a specific disease or relieving a specific pain.

While today's patients may not consciously expect that the physician's influence and healing powers will take many forms in a complex interpersonal relationship, human nature is still the same, and patients still want from their doctors many nonspecific forms of emotional support which can promote a sense of well-being and better health. Though modern doctors may feel a great deal of time pressure to see many patients each day and to focus narrowly their healing efforts, the physician must also be sensitive to the many needs of patients, who believe that the physician is possessed of wisdom and understanding. Sensitivity to such desires and needs will promote effective medical care in all specialties, with all patients. A view that such patients are unusually needy and demanding will not serve the cause of effective medical care.

Finally, in today's mobile and geographically evermore united world, the importance of recognizing the needs of patients from parts of the world other than that of the physician's is a challenge to the practitioner. The physician must be open to the limitations of his or her knowledge of the expectations, beliefs and likely behavior of patients from different cultures, nations, religions, and ethnic and socioeconomic backgrounds. The physician must recognize this challenge and one hopes, embrace it with enthusiasm. It can make the practice of medicine a more exciting experience.

#### Clinical Vignette 1

A 20-year-old female patient suffered a painful athletic injury. She was unsure exactly how her injury had occurred, but she did recall falling on her shoulder on the tennis court while running after a sharply hit ball. She went to the physician fearing that she had damaged her collarbone. When she was informed that there was no fracture, that her pain was due to a bruised muscle and would go away with ice, heat and aspirin, she immediately felt better. Not only was she relieved but also her perception and experience of the pain actually changed: "It doesn't seem to hurt as much now".

#### Clinical Vignette 2

Somewhat different was the situation of a 30-year-old male patient who developed chronic pain after an athletic injury. The patient had to convince himself to visit the physician. He felt he was being a "baby" to complain. One week after the injury, he went to his family physician who perfunctorily prescribed a strong painkiller and offered a follow-up appointment a month later. He left feeling that he had been a nuisance. The following week was a particularly bad one for the patient; the pain was severe. But the patient stopped taking the prescribed medication, did not keep the follow-up appointment, and never returned for help. This patient continued to experience pain, unnecessarily, for years. In large part, this was because the physician offered no hope; therefore follow-up care, including physical therapy and alternative medications, could not be provided

The physician-patient relationship is also a source of information for the physician. The way the patient relates to the physician can help the physician understand the problems the patient is experiencing in her or his interpersonal relationships. The nature of the physician-patient relationship can also provide information about relationships in the patient's childhood family, in which interpersonal patterns are first learned. With this information, the physician can better understand the patient's experience, promote cooperation between the patient and those who care for her or him, and teach the patient new behavioral strategies in an empathic manner, understanding the patient's subjective perspective, that is, feelings, thoughts and behaviors.

#### Clinical Vignette 3

A 45-year-old single man was hospitalized for treatment of a bleeding ulcer. The patient had no past history of ulcers. Despite reassurance, he continued to feel hopeless. A psychiatric consultant was called to evaluate the patient. She found him to be needy, but could not understand why he was so pessimistic. The psychiatrist recognized the importance to this patient of showing interest in him, showing concern for his condition, and spending time with him. The patient's response was noteworthy; he clearly enjoyed the psychiatrist's company but seemed unusually sad when their times together ended. The psychiatrist asked the patient if this was a correct perception and, if so, why it was the case. The patient responded that the psychiatrist reminded him of his mother. Further inquiry revealed that the patient's mother had died several years ago of colon cancer. The psychiatrist inquired about the symptoms the mother had during her terminal illness. The symptoms were similar to the patient's symptoms: bleeding in the digestive tract and gastrointestinal pain.

The psychiatrist then understood the complex process through which the patient was feeling inordinately pessimistic. Transference was evident in his experience of each departure as an unconscious reminder of the loss of his mother. The patient's identification with his mother (as part of managing her death) was also the source of his unspoken expectation that he, too, was dying of colon cancer. It was the pattern of the relationship between the psychiatrist and the patient, the sadness shown whenever the psychiatrist left, that provided the information necessary to help the patient. Increasing the patient's understanding of his medical condition, specifically how it was different from his mother's, relieved his emotional pain, and he began on the road to recovery.

These clinical vignettes illustrate that the physician-patient relationship is composed of both the reality-based component (the working alliance or therapeutic alliance) and the fantasy-based component (the transference) derived from the patient's patterns of interpersonal behavior learned in childhood. Either or both of these may maximize or limit the patient's sense of reassurance, available information, feelings of comfort and sense of hope (Meissner, 1996). In this way, the nonspecific curative aspects of the physician-patient relationship may be enhanced or diminished.

## Formation of the Physician–Patient Relationship

### Assessment and Evaluation

The physician–patient relationship develops during the assessment and evaluation of the patient. The patient observes the thoroughness and sensitivity with which the physician collects information, performs the physical examination, and explains needed tests. At each step, the physician’s clarification of the treatment goals and interventions either builds up the patient’s expectation of help and feelings of safety or creates increasing disease for the patient. In many aspects and, in particular, in the physician’s compassion and patience, he/she is like a good teacher, establishing the context in which learning and growth may occur and anxiety decrease (Banner and Cannon, 1997). Alertness to the patient’s fears and misunderstandings of the evaluation process can minimize unnecessary disruptions of the relationship and provide information on the patient’s previous experiences with medical care and important authority figures. These past experiences form the patient’s present expectations of either help or disappointment (Smith and Thompson, 1993) (Table 4.1).

### Rapport

Early in the relationship between a psychiatrist and a patient, the patient requests help with his or her pain, uncertainty, or discomfort. The psychiatrist initiates the “contract” of the relationship by acknowledging the patient’s pain and offering help. In this action, the psychiatrist has recognized the patient’s ill-health and acknowledged the need for and possibility of removing the disease or illness. In this first stage of the development of rapport, the way of relating between the physician and the patient, the physician–patient relationship has begun to organize the interactions. Through the physician’s and the patient’s shared recognition of the patient’s pain, the basis for rapport – a comfortable pattern of working together – is established.

The psychiatrist’s ability to empathize, to understand in feeling terms every patient’s subjective experience, is important to the development of rapport. Empathy is particularly important in complex interpersonal behavioral problems in which the environment (family, friends, caretakers) may wish to expel the patient, and the patient has therefore lost hope. Suicidal patients, adolescents involved in intense family conflicts and patients in conflict with their medical caregivers can often be convinced to cooperate with the evaluation only when the psychiatrist has shown accurate empathy early in the first meeting with the patient. When the physician acknowledges the patient’s pain, the patient feels less alone and inevitably more hopeful (Marziali and Alexander, 1991). This rapport establishes a set of principles of

and expectations for the physician–patient interaction. On this basic building block more elaborate goals and responsibilities of the patient can be developed.

### Clinical Vignette 4

A young man sought treatment for ill-defined reasons: he was dissatisfied with his work, his social life and his relationship with his parents. He was unable to say how he thought the psychiatrist could help him, but he knew he was experiencing emotional pain: he felt sadness, anxiety, inhibition and loss of a lust for living. He wanted help. The psychiatrist noted the patient’s tentative style and heard him describe his ambivalence toward his controlling and directing father. With this in mind, the psychiatrist articulated the patient’s wish for help and recognized with him his confusion about what was troubling him. She suggested that through discussion they might define together what he was looking for and how she might help him. This description of the evaluation process as a joint process of discovery established a rapport based on shared work that removed the patient’s fears of control and allowed him to feel heard, supported, and involved in the process of regaining his health.

### The Therapeutic or Working Alliance

For a patient to trust and work closely with a physician it is essential that there be a reality-based relationship outside the conflicted ones for which the patient is seeking help (Rawn, 1991; Friedman, 1969). With more disturbed patients considerable skill is required of the physician to reach this reality-based part of the patient and decrease the patient’s fears and expectations of attack or humiliation. Even for healthy patients, the physician must bridge the gap between the patient and the physician that is always present because of their different backgrounds and perceptions of the world. This gap is an expectable result of differences between the physician’s and the patient’s culture, gender, ethnic background, socioeconomic class, religion, age, or role in the physician–patient relationship. The experienced physician makes communication across the gap seem effortless, using a different “language” for each patient. The student often sees this as an art rather than as a skill to be learned.

The therapeutic alliance is extremely important in times of crisis such as suicidality, hospitalization and aggressive behavior. But it is also the basis of agreement about appointments, fees and treatment requirements. In psychiatric patients, this core component of the physician–patient relationship can be disturbed and requires careful tending. Frequently, the psychiatrist may feel that he or she is “threading a needle” to reach and maintain the therapeutic alliance while not activating the more disturbed elements of the patient’s patterns of interpersonal relating.

The therapeutic or working alliance must endure in spite of what may, at times, be intense, irrational, delusional, characterologic, or transference-based feelings of love and hate. The working alliance must outweigh or counterbalance the distorted components of the relationship. It must provide a stable base for the patient and the physician when the patient’s feelings or behaviors may impair reflection and cooperation. The working alliance embodies the mutual responsibilities both physician and patient have accepted to restore the patient’s health. Likewise, the working alliance must be strong enough to ensure that the

**Table 4.1** Mechanisms for the Formation of the Physician–Patient Relationship

Development of physician–patient rapport
Therapeutic or working alliance
Transference
Countertransference
Defense mechanisms
Patient’s mental status

treatment goes forward even when both members of the dyad may doubt that it can. The alliance requires a basic trust by the patient that the physician is working in his or her best interests, despite how the patient may feel at a given moment. Patients must be taught to be partners in the healing process and to recognize that the physician is a committed partner in that process as well. The development of common goals fosters the physician and patient seeing themselves as having reciprocal responsibilities: the physician to work in a physician-like fashion to promote healing; the patient to participate actively in formulating and supporting the treatment plan, “trying on” more adaptive behaviors in the chosen mode of treatment, and taking responsibility for his or her actions to the extent possible (Ursano and Silberman, 1988).

Important to the reality-based relationship with the patient is the physician’s ability to recognize and acknowledge the limitations of her or his knowledge and to work collaboratively with other physicians. When this happens, patients are most often appreciative, not critical, and experience a strengthening of the alliance because of the physician’s commitment to finding an answer. When a patient loses confidence in the physician, it is often because of unacknowledged shortcomings in the physician’s skills. The patient may lose motivation to maintain the alliance and seek help elsewhere. Alternatively, the patient may seek no help.

### Transference and Countertransference

Transference is the tendency we all have to see someone in the present as being like an important figure from our past (Freud, 1958). This process occurs outside our conscious awareness; it is probably a basic means used by the brain to make sense of current experience by seeing the past in the present and limiting the input of new information. Transference is more common in settings that provoke anxiety and provide few cues to how to behave – conditions typical of a hospital. Transference influences the patient’s behavior and can distort the physician–patient relationship, for good or ill (Adler, 1980).

Although transference is a distortion of the present reality, it is usually built around a kernel of reality that can make it difficult for the inexperienced clinician to recognize rather than react to the transference. The transference can be the elaboration of an accurate observation into the “total” explanation or the major evidence of some expected harm or loss. Often the physician may recognize transference by the pressure she or he feels to respond in a particular manner to the patient, for example, always to stay longer or not abruptly leave the patient (Sandler *et al.*, 1973).

Transference is ubiquitous. It is a part of day-to-day experience, although its operation is outside conscious awareness. Recognizing transference in the physician–patient relationship can aid the physician in understanding the patient’s deeply held expectations of help, shame, injury, or abandonment that derive from childhood experiences.

Transference reactions, of course, are not confined to the patient; the physician also superimposes the past on the present. This is called countertransference, the physician’s transference to the patient (Table 4.2). Countertransference usually takes one of two forms: concordant countertransference, in which one empathizes with the patient’s position; or complementary countertransference, in which one empathizes with an important figure from the patient’s past (Racker, 1968). For example, concordant countertransference would be evident if a patient were describing

**Table 4.2** Types of Countertransference

<p>Concordant countertransference The physician experiences and empathizes with <b>the patient’s</b> emotional experience and perception of reality</p> <p>Complementary countertransference The physician experiences and empathizes with the emotional experience and perception of reality of <b>an important person from the patient’s life</b></p>
---

an argument with his or her boss, and the psychiatrist, perhaps after a disagreement with the psychiatrist’s own supervisor and without having collected detailed information from the patient, felt, “Oh yeah, what a terrible boss”. Similarly, complementary countertransference would be evident if the same psychiatrist felt, “This person (the patient) does not work very hard, no wonder the boss is dissatisfied,” and felt angry with the patient as well. Paying close attention to our personal reactions while refraining from immediate action can inform us in an experiential manner about subtle aspects of the patient’s behavior that we may overlook or not appreciate. In the preceding example, the psychiatrist with the concordant countertransference might be identifying with the patient’s subtle need to fight with authority. The psychiatrist with the complementary countertransference might have identified with the patient’s boss, seeing only the patient’s more passive wishes.

Countertransference occurs in all “sizes and shapes”, more or less mixed with the physician’s past but often greatly influencing the physician–patient relationship. The wish to save or rescue a patient is commonly experienced and indicates a need to look for countertransference responses. When a patient is seriously ill, such as with cancer, we may increasingly want to treat the patient more aggressively, with procedures that may hold little hope, create substantial pain, and perhaps even be against the patient’s wishes. The physician’s feelings of loss of a valued person (in the present and as a reminder of the past) or feelings of failure (loss of the physician’s own power and ability) can often fuel such reactions. More subtle factors, such as the effects of being overworked, can result in unrecognized feelings of deprivation leading to unspoken wishes for a patient to quit treatment. When these feelings appear in subtle countertransference reactions, such as being late to appointments, becoming tired in an hour, or being unable to recall previous material, they can have powerful effects on the patient’s wish to continue treatment.

Major developmental events in physicians’ lives can also influence their perceptions of their patients. When a psychiatrist is expecting the birth of a child, she or he may be overly sensitive to or ignore the concerns of a patient worried about a significant illness in the patient’s child. Similarly, a physician with a dying parent or spouse may be unable to empathize with a patient’s concerns about loss of a job, feeling that it is trivial.

### Defense Mechanisms

All people, including patients, employ mechanisms of defense to protect themselves from the painful awareness of feelings and memories that can provoke overwhelming anxiety. Defense mechanisms are specific cognitive processes: ways of thinking that the mind employs to avoid painful feelings (Freud, 1966). They are often characteristic of a person and form a style of

### Clinical Vignette 5

A psychiatrist was called to evaluate an agitated older adult resident of a nursing home. After she had interviewed the energetic, sad and anxious patient, the psychiatrist found herself unexpectedly sad, confused and unsure about what to do. This was not a new case for the psychiatrist, who had treated many similar cases. In considering her response, her thoughts turned to her grandmother with whom she had lived when she was 8 years old, and who had been displaced from her residence and moved to a nursing home in another city by well-meaning children who wanted her near them. After the move, her grandmother had become depressed and disoriented and died 3 months later. The psychiatrist recalled feeling confused at the time of her grandmother's death, wondering why she had died when she had just moved to an attractive new home. Recalling her confusion, the psychiatrist could think more clearly about her present patient and wondered if the patient might be depressed. She talked further with the nurses and found symptoms of depression in addition to the nighttime agitation. This new information altered her decision on the type of medication to begin with and the need for psychotherapy in addition to medication.

cognition (Shapiro, 1965). Common defense mechanisms include projection, repression, displacement, intellectualization, humor, suppression and altruism (Table 4.3).

Defense mechanisms may be more or less mature depending on the degree of distortion of reality and interpersonal disruption to which they lead. This patterning of feelings, thoughts and behaviors by defense mechanisms is involuntary and arises in response to perceptions of psychic danger (Vaillant, 1992). The patient's characteristic defense mechanisms, the cognitive processes used to lower anxiety and unpleasant feelings, can greatly affect the physician–patient relationship. Defense mechanisms operate all the time; however, in times of high anxiety, such as in a hospital or during a life crisis, patients may become much less flexible in the defenses they use and may revert to using less mature defenses.

**Table 4.3 Common Defense Mechanisms**

Healthier Defenses	More Primitive Defenses
Sublimation	Splitting
Humor	Projection
Repression	Projective identification
Displacement	Omnipotence
Intellectualization	Devaluing
Reaction formation	Primitive idealization
Reversal	Denial
Identification with the aggressor	Conversion
Asceticism	Avoidance
Altruism	
Isolation of affect	

Clinical Vignettes 6 and 7 are examples of defense mechanisms (conversion and avoidance or repression) affecting the treatment relationship. In Vignette 6, the conversion reaction that resulted in the paralysis expressed both the patient's anger and his conflict over what to do. In Vignette 7, the physician knew that the

### Clinical Vignette 6

A 36-year-old army first sergeant was hospitalized for the evaluation of acute paralysis of his right hand. When the results of a neurological work-up revealed no evidence of organic pathology, psychiatric consultation was obtained. The patient denied any past psychiatric history or significant alcohol or other substance abuse. He described a healthy family support system but then hesitated, saying, "You know, Doc, there's one thing I just haven't been able to talk about with anyone." He proceeded to speak of the extreme pressure he was feeling on the job, where he had found out that his boss (the company commander) was behaving unethically. The patient stated, "I feel like I'm between a rock and a hard place – if I report it, I'm being disloyal to my boss, but if I don't, I'm betraying my soldiers and the army". After further elaborating his feelings of anger and disgust toward his boss, the patient asked to terminate the interview but agreed to talk with the psychiatrist again in the morning.

Returning the next morning, the psychiatrist was greeted by the patient, who was brushing his teeth, using his right hand. "Hey, Doc, I'm good to go!" The patient then described what happened the evening before. "I was telling my wife about how I've got to get out of here and get back to work, because, after all, I'm the commander's right-hand man. And you know what, Doc? My hand started to work! Get me out of here, I'm not crazy after all!" The patient then reviewed the process, aided by the psychiatrist, and was able to further his understanding of the link between his conflicted rage toward his boss and how it was expressed symbolically as an involuntary physical paralysis of his right hand. He resolved: "I'm gonna do the right thing. I got to live with myself", and planned to report the commander's misconduct on return to work. He was discharged from the hospital later that day, having regained full use of his hand.

### Clinical Vignette 7

A 20-year-old man came for consultation because of uncertainty about his career. He soon revealed that he felt profoundly sad, hopeless, helpless and even suicidal. He had a family history of depression. The physician and patient agreed to employ antidepressant medication aggressively. Yet over a period of several weeks the patient did not improve. When the physician asked why that might be happening, the patient revealed that he had frequently forgotten to take the prescribed medication and had forgotten to tell the physician that this was the case during two meetings. The physician explored the reasons for this, and together the physician and the patient learned that the patient felt ashamed of having been diagnosed as depressed

**Clinical Vignette 7** *continued*

and of having been considered to require medication. He felt he was not his own master and had experienced this as a severe blow to his self-esteem. Taking the medication was a reminder of this “flaw”. Hearing himself say this and feeling the physician’s empathic support, the patient recognized the irrationality of his behavior and felt relieved. In addition, the physician now understood better the intensity of the patient’s feelings and changed the prescription to once-a-day dosage at bedtime to decrease the patient’s sense of shame and increase compliance with the treatment.

forgetting was neither intentional nor conscious but was directed at denying the need for treatment. In these cases, recognizing the defenses was important to knowing how to relate to the patient (Clinical Vignette 6) and avoid a countertransference reaction of anger at the patient for lack of compliance (Clinical Vignette 7).

**Mental Status of the Patient**

The patient’s mental status is a major determinant of the formation and nature of the relationship with the physician. A young, healthy patient with an acute disorder has different needs and expectations than a somewhat older person who comes for help with a condition that has been present for a number of years. Both differ from the older adult who comes to the physician expecting that the future will be filled with physical and emotional losses.

It can be seen when comparing these two clinical vignettes that the mental status of the patient helps define the nature of

**Clinical Vignette 8**

A 25-year-old recent law school graduate came to a psychiatrist following a romantic disappointment. He reported that he was very sad because his girlfriend had chosen to move to a different city, which he believed foretold the end of their relationship. He added that he had been having trouble sleeping for several weeks, and was worried because his exhaustion was causing problems in his ability to perform his work. When the physician took a careful history, he learned that this young man had led a successful life, and that his social and sexual development had been quite unremarkable. He had had good friends and close friendships, and several girlfriends in his life. He said he would miss his girlfriend, but that he never intended to marry her. The doctor indicated to her patient that sometimes, after such a disappointment, it was quite common for there to be a period of anxiety and that his sadness was a good sign, showing that he had a good capacity to attach and mourn the loss of a close friend. The psychiatrist also suggested that the patient may be more angry with the girlfriend than he had recognized, with which the patient agreed. The doctor prescribed a mild sleep medication, suggesting it may not even be required, and scheduled a follow-up appointment in a month. When the patient returned, he reported that he had used only two of the sleeping pills and had thrown the rest away. He did not want to schedule another appointment; he expressed gratitude to the psychiatrist and they parted company.

**Clinical Vignette 9**

A 70-year-old widowed lawyer was vigorous, active, financially comfortable, with many friends and professional associates. She explained to the psychiatrist that the last year had, however, been very difficult for her. Six months before, her husband of 45 years had died after a 2-year struggle with congestive heart failure. She now found herself seriously depressed, despite her active life. She was thinking actively about giving up her law practice, though she was very involved in several ongoing cases, which she had previously found interesting and which held the promise of significant financial reward. She went on to say that she had no appetite. She was chronically sleep deprived and was losing interest in her friends, children and grandchildren. When taking a careful history, the psychiatrist also learned that this patient had suffered from a serious depression 35 years earlier, when she lost a pregnancy, and that this depression lasted for a year. It eventually resolved after she took a tricyclic antidepressant and engaged in brief, insight-oriented psychotherapy. In that therapy, her relationship with her own depressed mother had been discussed. With all this information, the psychiatrist suggested she and her patient meet weekly and that the treatment include a pharmacological intervention to help with the patient’s current depression. This treatment ended successfully 1 year later.

the physician–patient relationship, though in both cases the treatment relationship was of relatively brief duration and ended successfully.

The patient’s mental status in this case was the focus of and major factor in the structure of a long psychotherapy that greatly assisted the rehabilitation of interpersonal skills and the

**Clinical Vignette 10**

A 40-year-old man came to a psychiatrist with a long history of emotional difficulties. He had been a healthy and happy college student when he developed a skin abscess, which caused a septicemia and a brain infection. After this, his entire life changed. Although college was quite challenging, he was able to finish it, but had difficulty concentrating, his judgment was poor, his impulse control impaired. He had difficulty remembering words, and he realized that his previously adequate social skills had been lost. Where once he had been charming and known for his sense of humor, now he was dull and in many ways boring. Yet there was more to him than that, and he longed for an opportunity to speak with an understanding listener in the hope that through such a relationship he might be able to make constructive changes in his life. He knew what had been lost, he wanted to understand his limitations better, and he wanted to be able to function well enough to keep a job. A more remote goal was to have a long-term relationship with a woman. His consulting psychiatrist knew that were she to take on this patient it would be for the long haul. Fortunately, there were no financial barriers to treatment, and the pair worked together on a weekly basis for many years. In the course of that treatment, the

patient came to understand the social situations that made him anxious and the way his emotional states of mind influenced changes in his cognitive function. He developed the ability to work and love more effectively; he met a woman who was kind and loving. The psychiatrist was invited to his wedding. She attended the religious service but quietly left the reception after congratulating her patient and his wife. By that time, years into the physician–patient relationship, the patient saw his physician as a wise observer, an advisor and a trusted friend. To the physician, her patient was a happy reminder of how much a person can strive to improve his life, and a rich source of learning about the interaction of emotion, cognitive function and behavior.

understanding of his cognitive limitations and newly changed cognition. The ability to work with an empathic listener while confronting limitations and feelings of shame and embarrassment is a special opportunity of the well-formed doctor–patient relationship.

## Special Issues in the Physician–Patient Relationship

### Phase of Treatment

The treatment phase – early, middle, or late (Table 4.4) – affects the structure of the physician–patient relationship in terms of both the issues to be addressed and the task to be accomplished by the physician and the patient. The early stage of treatment involves developing a rapport, forming shared initial goals, and initiating the working alliance. Education of the patient is important to the success of the physician–patient relationship in this stage, so that the patient learns what he or she can expect. In the middle stage of treatment, the physician and patient continuously refine their shared goals, and various interventions are tried. While this takes place, transference and countertransference are likely to emerge. How these are recognized and managed is critical to whether the relationship continues and is therapeutic.

In the later phase of treatment, the assessment of the outcome and plans for the future are the primary focus. The physician and the patient discuss the end of their relationship in a process known as termination. Successes and disappointments associated with the treatment are reviewed. The physician must be willing to acknowledge the patient’s disappointments, as well as recognize her or his own disappointments in the treatment. The therapeutic alliance is strengthened in this stage when the physician accepts expressions of the patient’s disappointments, encourages such expressions when they are not forthcoming,

**Table 4.4** Key Features of Treatment Phases

Early: developing rapport, forming shared initial goals, initiating the working alliance  
 Middle: refining shared goal, using a variety of trial interventions  
 Late: assessing outcome, resolving presenting problems, planning for future

**Table 4.5** Factors Affecting the Physician–Patient Relationship

Phases of treatment: early, middle, late

 Health and illness of the physician

and prepares the patient for the future. Such preparations include orienting the patient as to when he or she might seek further treatment (Ursano and Silberman, 2002). Solidifying the physician–patient relationship at the end of the treatment can be critical to the patient’s self-esteem and willingness to return if symptoms reappear (Table 4.5).

As a part of the termination process the physician and the patient must review what has been learned, discuss what changes have taken place in the patient and the patient’s life, and acknowledge together the sadness and joy of their leave-taking. The termination involves a mourning process even when treatment has been brief or unpleasant. Of course, when the physician–patient relationship has been rewarding, and both physician and patient are satisfied with what they have accomplished, mourning is more intense and often characterized by a bittersweet sadness.

### Treatment Settings

The physician–patient relationship takes place in a variety of treatment settings. These include the private office, community clinic, emergency room, inpatient psychiatric ward and general hospital ward. Psychiatrists treating patients in a private office may find that the relative privacy of this setting enhances the early establishment of trust related to confidentiality. In addition, the psychiatrist’s personality is more evident in the private office where personal factors influencing choice of decor, room arrangement and location play a role. However, in contrast to the hospital or community setting, the private office generally lacks other evidence of the physician’s competence and humanness. In hospital and community settings, when a colleague greets the physician and the patient in the hall, or the physician receives a call for a consultation by a colleague or for a meeting, it indicates to the patient that the physician is qualified, skilled and humane.

On the other hand, therapeutic work conducted in the community clinic, emergency room and general hospital ward often requires the psychiatrist and patient to adapt rapidly to meeting one another, assessing the problem, establishing treatment goals, and ensuring the appropriate interventions and follow-up. The importance of protecting the patient’s needs for time, predictability and structure can run counter to the demands of a busy service and unexpected clinical and administrative requirements. The psychiatrist must stay alert to the patient’s perspective but not all interruptions can be avoided. The patient can be informed and accommodated as much as possible, and any feelings of hurt, disappointment, or anger can be listened for by the physician and responded to empathically. At times, patients, particularly those with borderline personality disorder, may require transfer to another psychiatrist whose schedule can accommodate the patient’s exquisite needs for stability.

The boundaries of confidentiality are necessarily extended in hospital and community settings to include consultation with

other physicians, nursing staff and often family members (Wise and Rundell, 2002). Particular attention must always be given to the patient's need for and right to respect and privacy. Regardless of the setting, patients receiving medication must be fully informed about the potential risks and benefits of and alternatives to the recommended pharmacological treatment (Kessler, 1991). Patients must be educated about the risks and benefits of receiving prescribed treatment and of not receiving treatment. This is an important component of maintaining the physician–patient relationship. Patients who are informed about and involved in decisions about medication respect the physician's role and interest in their welfare. Psychiatrists must also pay particular attention to the meaning a patient attaches to any prescribed medication, particularly when the time comes to alter or discontinue its use (Ursano *et al.*, 1991).

The change from inpatient to outpatient therapy involves the resumption of a greater degree of autonomy by the patient in the physician–patient dyad. The physician must actively encourage this separation and its hope for the future. This transition is delicate for any therapeutic pair.

### Managed Care

Managed care, broadly defined as any care of patients that is not determined solely by the provider, currently focuses on the economic aspects of delivering medical care, with little attention thus far to its potential effects on the physician–patient relationship (Goodman *et al.*, 1992). Discontinuity of care and the creation of unrealistic expectations on the part of patients have been raised as likely deleterious effects on that relationship (Emanuel and Brett, 1993). Other issues that can affect the physician–patient relationship include the erosion of confidentiality, shrinkage of the types of reimbursable services, and diminished autonomy of the patient and the physician in medical decision-making. Additionally, many managed care systems dictate a split treatment model, with the psychiatrist prescribing psychopharmacologic treatment and a separate clinician providing psychotherapy. In such a system, there are complicated challenges faced both by clinicians and patients. With neither party in complete control of decisions, the physician–patient relationship can become increasingly adversarial and subservient to external issues such as cost, quality of life, political expediency and social efficiency (Sieglar, 1993).

## The Physician–Patient Relationship in Specific Populations of Patients

### Cross-cultural and Ethnic Issues

Addressing cross-cultural issues such as race, ethnicity, religion and gender is vital to the establishment and maintenance of an effective physician–patient relationship (see Chapter 2 and 21). Failure to clarify cultural assumptions, whether stemming from differences or similarities in background, may impede the establishment of a trusting therapeutic alliance, making effective treatment unlikely (Cheng and Lo, 1991).

### Children, Adolescents and Families

Establishing an effective physician–patient relationship with children, adolescents and families is one of the most challenging and rewarding tasks in the practice of psychiatry. Rather than being treated as “little adults”, children and adolescents must be approached with an appreciation for their age-appropriate

developmental tasks and needs. When physicians treat this population, they must establish a trusting relationship with both the patient and the parents. Preadolescent children face the psychosocial developmental tasks of establishing trust, autonomy, initiative and achievement. By understanding the facets of normal childhood development, physicians may help parents understand the nature of their child's disturbance and work within the family system to establish effective mechanisms for coping and recovery (Angold, 2000; Erikson, 1950).

Adolescent patients, facing the task of establishing an individual identity, pose particular challenges to the physician–patient relationship. Adolescents are particularly sensitive to any signals from the physician that their powers of decision, their intelligence, or their perceptions are being ignored. The critical time for engagement with the adolescent is often in the first session, sometimes even in the first few minutes (Katz, 1990). Defiance, detachment and aggression may be anticipated and defused with a steady therapeutic presence grounded in consistent boundaries and open acknowledgment of the adolescent patient's distress (Colson *et al.*, 1991).

In working with families, physicians in general and psychiatrists in particular must clearly address questions and concerns regarding all aspects of treatment and convey respectful compassion for all members. The therapeutic alliance, or “joining” with the family and patient, requires developing enough of a family consensus that treatment is worth the struggle involved. Taking sides and engaging with individual and family power struggles can be particularly destructive to the physician–patient relationship in families. Rather, it is the physician's ability to relate to the family as a multifaceted organism, massively interconnected, transcending the sum of its parts, that often allows treatment to progress and, in the best scenarios, allows for growth and understanding to occur (Fleck, 1985; Ziegler, 1999).

### Terminally Ill Patients

Terminally ill patients share concerns related to the end of the life-cycle. Elderly patients at all levels of health face the developmental task of integrating the various threads of their life into a figurative tapestry that reflects their lifelong feelings, thoughts, values, goals, beliefs, experiences and relationships, and places them into a meaningful perspective. Patients newly diagnosed with a terminal illness such as metastatic cancer or acquired immunodeficiency syndrome may be particularly overwhelmed and initially unable to deal with the demands of their illness, especially if the patient is a younger adult or child. Psychiatrists may enhance the terminally ill patient's ability to cope by addressing issues related to medical treatment, pharmacotherapy, psychotherapy, involvement of significant others, legal matters and institutional care (Lederberg and Holland, 2000). Patients struggling with spiritual or religious concerns may benefit from a religious consultation, a resource that is frequently unused.

Countertransference feelings ranging from fear to helplessness to rage to despair can assist the therapist greatly in maintaining the physician–patient relationship and ensuring appropriate care. Physicians working with patients with acquired immunodeficiency syndrome must frequently confront their own feelings and attitudes toward homosexuality (McKusick, 1988). Issues commonly encountered with disabled patients include inaccurate assumptions about their ability to function fully in all areas of human activity, including sex and vocation. Terminally ill patients may evoke reactions of unwarranted pessimism, thwarting the physician's ability to help the patient

maximize hope for the quality of whatever time may remain. Patients and their family members often look to their physician for guidance.

## Conclusion

The physician–patient relationship is essential to the healing process and is the foundation on which an effective treatment plan may be negotiated, integrating the best of what medical technology and human caring can provide. The centrality of this relationship is particularly true for psychiatric physicians and their patients. In the psychiatrist–patient relationship, empathy, compassion and hope frequently serve as the major means of alleviating pain and enhancing active participation in all treatment interventions: biological, psychological and social.

The development of the physician–patient relationship depends on skilled assessment, the development of rapport through empathy, a strong therapeutic alliance and the effective understanding of transference, countertransference and defense mechanisms. Current research findings support the purposeful use of common therapy factors, of which the therapeutic alliance is the most powerful, to enhance clinical outcome.

The development of the physician–patient relationship is influenced by numerous factors, including the phase of treatment, the treatment setting, transitions between inpatient and outpatient care, managed care and changes in the physician's health. The astute physician is attuned to the needs and characteristics of specific populations of patients, adopting the therapeutic approach that most effectively bridges the gap between physician and patient and leads to a healing relationship.

# Professional Ethics and Boundaries

## Introduction

In the last several decades, advances in psychiatry have made it possible to treat mental disorders that were previously unamenable to successful intervention. There has been a dark side to this progress, however, because futuristic anticipation of subduing disease and forcing nature to surrender her secrets has led many practitioners to outrun their headlights. Like technical sorcerers of science fiction confusing promise with reality, we are in danger of being lulled into an intellectual arrogance that can cause us to forget what it means to be professionals. One manifestation of this process has been the defensive reliance by clinicians on reductionistic explanations for complex and multidetermined disorders, combined with a neglect of the important role of trust and empathy as a curative factor in treating mental disorders.

A bewildering potpourri of treatment options and methods for financing healthcare present psychiatrists with other sources of confusion. Patients' health and safety often depend upon our ability to make rapid clinical decisions regarding diagnosis and to utilize an optimal psychotherapeutic or psychopharmacologic approach. The psychiatrist's dilemma is similarly compounded by conflicts between the cost-determined restrictions of managed care and the sacred promise to advocate primarily for patients' welfare.

Building a cooperative and trusting relationship with patients has always been an essential factor enabling clinicians to foster the healing process. In ancient times, when there were few specific remedies available, physicians relied on a highly integrative view of the sick person. For example, ancient Egyptian medicine did not make a special distinction between soma and psyche in considering physical and mental disorders, and therefore attached no special stigma to the mentally ill (Okasha and Okasha, 2000). Similarly, the Rabbinic sage and physician Maimonides (1135–1204 AD) (1944), relying on scriptural and clinical wisdom, taught that both physical and mental illness resulted from imbalances in somatic and mental processes, and that physical health and mental health are interdependent (Gorman, 2001).

In most instances, modern technology augments but cannot substitute for a trusting doctor–patient relationship. Patients seeking medical care must suspend ordinary social distance and critical judgment if they are to allow physicians to enter their physical and psychological space. While neither the law nor medical ethics relieve patients from taking an active responsibility for treatment outcome (American Medical Association, 1993), society places a greater burden upon the healer – a mandate to act with the spe-

cial care and vigilance expected of a fiduciary (Frank and Frank, 1991; Simon, 1987) or of a Common Carrier (Epstein, 1994, pp. 59–61) as a precondition for granting licenses to practice.

As we review in this chapter, the ability to sustain a professional attitude and to practice within a set of coherent boundaries forms the foundation of proper psychiatric treatment, regardless of theoretic orientation or treatment modality. An understanding of psychiatric ethics plays a vital role in the psychiatrist's ability to keep proper boundaries because these values provide a stable beacon in the cognitively perplexing fog that so often pervades the treatment situation.

## Ethical Behavior and its Relationship to the Professional Attitude

The term **professional** derives from medieval times, when scholastics were expected to “profess” their belief in a doctrine (Dyer, 1988, p. 17). In modern times, a professional is expected to be a learned person who has acquired special knowledge of a subject that is of vital importance for the welfare of the community. Having expertise is not enough, however. A professional is also obliged to adhere to certain societal responsibilities that are founded upon a code of ethical behavior and an attitude of service to those in need. A professional commitment to ethical behavior and service must take precedence over monetary compensation (Dyer, 1988, p. 16). All physicians, including psychiatrists, are bound by such a covenant – a sacred vow to place patient well-being before other considerations (Webb, 1986). In Western medical tradition, this obligation primarily derives from the teachings of Hippocrates in the 5th century BC. Hippocrates' Oath is the predominant pledge recited at the graduation exercises at American medical schools (Dickstein *et al.*, 1991), and contains three of the six core principles of modern medical ethics: **beneficence**, **nonmaleficance**, and **confidentiality**:

I will follow that system of regimen which according to my ability and judgment, I consider for the benefit of my patients, and abstain from whatever is deleterious and mischievous.... With purity and holiness I will pass my life and practice my Art.... Into whatever houses I enter, I will go into them for the benefit of the sick, and will abstain from every voluntary act of mischief and corruption; and, further, from the seduction of females or males, of freemen and slaves. Whatever, in connection with my professional practice or not, in connection with it, I see or hear, in the life of men, which ought not to be spoken of abroad, I will not divulge, as reckoning that all such should be kept secret (Hippocrates, 1929).

**Table 5.1** Six Basic Principles of Medical Ethics

Principle	Description
Beneficence Nonmaleficance	Applying one's abilities solely for the patient's well-being Avoiding harm to a patient
Autonomy	Respect for a patient's independence
Justice	Avoiding prejudicial bias based on idiosyncrasies of the patient's background, behavior, or station in life
Confidentiality	Respect for the patient's privacy
Veracity	Truthfulness with oneself and one's patients

Reprinted with permission from Epstein RS (1994) *Keeping Boundaries. Maintaining Safety and Integrity in the Psychotherapeutic Process*. Copyright, American Psychiatric Press, Washington DC.

The other three general principles of medical ethics include autonomy, justice and veracity (see Table 5.1 for a description and summary of all six ethical principles; Epstein 1994, p. 20). The American Psychiatric Association (APA) (1973) adopted the American Medical Association's (AMA) *Principles of Medical Ethics*, publishing it along with special annotations applicable for psychiatric practice. The APA has produced six revisions of these annotations. The seven sections of the AMA principles are summarized in Table 5.2. Table 5.3 summarizes some of the salient ethical annotations for psychiatrists (American Psychiatric Association, 1993).

The World Psychiatric Association (World Psychiatric Association [WPA] 1999–2002; World Psychiatric Association Ethical Statements, 2000) developed and approved ethical guidelines, starting with the Declaration of Hawaii in 1977, galvanized by concerns about the abuse of psychiatry. A long process of investigation within the domain of professional ethics provided the foundation for the Declaration of Madrid that was endorsed by the General Assembly of the WPA in 1996. In its final form, the Declaration of Madrid included seven general guidelines that focused on the aims of psychiatry. They are summarized as follows:

1. Psychiatry's concern should be to provide the best treatment and rehabilitation for persons with mental disorders, consistent with scientific knowledge, ethical principles, and with the least possible restriction on the freedom of the patient.
2. Psychiatrists have a duty to keep abreast of scientific developments. Psychiatrists trained in research should seek to advance the frontiers of knowledge.
3. The psychiatrist–patient relationship must be based on mutual trust and respect, and should allow the patient to make free and informed decisions. The psychiatrist has a duty to accept the patient as a partner in the therapy and to empower the patient with necessary information for rational treatment decisions.
4. Psychiatrists should consult with families of incapacitated patients to safeguard the human dignity and the legal rights of the patient. Treatment should not be given against the patient's will, unless withholding treatment would endanger the life of the patient or others. Treatment must always be in the best interest of the patient.

**Table 5.2** Summary of the Principles of Ethics of the American Medical Association

Section	Statement of Principle
Preamble	The medical profession's ethical standards are designed primarily for the well-being of patients. As professionals, physicians are required to acknowledge a responsibility to patients, to society, to self and to their colleagues.
Section I	Dedication to competent, compassionate care. Respect for human dignity.
Section II	Obligation to deal honestly with patients and colleagues and to expose physicians who are incompetent or fraudulent.
Section III	Respect for the law. Obligation to seek changes in laws harmful to patient's care.
Section IV	Respect for the rights of patients and colleagues. Within legal constraints, preservation of confidentiality.
Section V	Commitment to continued education, sharing of relevant knowledge, and obtaining necessary consultation.
Section VI	Except in emergency, freedom to decide whom to treat, with whom to associate, and the setting in which one serves.
Section VII	Acknowledge the responsibility to contribute to improving the community.

**Table 5.3** Summary of Selected Ethical Principles for Psychiatrists

Principle	Annotations
Competent care	The psychiatrist must scrutinize the effect of his/her conduct on the boundaries of the treatment relationship.
Honest dealing	Sex with a current or former patient is unethical. Information given by patients should not be exploited. Contractual arrangements should be explicit. Fee splitting is unethical.
Confidentiality, respecting colleagues	Restraint in release of information to third parties. Adequate disguise of case presentations. Disclosure of lack of confidentiality in nontreatment situations. Sex with students or supervisees may be unethical.

Reprinted with permission from American Psychiatric Association (1993) *Principles of Medical Ethics with Annotations Especially Applicable to Psychiatry*. Copyright, American Psychiatric Association, Washington DC.

5. Psychiatrists performing assessments, especially when retained by a third party, have a duty to inform the person being examined about the purpose of the intervention, the use of the findings, and the possible repercussions of the assessment.
6. Unless there is a threat of serious harm to the patient or other persons, psychiatrists should keep all patient information in confidence, and use such information only for the purpose of helping the patient. Psychiatrists are prohibited from making use of such information for personal, financial, or academic benefits.
7. It is unethical to conduct research that is not in accordance with the canons of science. Research activities should be approved by an appropriate and ethically constituted oversight committee. Because of the vulnerability of psychiatric patients, extra caution and strict ethical standards should be employed to safeguard patients' autonomy, patients' mental and physical integrity, and the selection of population groups.

An appendix in the Declaration of Madrid includes additional guidelines on specific ethical issues in psychiatry, including the following (World Psychiatric Association, 1999–2000; World Psychiatric Association Ethical Statements, 2000):

### **WPA Guidelines on Euthanasia**

The physician's role, first and foremost, is to promote health, reduce suffering, and protect life. The psychiatrist, whose patients may include those who are severely incapacitated or incompetent to reach an informal decision, should be particularly careful about actions that could lead to the death of individuals who cannot protect themselves because of disability, and should be vigilant to the possibility that a patient's views could be distorted by mental illness such as depression. In such situations, the psychiatrist's role is to treat the illness.

### **WPA Guidelines on Torture**

A psychiatrist should not take part in any process of mental or physical torture even when authorities attempt to force their involvement in such acts. Furthermore, a psychiatrist should not participate under any circumstances in legally authorized executions, nor participate in assessments of competency to be executed.

### **WPA Guidelines on Sex Selection**

It is unethical for a psychiatrist to participate in decisions to terminate pregnancy for the purpose of sex selection.

### **WPA Guidelines on Organ Transplantation**

Psychiatrists should seek to protect their patients and help them exercise self-determination to the fullest extent possible. The role of the psychiatrist is to clarify the issues surrounding organ donations and to deal with the religious, cultural, social and family factors to ensure that informed and proper decisions be made by all concerned.

### **WPA Guidelines on Genetic Research and Counseling in Psychiatric Patients**

Psychiatrists participating in genetic research should be mindful that the ramifications of genetic information are not limited to the individual subject or patient but can lead to far-reaching repercussions and consequences that can have a negative and disruptive effect on the larger family or community. Psychiatrists

are ethically obligated to observe proper practice, avoid the risks associated with premature disclosure, misinterpretations, or misuse of genetic information, and should never advise a pregnant woman with mental disorders to get an abortion based on the medical or genetic basis of her mental illness. They should not refer patients to genetic testing unless there are satisfactory levels of quality assurance and adequate genetic counseling available to the patient.

Further guidelines on the relationship between psychiatrists and the media, ethnic discrimination, ethnic cleansing, and genetic research and counseling were endorsed by the WPA General Assembly in 1999.

### **WPA Guidelines on Ethnic Discrimination and Ethnic Cleansing**

The Madrid Declaration defines ethnic discrimination as basically racist, as it fails to accept diversity and humanity's common heritage. In its most malignant form, ethnic cleansing is a crime against humanity. In this regard, psychiatrists should not discriminate nor help to discriminate against patients on ethnic grounds, nor be involved in any activity that promotes ethnic cleansing.

### **WPA Guidelines on Psychiatrists Addressing the Media**

It is important that psychiatrists use the media in an affirmative way for a variety of goals that promote good mental health care, such as advocating for the destigmatization of mental disorder and mental patients. In all their interactions with the media, psychiatrists are obliged to advocate for the mentally ill and to maintain the dignity of the profession. Psychiatrists should be mindful of the effect of their statements on the public perception of the profession and patients, and abstain from making statements or undertaking public activities that may be demeaning to either. Patients' confidentiality should be maintained, and the sensationalization of mental illness should be avoided. Regarding the disclosure of research findings, psychiatrists should be cautious to report only results that are generally accepted by experts, and to convey the presentation of such results in a way that serves patients' welfare and dignity.

### **The Coherent Treatment Frame and the Role of Therapeutic Boundaries in Effective Psychiatric Treatment**

The "frame" of a social interaction was defined by Goffman (1974) as consisting of the spoken and unspoken expectations defining meaning and involvement in a given situation. For example, patients seek out psychiatrists based on a tacit assumption that the doctor is a reliable and experienced clinician who has the ability to assist them in finding relief for distress. However, many patients tend to frame their treatment in pathological ways. For example, some will attempt to pressure the psychiatrist into the role of a magical wizard who will confer unconditional love and pleasure. Whatever method the patient employs to frame the relationship, any abrupt disappointment or rupture of these unspoken expectations often results in intense and disruptive feelings of mortification and betrayal. A sudden breach of a social frame can lead to the dissolution of one's sense of meaning and connection, and is often accompanied by intense feelings of shame. By examining verbal and behavioral responses following violations of the treatment frame, Langs (1984–1985) was able to document that

**Table 5.4 Factors Common to All Successful Psychotherapy**

Principle	Method Applied
Inspiring trust	The therapist establishes an emotionally arousing, trusting, and confidential relationship.
Coherent structure	A structured setting is formed that is associated with the healing process.
Rationale explained	A reasoned treatment method is offered that plausibly explains the patient's problems.
Cooperative engagement	Therapist and patient actively work together in the program. Both believe that it will work.

Source: Frank JD and Frank JB (1991) *Persuasion and Healing. A Comparative Study of Psychotherapy*, 3rd edn. Johns Hopkins University Press, Baltimore.

patients usually perceive the offending therapist as an unreliable and mentally unstable person – someone seeking perverse pleasure at another person's expense.

The psychiatrist's task is to provide a coherent therapeutic frame within which to contain the patient's illness. The psychiatrist's frame makes it secure to proceed with the specific therapeutic modality, just as the surgical suite provides a safe environment for operative techniques. The treatment frame enables the patient to maintain a feeling of trust and connectedness while learning to deal with the unrealistic nature of his/her expectations. The frame comprises various boundary factors that include acting in a reliable way, showing respect for the patient's autonomy by explaining the potential risks and benefits of the treatment method, maintaining confidentiality, avoiding exploitation of the patient's sexual feelings, and resisting the patient's manipulative efforts by explaining the maladaptive nature of such behavior (Epstein, 1994; Simon, 1992).

Frank and Frank (1991) conducted an extensive review of the literature concerning psychotherapy outcome. They determined that there were four basic factors common to all successful psychotherapies (see Table 5.4), and that treatment efficacy relied upon the ability of the therapist to form a structured, mutually trusting, confidential and emotionally arousing relationship. Their findings sustain the argument that maintaining a coherent treatment frame is an essential part of all psychiatric treatment, regardless of the therapeutic paradigm being employed. These issues are important whether the patient is being treated solely with psychotropic medication management, cognitive-behavioral therapy, or psychoanalysis.

## Boundary Violations

Psychiatric treatment cannot be conducted without doctor and patient entering into each other's space, just as it is impossible to perform a bloodless laparotomy. Gutheil and Gabbard (1993) termed such incursions occurring during the therapeutic process **boundary crossings**. They defined boundary violations as boundary crossings that cause injury to the patient. However, it is not always easy to be sure of the consequences of such a

“crossing”, since harmful effects may be delayed or concealed. Many patients are unable to articulate their sense of injury because the psychiatrist's aberrant behavior may appear so similar to exploitation they have experienced in previous pathological relationships. For example, patients who were sexually abused in childhood are more likely to acquiesce to an amorous advance by a psychiatrist and to avoid complaining about feeling used, because they fear the threat of the psychiatrist's rejection and retaliation. Certain nonsexual boundary crossings such as conflicts of interest might seem harmless on the surface but can interfere with patients' ability to feel safe in their psychiatrist's care and will diminish their chances for optimal recovery. In this context, a boundary violation can be defined as any infringement that interferes with the primary goal of providing care or causes harm to the patient, the therapist, or the therapy itself (Epstein, 1994, p. 2).

Prior to the 1970s, open discussion on the topic of psychiatrist-patient sex was virtually taboo and considered “too hot to handle” as a subject for publication in scientific journals (Dahlberg, 1970). Professional societies demonstrated an inconsistent and ambiguous attitude of “amused tolerance” (Pope and Bouhoutsos, 1986, p. 161) towards mental health practitioners engaging in sexual behavior with their patients.

The public has become increasingly interested in the subject of psychiatric boundary violations in the past 25 years, particularly those involving sexual exploitation. State licensing boards, professional ethics committees and civil juries are much more likely to mete out strong sanctions against violators than ever before. These attitudinal changes have taken place in spite of the fact that popular movies continue to romanticize the idea of psychiatrist-patient sexuality, and almost always seem oblivious to the horrendous feelings of shame, betrayal and devastation that patients experience when these things happen to them in real life.

The public's intolerance of sexual involvement between psychiatrists and patients has resulted in part from the increasing empowerment of the victims of incest, rape and spousal abuse, and a better understanding of the psychological sequelae that follow mental trauma such as post traumatic stress disorder (PTSD). In addition, psychiatric patients have become more willing to expose unethical or exploitative behavior on the part of clinicians, particularly when it involves sexual activity. This trend has been augmented by the fact that courts and professional licensing bodies are now more inclined to render sanctions for injuries that are solely psychological in nature.

Quantitative estimates of the frequency of sexual boundary violations among mental health professionals derive from survey studies conducted over the last 20 years (Pope and Bouhoutsos, 1986; Kardener *et al.*, 1973; Perry, 1976; Holroyd and Brodsky, 1977; Gartrell *et al.*, 1986; Borys and Pope, 1989; Schoener, 1990). A review of these studies shows that from 5.5 to 13.7% of male mental health clinicians admitted to engaging in sexual activity with patients. Epstein (1994, pp. 207–208) calculated a crude weighted average from Schoener's (1990) comprehensive review of survey studies reporting frequency of sexual violations by clinicians' gender. From ten studies involving a total of 5816 respondents (excluding a large survey of nurses), an average of 7.4% of male and 2.3% of female clinicians admitted to engaging in sexual behavior with patients. These data suggest that male clinicians are about three times more likely to admit they have become sexually involved with patients. Although more recent studies suggest that sexual exploitation by mental

health practitioners might be occurring less frequently, increasing media reports of severe sanctions taken against offending therapists have probably diminished the validity of self-report questionnaires.

Studies of nonsexual violations suggest that many mental health clinicians still have serious problems maintaining professional boundaries with patients (Borys and Pope, 1989; Epstein *et al.*, 1992). Epstein and colleagues (1992) queried 532 psychiatrists practicing in the USA about their behavior with patients within a prior 2-year period, using the Exploitation Index (EI) developed by Epstein and Simon (1990). They found that 19% of respondents reported engaging in a personal relationship with patients after treatment was terminated, 17% told patients personal details of their life in order to impress them, and 17% joined in activities with patients to deceive a third party such as an insurance company (see Table 5.5, reviewing the frequency of nonsexual boundary violations among respondents in this study). Xiangyi and Tiebang (2001) surveyed mental health clinicians in China using a Chinese translation of the EI. They found a rate of endorsement of boundary violations that was similar to the findings in the US study, although there were distinct variations in the pattern of certain responses that the authors attributed to cultural differences between the two populations.

Simon (1989) emphasized that when clinicians engage in nonsexual infringements of the treatment relationship, it is often a prelude to subsequent sexual behavior. Sexual involvement with patients often starts with excessive personal disclosure, accepting and giving gifts, requesting favors, and meeting patients outside of the office setting. Like a seduction, the behavior escalates over time until it culminates in sexual contact (Simon, 1989).

Regardless of the specific type of infringement involved, there are common elements to all boundary violations. Peterson (1992) argued that such activity emanated from a disturbed and disconnected relationship. She suggested four basic behavioral themes in this regard, including efforts on the part of the clinician to reverse roles with the patient, to intimidate the patient to maintain secrecy, to place the patient in a double bind, and to indulge professional privilege. Indulgence of privilege is often accompanied by a sense of entitlement on the clinician's part, such that he/she regards the patient as a wholly owned subsidiary.

**Table 5.5** Summary of Survey Results of Nonsexual Boundary Violations Among 532 Psychiatrists

Behavior	Percentage
Using touch (exclusive of handshake)	45
Treating relatives or friends	32
Personal relationships post termination	19
Personal disclosure	17
Colluding with patient against third party	17
Influencing patient for political causes	10
Using patient communication for financial gain	7

Epstein (1994, pp. 89–110) outlined the progression of boundary violations as they originate from dysregulation in the clinician's personal ego boundaries. Circumstances impairing the clinician's ability to cope with patients and their problems may include deficient knowledge, general stress, mental disorder, or a treatment-induced regression. These factors may lead the clinician to employ maladaptive intrapsychic or behavioral coping mechanisms that manifest in the form of therapeutic boundary violations. Other general factors common to all boundary violations include a slippage of the original purpose of the treatment (Epstein, 1994, pp. 97–98), pseudoelecticism (Epstein and Janowsky, 1969), a narcissistic sense of specialness (Epstein, 1994, pp. 107–110; Epstein and Simon, 1990), and efforts to deprofessionalize the relationship by fostering an atmosphere of "pseudoequality" between clinician and patient (Peterson, 1992).

The double-binding messages that exploitive clinicians employ often represent a way for them to project their own disavowed feelings of shame and inadequacy onto vulnerable patients. For example, a therapist may deceive a patient suffering from low self-esteem and sexual dysfunction by encouraging her to have sex with him. He may rationalize:

You have told me that you feel unattractive and inadequate as a woman. Since therapy is supposed to help you with your problems, I will help show you how attractive and effective you are as a woman by having sex with you.

Psychotherapy and erotic behavior can both be construed as subcategories of the superordinate class of "activities that help people feel better" (Epstein, 1994, p. 102). In the example cited above, the exploitive therapist blurs the logical boundaries between the two subcategories and fails to inform the patient that sexual behavior with him is likely to be harmful to her. Blurring of logical categories is an essential aspect of double-binding messages. Patients who are subjected to such reasoning are often in a dependent and cognitively regressed state and are unable to understand the logical absurdity of the double bind. They fear that if they refuse to comply with the therapist's suggestions, they will be rejected for failing to cooperate with the therapist.

It is important to place the burgeoning literature on boundary violations in its social context. An aroused public has been exposed to recurring reports of psychiatrists and other mental health professionals, who have been disciplined or sued for behavior such as sexual involvement with patients and spouses of patients; using information learned in patients' psychotherapy sessions to gain inside data on financial investments; and accepting large bequests from elderly patients. Each new scandal serves to erode society's trust in the integrity of psychiatry as a profession and makes it more difficult for the mentally ill to obtain needed treatment. Compounding this problem is the fact that some of these well-publicized reports of boundary violations involved highly trained psychiatrists who were leaders in their field and who served as important role models for students in professional training.

As has occurred many times before in history, societal changes tend to overshoot the mark, leading some observers to caution against an hysterical "witch hunt" against suspected offenders. Slovenko (1991) cautioned that the current climate has become ripe for an increasing number of false accusations to be made against innocent clinicians. Gutheil (1992) has documented such cases and provided guidelines for proper forensic psychiatric evaluation following allegations of sexual misconduct.

## Components of the Coherent Psychiatric Frame

The purpose of the therapeutic frame is to protect the patient's safety and to promote recovery. It is the therapist's responsibility to structure the frame through word and deed. Langa (1984–1985) stressed that a healthy and secure therapeutic environment is predicated on reducing variability and uncertainty in the treatment setting as much as possible. Table 5.6 summarizes the major boundary factors comprising the coherent treatment frame. Careful attention to these boundary issues can assist treating psychiatrists to communicate defining messages that strengthen the differentiation of role and identity between patient and practitioner.

The diversity of opinion regarding optimal methods of treatment for specific psychiatric disorders makes it very difficult to devise a set of specific guidelines that are appropriate for psychiatrists adhering to a wide spectrum of theoretical orientations. Dyer (1988, pp. 45–57) emphasized how problematic it is to define a comprehensive ethical system, whether it is based on a set of specific rules (deontological ethics), on a list of values and goals (teleological ethics), or from consideration of the emotional and practical consequences of a given course of action (consequentialist ethics). A parallel dilemma exists when it comes to defining psychiatric boundaries. For this reason, guidelines for psychiatrists should enhance patient safety, foster adherence to established clinical principles, and help to avoid specific consequences that are detrimental to either patient or practitioner. Such an approach is consistent with an intensifying interest in reducing preventable medical error. In his seminal work on human error, Reason (1990, p. 69) outlined three major types of performance as a way to address the sources of preventable human error. These categories include rule-based performance, skill-based performance and knowledge-based performance. As an example, Reason described how the use of inadvisable rules leads to rare but preventable collisions at sea, citing studies reporting how experienced maritime pilots expose themselves and others to unnecessary and potentially serious risk by allowing their own vessel to navigate too closely to adjacent ships even when there is plenty of sea room to avoid such proximity:

The confidences these and other experienced operators have in their ability to get themselves out of trouble can maintain inadvisable rule behavior. This is particularly so when a high value is attached to recovery skills and where the deliberate courting of a moderate degree of risk is seen as a necessary way of keeping these skills sharp.

With regard to rule-based procedures for reducing error in psychiatric practice, each boundary issue can be examined from the point of view of clearly **indicated** procedures, **relatively risky** procedures and **contraindicated** procedures (Epstein, 1994, pp. 113–117). In the ensuing discussion of components of the psychiatric frame, lists of these various types of procedures are adapted from Epstein's earlier work on boundaries (Epstein, 1994, pp. 119–236).

Riskier procedures that fall into the "gray zone" are not necessarily unethical or unsound. However, psychiatrists engaging in such activities should be aware of the circumstances under which they increase or reduce the chance for injury either to the patient or themselves. For example, under most conditions, it is probably unwise to attempt psychiatric treatment of one's next-door neighbor. Nevertheless, practitioners living in remote areas or working in confined ethnic communities might, as a matter of

**Table 5.6** Major Boundary Issues Contributing to the Formation of a Coherent Treatment Frame

Boundary Issue	Function and Purpose	Implicit Message to Patient
Stability	Consistency as to time, place, location, parties involved and treatment method	"The doctor is reliable. This treatment can contain my irrationality."
Avoiding dual relationships	Utmost fidelity to the primary purpose of helping the patient	"The doctor focuses his/her attention on my problem, and is not sidetracked."
Neutrality and promoting patient autonomy	Avoiding abuse of power and promoting the patient's independence	"The doctor values my ideas and encourages me to exercise choices."
Noncollusive compensation	Scrupulous and forthright terms of remuneration for the clinician	"Aside from the payment, I don't have to gratify the doctor."
Confidentiality	To protect the patient's privilege of keeping his/her communications secret	"My thoughts and feelings belong to me, not to the doctor."
Anonymity	Avoids seductiveness and role reversal	"This is a place to bring my issues, not a forum for the doctor's personal problems."
Abstinence	Encourages verbalization rather than action in dealing with feelings and conflicts	"There is a big difference between wishes and reality."
Preserving the clinician's safety and self-respect	Discourages the patient's destructive behavior, sets a good role model for establishing healthy self-esteem.	"It is possible to have a close relationship without someone getting hurt."

practicality, be forced to treat such a patient for whom no reasonable alternative exists. The hazard of no treatment may outweigh other factors in the situation. However, the fact that psychiatrists sometimes must treat patients under risky circumstances does not mean they should disregard the increased hazard they are

assuming or forget about optimal treatment standards, just as the exigencies of battlefield surgery do not obviate the need to strive for aseptic technique.

Psychiatrists should safeguard against any semblance of inappropriate behavior even if the activity can be justified as seemingly harmless. For example, seeking social activities with patients outside of the treatment setting can be interpreted by patients or their family members as seductive. Gutheil and Gabbard (1993) have emphasized that the very appearance of undue familiarity with a patient may, in and of itself, hamper successful defense against false allegations of professional wrongdoing.

## Stability

Configuring a stable and consistent treatment setting is analogous to the “holding environment” provided by parents in early childhood (Winnicott, 1960). Patients with psychiatric illnesses will find it very difficult to entrust their lives to a psychiatrist whom they perceive to be unreliable. Indicated measures regarding stability include formulating an agreement with the patient for a treatment regimen that will take place according to a specific method and schedule, encouraging truthful disclosure and cooperation; establishing a commitment to beginning and ending sessions on time, discouraging interruptions during treatment sessions; offering advance notice as to when the psychiatrist will be absent, providing for coverage by another practitioner when the psychiatrist is off duty, maintaining coherent therapeutic demeanor; and maintaining relative consistency as to who participates in the treatment situation.

It is generally unwise for a psychiatrist to disparage a patient’s complaints about issues like the doctor’s tardiness in starting sessions or to become defensive when explaining the meaning of the patient’s distress about such complaints. Many psychiatrists experience patients’ demands for consistency as a form of control and imprisonment. Out of anger, they may react to these patients as if their wishes for reliability and concern were infantile and irrational:

Your complaints about my lateness are a reflection of your need to control me.

The psychiatrist’s tardiness might in fact be creating tremendous anxiety because it reminds the patients of parents who never took their feelings into account.

## Avoiding Dual Relationships

Psychiatrists should avoid treatment situations that place them in a conflict between therapeutic responsibility to patients and third parties. Examples of dual relationships in psychiatric practice include clinicians treating their own relatives and friends, the same therapist employing concurrent family and individual therapy paradigms with a given patient, and clinicians testifying as forensic witnesses for current psychotherapy patients. Although it is a very common practice (Epstein *et al.*, 1992), accepting psychotherapy patients referred by one’s current or former patients embraces certain risks that must be considered (Pope and Vetter, 1992). For example, a current patient might refer an attractive friend for therapy as a way of either seducing the therapist or sabotaging the treatment (Langs, 1973).

Role conflicts are quite widespread (Pope and Vetter, 1992) and interfere with the practitioner’s single-mindedness of purpose as a healer. Chodoff (1993, pp. 457–459) placed special

emphasis on this issue by arguing that advocating for the needs of the mentally ill was one of psychiatry’s primary societal responsibilities. By eroding public trust, dual relationships interfere with the ability of psychiatrists to carry out their vital functions in the community.

The burgeoning expansion of prepaid care in the USA in the last two decades has provoked concern about a new source of role conflict for psychiatrists. Managed care has been espoused as an important modality to reduce unnecessary treatment by encouraging preventive care and promoting cost-consciousness among physicians (Fries *et al.*, 1993). Stephen Appelbaum (1992) argued that psychotherapists practicing under the old fee-for-service model were more inclined to provide unnecessarily prolonged treatment than those working under an organizational system that prevented direct monetary involvement between patient and practitioner.

On the other hand, increasing coverage of the population of the USA under a system of managed care has generated serious concerns regarding potential conflicts of interest (McKenzie, 1990). This disquietude is particularly noticeable in the field of psychiatry. Many managed care organizations (MCOs) have severely restricted the number of psychiatrists within a given community allowed to serve on their treatment panels. Patients’ access to their regular treating practitioner have been further limited, even when the doctor is allowed to enroll on the panel. For example, under the rules of some MCOs, a psychiatrist might be prevented from maintaining continuity of care for outpatients needing hospitalization. During their hospital stay, such patients must be attended by a preselected group of psychiatrists who conduct all hospital treatment for the plan.

Although there is little scientific data to support the contention that restricted managed care panels are necessary for lowering costs, it is important that both patients and clinicians be informed about the hazard such a system of care entails. Since participation on a panel is often contingent on cost-efficiency profiles, psychiatrists who derive a significant portion of their income from a given MCO are discouraged from advocating for patients needing more expensive care. In addition, some MCOs refuse to pay for integrated treatment for mentally ill patients by psychiatrists enrolled in their panel. Instead, these MCOs insist on a split treatment model in which the patient obtains psychotherapy from a social worker or psychologist and is allowed only brief medication management visits with a psychiatrist. Psychiatrists attempting to do medication management under this model often have little contact with the psychotherapist, are very restricted in the frequency and duration of visits with the patient, and are thereby limited in making overall clinical decisions that might become necessary. Such a situation creates an ethical bind for the psychiatrist in which the medical responsibility is not accompanied by a commensurate degree of authority to direct the treatment process.

In the face of reports of physicians claiming they were terminated from managed care contracts because they protested treatment denials, fear of retaliation for patient advocacy has mounted (McCormick, 1994). Judge Marvin Atlas (1993) has suggested that psychiatrists who fail to give informed consent regarding the risks to the patient of their role conflicts would be exposing themselves to civil damages in the event of an adverse outcome. Although the extent of the legal duty to disclose risk factors under managed care is unresolved, Paul Appelbaum (1993) proposed that mental health clinicians inform beginning patients that payment for treatment under managed care might be stopped before the patient feels ready to terminate.

Limitations as to who may serve on a managed care panel and what functions the clinician may perform are other factors that have strong potential for creating disruption in the continuity of care. For example, Westermeyer (1991) described seven case histories in which psychiatric patients treated under managed care committed suicide or suffered serious clinical deterioration. Clinically uninformed managed care practices appeared to serve as critical aggravating factors for each of these patients. In the cases of two individuals who killed themselves, the employer had switched contracts to different managed care companies and the patients were forced to transfer to new clinicians. These disruptions appeared to play an important role in the patients' suicides.

Although more research is required to evaluate the full ramifications of managed care on psychiatric populations, recent studies suggest that some groups face adverse outcomes under this system. For example, Rogers and colleagues (1993) found that, on average, patients with depression who were treated by psychiatrists under prepaid treatment plans acquired new limitations in their physical or day-to-day functioning over a 2-year period, whereas those treated in the traditional fee-for-service setting did not.

### Autonomy and Neutrality

Freud (1912, 1913) recommended that psychoanalysts adhere to a position of neutrality with their patients by refraining from the temptation to take sides in the patient's internal conflicts or life problems. This advice has relevance for all psychiatric treatment, insofar as it espouses the idea that practitioners should maintain profound respect for their patients' autonomy and individuality. This is a fundamental therapeutic stance that fosters independence, growth and self-esteem. It reinforces the idea that the clinician believes the patient to be the owner of his/her body, life and problems. The patient receives the following message:

The doctor tries to help by assisting me to learn about myself, not by trying to take control of me.

Patient autonomy has not always been accorded its current importance in the hierarchy of priorities in medical practice in the USA. According to Blackhall and colleagues (1995), in 1961, 90% of physicians in the USA did not inform their patients of a diagnosis of cancer. By 1979, 97% of American physicians made it their policy to inform patients with cancer of their diagnosis (Blackhall *et al.* 1995). This change appears to be the result of physicians assuming less of a paternalistic attitude and becoming more enlightened and respectful of patients' right to participate in medical decisions. In some parts of the world, similar changes have occurred in clinical practice with mentally ill patients.

Cultural, ethnic and probably sociodemographic factors strongly shape attitudes regarding patient autonomy and informed consent. In some cultures, a higher value may be placed on the harmonious functioning in the interlocking pattern of family relationships than on the autonomy of individual family members. For example, according to Okasha (2000), patients reared in some cultures may not wish to continue treatment with a physician who is not sensitive to the importance of involving the family directly in communications about the patient's illness. The psychiatrist should diligently explore the role that cultural and family relationships play in the patient's healthy mental functioning and be guided primarily by the patient's communications about their degree of comfort or conflict with these family relationships. Psychiatrists should be considerate and respectful

of cultural differences between themselves and their patients and be particularly cautious about interpreting those differences as a pathological process.

Mindful of cultural issues, indicated ways of encouraging autonomy include encouraging informed consent by outlining the potential benefits, risks and alternatives for a proposed treatment approach; explaining the rationale for the treatment; and fostering the patient's participation in the treatment process. Paradoxically, acutely suicidal patients often require the psychiatrist to assume temporary responsibility for their safety. In most cases this serves to augment the patient's sense of autonomy through a coherent modeling process (Bratter, 1975), because true independence is impossible without self-governance.

Clinical actions that may interfere with the patient's autonomy include advice regarding nonurgent, major life decisions, attempting to exert undue influence on issues unrelated to the patient's health, reluctance to allow patients to terminate treatment, seeking gratification by exerting power over patients, and using power over patients as a form of retaliation.

### Coherent and Noncollusive Compensation

Although there are rewards to be obtained from working in an interesting and creative profession, this is best applied to one's collective professional endeavors. With a specific patient, monetary compensation is the only gratification psychiatrists should realistically expect (Epstein and Simon, 1990). When compensation is direct, there should be a set fee, and the patient should be responsible for the scheduled appointment time. When compensation is indirect or salaried, the psychiatrist must avoid colluding either with the patient against the party paying for the treatment or with the third party against the patient (see the previous section on avoiding dual relationships). Whatever method is being used for paying for mental health treatment, a coherent and noncollusive arrangement imparts the message to the patient:

The doctor has needs of his/her own, but they are limited to a salary or fee. Aside from financial obligations, I don't have to please, gratify, or nurture my doctor.

The practice of charging for missed appointments under the traditional fee-for-service paradigm is often misunderstood by patients because their experience with physicians in other branches of medicine has usually been that they were charged on a fee-for-procedure, rather than fee-for-time, basis. Charging for missed appointments is justifiable from an ethical standpoint as long as the rationale is clearly explained to the patient at the beginning of treatment and the patient agrees to it. In addition, no attempt should be made to hide the fact of billing for missed appointments from third-party payers. Some states have an absolute prohibition against billing for missed appointments under entitlement programs such as Medicaid and Medicare (Epstein, 1994, p. 169). Within certain guidelines, it is permissible to bill the patient (but not Medicare) for missed appointments under the Medicare program (Epstein, 1994, pp. 169–170). Readers are cautioned that regulations regarding Medicaid and Medicare are subject to periodic legislative revisions and may vary according to jurisdiction.

Generally risky compensation arrangements include working for a treatment organization one perceives to be financially exploitive, accepting inexpensive gifts from patients especially when such gifts are not part of a culturally expected mode of behavior, bartering goods or services in return for treatment,

referring patients for treatments or procedures in which one has a proprietary financial interest, and neglecting the patient's failure to adhere to the original agreement regarding payment of fees. Certain practices are absolutely contraindicated and likely to be destructive, including fraudulent billing, accepting expensive gifts, fee splitting, colluding with the patient or third party, and use of financial insider information.

## Confidentiality

It is essential that psychiatrists treat their patients' communications as privileged. This means that patients alone retain the right to reveal information about themselves. The advent of managed care has raised even greater concern about the privacy of patients' personal communications with their psychiatrists because of the potential for an increasing number of persons connected with the MCO to have access to material from patients' files. Psychiatrists should caution their patient about the potential limitations to confidentiality and be prepared to explore the consequences of these exceptions. For example, if a patient is raising his/her mental health as an issue in litigation, some or all communications to a psychiatrist could be legally discoverable. Coherent boundaries with regard to confidentiality send the message to the patient:

My thoughts and feelings belong to me. The doctor does not treat them as if they belong to him/her.

Indicated means of preserving confidentiality include obtaining proper authorization from patients before releasing information, explaining the need for confidentiality with parents of children and adolescents, and involving all participants in family and group psychotherapy in agreements about confidentiality. Problematic activities that may endanger confidentiality include stray communications with concerned relatives of patients in individual psychotherapy, where there is no prior expectation on the patient's part about discussions with relatives; discussion of privileged information with the psychiatrist's own family members; releasing information about deceased patients; and failure to properly disguise case presentations.

## Anonymity

Many psychiatrists associate the principle of relative anonymity with Freud's advice to psychoanalysts (Freud, 1912):

The doctor should be opaque to his patients and, like a mirror, should show them nothing but what is shown to him.

Freud argued that it was dangerous for psychoanalysts to expose their own mental problems or intimate life details in a spurious attempt to place themselves on an "equal footing" with patients (Freud, 1912, pp. 117–118). The merit of this recommendation extends beyond its origin in psychoanalytic technique to a fundamental boundary issue applicable to all forms of psychiatric treatment. It serves as a reminder to both patient and clinician of the professional purpose of the relationship. Avoiding unnecessary personal disclosure to patients protects both patient and practitioner from a reversal of roles – one of the critical themes recurring in boundary violations in general (Peterson, 1992). Many patients experience excessive self-disclosure by the psychiatrist as seductive and it has been frequently observed to be a precursor to subsequent sexual involvement (Schoener and Gonsiorek, 1990, p. 403). By maintaining a policy of relative anonymity, the patient receives the following message about the treatment:

This is a place where I can bring my issues. The doctor doesn't burden me with his/her stuff.

Certain forms of self-disclosure are indicated in the course of work with psychiatric patients, including appraising patients of the clinician's qualifications and treatment methods as part of informed consent, discussing reality factors about the psychiatrist's health status or intentions regarding retirement that will impact on the patient's treatment decisions, and using "reality checks" to help patients contain disturbed and frightening fantasies.

## Abstinence

Abstinence means that psychiatrists should discourage direct forms of pleasure such as touching or sexuality in the course of their interactions with patients. In the therapeutic relationship, the patient's ability to consent to sexual activity with the psychiatrist is vitiated by the knowledge the latter possesses over the patient and by the power differential that vests the psychiatrist with special authority.

For patients, actual gratification from the psychiatrist is best confined to realistic goals for recovery and emotional growth. Psychiatrists should limit themselves to the pleasure of getting paid for a job well done and for the opportunity to participate in an interesting and creative profession. Although steadfast application of this boundary can be quite frustrating for both doctor and patient, it pays excellent dividends in the long run by encouraging autonomy and a more mature way of dealing with impulses. The rule of abstinence as a therapeutic boundary has an analogous function to the incest taboo as a social organizer. In all known human cultures, the incest taboo has survival value because, during childhood development, it serves to strengthen the sense of individuality and personal boundaries so necessary for growth, independence and social responsibility (Parker, 1976).

From a practical standpoint, psychiatrists can strengthen their patients' boundaries in this regard by resisting behaviors such as physical touching, accepting gifts, socialization outside treatment and sexual involvement. The patient receives the following messages from a clinician who is able properly to adhere to this principle:

The doctor is more interested in my health than his/her own gratification and doesn't try to take possession of me. I am learning that I can have wishes that needn't result in action.

There are occasions when psychiatrists are obligated to employ physical procedures such as taking blood pressures, checking for extrapyramidal symptoms, restraining dangerous patients, or administering electroconvulsive therapy. Indeed, clinical touching of patients is considered an integral part of the physician–patient relationship because of its important role in physical examination and therapeutic procedures. Even though psychiatrists are physicians, they are obligated to use much more restraint in this regard than is expected of colleagues in other branches of medicine. It is probably too invasive for the same physician, on a protracted basis, simultaneously to intrude both into the patient's psychological and physical spaces.

Other risky forms of gratification include embracing or kissing patients, eating and drinking with patients, socializing with patients outside of the therapy setting, and failure to understand and resolve recurrent or obsessive sexual fantasies about a patient. Engaging in sexual behavior with current or former patients is contraindicated because it is almost invariably destructive, even though the damage may not be immediately manifest.

The APA (American Psychiatric Association, 1993) took a principled and unequivocal stand regarding sexual activity between psychiatrists and their current or former patients:

Additionally, the inherent inequality in the doctor–patient relationship may lead to exploitation of the patient. Sexual activity with a current or former patient is unethical.

The APA's position is in agreement with the principles espoused in the Hippocratic Oath, which clearly mandates that a physician approach a patient “for the benefit of the sick, and... abstain from every voluntary act of mischief and corruption; and, further, from the seduction of females or males, of freemen and slaves”.

Despite the ancient basis of this proscription and convincing evidence in our times of the damaging effects of sexual relationships between therapists and former patients (Epstein, 1994, pp. 218–220; Luepker, 1990; Brown *et al.*, 1992), some authors have raised legal and theoretical challenges to the permanent prohibition contained in the APA guidelines (Appelbaum and Jorgenson, 1991). While refraining from calling for a repeal of APA's ethical proscription against sex with former patients, Malmquist and Notman (2001) argued that legal misapplications of imprecise and unproven concepts of transference and countertransference have exposed therapists who enter post termination sexual liaisons with their patients to inappropriate legal liability.

Research examining the causation and prevention of human error have provided neurocognitive evidence supporting the ancient wisdom of Hippocrates' injunction. Skilled performance is subject to potentially calamitous error when experts fail to follow empirically derived safety guidelines or lack an adequate knowledge base upon which to initiate critical interventions (Reason, 1990, pp. 76, 84, 86, 146–147). Skillful performance in conducting medical procedures are acquired from overlearned behavior that enables an expert to undertake complex cognitive and behavioral operations in a smooth and rapid fashion. Performance skills in which success depends on overlearned and automatic processes rely primarily on the procedural memory system (Cabeza and Nyberg, 2000). The Hippocratic mandate of approaching the patient solely for their benefit and to avoid mischief is a prime example of an overlearned, automatically embedded, error protection message acquired through years of medical training. Anything that interferes with such an intensively elaborated internal safeguard endangers patients' well-being.

Whether they realize it or not, psychiatrists who justify the permissibility of post termination sexual relationships are sabotaging their own overlearned commitment to act primarily in their patient's best interest and are exposing their patient to a biased and error prone treatment. This self-permissive attitude would make a psychiatrist more prone to engage in seductive grooming of a patient during the treatment process in anticipation of termination. In addition, biased by this attitude, a psychiatrist is likely to avoid making any communication to the patient that would discourage a subsequent romantic post termination liaison (Epstein, 2002). While a psychiatrist might consciously deny that this attitude is a violation of the Hippocratic dictum, in actual cases where psychiatrists have engaged in post termination sex with patients, their pretermination subliminal thinking ran like this:

I'm treating this patient only for her/(his) benefit. Like Hippocrates, I will abstain from every voluntary act of mischief and corruption and, further, from seduction. However, after I cure this very attractive patient, I will keep his/(her) phone

number, and after a respectable period of time, it will be a different matter, and we will see what will happen.

Note that this reasoning represents a form of dissociative thinking based on a primitive wish for inappropriate gratification with a patient that magically disavows the connection between post treatment behavior and pretreatment reality. All psychiatric treatment is based on the assumption that a psychiatrist's interventions by means of positive attitudes, words, deeds and medical interventions will have a lasting beneficial effect on the patient after the treatment has ended. There is no realistic escape from the fact that the reverse is also true, namely, that inappropriate attitudes, words, deeds and interventions are likely to have a lasting harmful effect on the patient after the treatment has ended.

### Self-respect and Self-protection

It is essential that psychiatrists protect themselves from being exploited by patients. This principle is necessary to protect clinicians and patients alike. Many patients seeking treatment have endured abusive relationships in which being victimized became the price for maintaining human connectedness. For such patients, efforts to exploit the psychiatrist may be an action-question that inquires:

Must one of us be injured in order for us to have a close relationship?

By setting a proper role model for self-respect and self-caretaking, the psychiatrist imparts the following message to the patient:

Relationships need not be structured on the basis that one or both parties must be exploited. If I as the doctor allow you to hurt me, I am setting a poor role model.

Psychiatrists should attempt to discuss the meaning of any exploitive behavior on the patient's part as soon as possible. With unstable or impulsive patients who are prone to acting out, confrontation should be timed to maximize safety. For example, it would be more prudent to interpret the manipulative aspects of a patient's suicidal behavior after the patient is admitted to a hospital. If a patient makes a sudden physical overture such as attempting a sexually provocative embrace, it must be dealt with the same urgency as a physical assault. The psychiatrist should inform the patient that such behavior is inconsistent with coherent treatment (Epstein, 1994; Shor and Sanville, 1974, pp. 228–231; 58). It is generally risky to allow repeated exceptions such as last-minute prolongation of sessions, repeated lateness in paying fees, excessive intrusion into the psychiatrist's personal space in the form of regular and frequent late night phone calls, or taking items from the office.

Certain psychiatrists find themselves avoiding confrontation with an exploitive patient out of fear of the latter's narcissistic rage. This is an indication of an escalating situation that may lead to further boundary violations either by the patient or the psychiatrist. A useful explanation of this behavior is provided in Gabbard's (1994) description of a subgroup of clinicians who become sexually involved with patients as part of a self-defeating pattern of behavior he termed “masochistic surrender”. These practitioners are unable to defend against being tormented by certain highly demanding patients. They succumb to the patient's importunings, sometimes while in a dissociated state, even though they may know their behavior is wrong. Gabbard (1994) argued that the aberrant behavior of these clinicians is rooted in an impaired ability to cope with their own aggressive feelings, resulting in their feeling that it would be sadistic to set limits on the patient.

**Table 5.7** Indicators of Potential Boundary Violations with Suggested Remedial Responses

Indicator	Suggested Remedial Response for Clinician
Clinician is frequently tardy starting sessions	Avoid criticizing patient for complaining about lateness. Reexamine reasons for tardiness in light of patients' need for a stable treatment frame.
Clinician changes the treatment paradigm in "midstream", i.e., switching from individual therapy with Mr A to couples therapy with Mr A and his wife.	Avoid dual relationships that may interfere with primary loyalty to the first patient. If dual relationships cannot be avoided, explain risks to patient(s) according to principle of informed consent.
Clinician frequently advises patients on matters not related to treatment process.	Consider if this is a general pattern of need for control in one's nonclinical relationships. If so, consider ways to help patient to make his/her own decisions.
Clinician often relates to patient as if he/she were a personal friend.	Listen for signs that the patient feels burdened. Acknowledge pattern of role reversal and importance of clinician's fiduciary obligations to patient.
Clinician accepts gifts from patient.	Try to explore patient's motive for the gift. Consider refusing the gift by explaining that it might interfere with the effectiveness of treatment. Be prepared to work with patient's shame in this regard.
Clinician feels overly resentful about having to keep boundaries because they feel too constraining and spoil the "fun" and creativity of being a therapist.	Remember that therapy is hard work that is often burdensome and frustrating, and that boundaries are necessary for the patient's safety.
Clinician seeks contact with patient outside therapy setting.	Avoid contact, and explain the reason to patients. In settings where social contact is likely, discuss problems and options with the patient in advance.
Clinician is unable to confront patients who are late paying fees, remove items from the office, repeatedly try to prolong sessions, or torment therapist with insatiable demands.	Listen to the content of patient's communications and dreams regarding people injuring one another. Explore fear of one's own anger, the patient's anger, or of setting limits.
Clinician often tries to impress patients with personal information about himself/herself.	Refrain from further disclosure and examine one's possible motives. Consider how such activity might relate to sexual feelings to patient or need to control patient.
Clinician becomes sexually preoccupied with patient, for example, feels a pleasurable sense of excitement or longing when thinking of patient or anticipating his/her visit.	Consider that one's sexual feelings may portend the reenactment of an actual or symbolic incestuous scenario from the patient's past. Remember that incestuous behavior or its symbolic equivalent infantilizes the victim. Obtain supervision and/or personal psychotherapy if sexual preoccupations continue unabated.

## Summary

The ethical and boundary issues discussed in this chapter were designed to stimulate a better understanding of an extremely thorny topic rather than to provide an exhaustive compendium. Table 5.7 summarizes selected indicators of potential boundary violations, along with remedial responses clinicians might employ to deal with these situations. A burgeoning literature regarding the psychological characteristics of clinicians who have problems with maintaining proper boundaries (Epstein, 1994; Gutheil and Gabbard, 1993; Epstein and Simon, 1990; Schoener and Gonsiorek, 1990; Gabbard, 1994; Twemlow and Gabbard, 1989; Gabbard, 1991; Geis *et al.*, 1985) provides useful guidance in this regard.

The difficulties psychiatrists may encounter in keeping boundaries derive from many sources. In the past, professional training programs have not addressed this issue systematically.

Recent proposals to bolster the study of ethics and boundaries in medical school and residency programs (Roman and Kay, 1997; Kay and Roman, 1999) will help to remediate this problem. It behooves psychiatrists to determine whether they have suffered deficiencies in training or adverse role modeling during the course of their professional development and whether their own emotional problems significantly interfere with maintaining coherent professional boundaries.

## Introduction

Psychiatrists' efforts to be helpful to their patients are driven by the desire to act in the "right" or ethical way. They also work within the context of the legal system which will often impact the way in which they provide care. While psychiatrists do not need to become experts in the practice of law or in the study of ethics, they should have an appreciation of how clinical work intersects with the law and the ethical foundations upon which their own decisions are made.

This chapter will begin by surveying the principles underlying the legal system, highlighting some of the landmark cases that impact our work as psychiatrists, and illustrating common clinical sources of interest and relevance to clinical practice. The chapter will conclude by reviewing the sources of psychiatric ethics, outlining the consensus principles of psychiatric ethics, and illustrating some important clinical areas which generate issues of ethical concern.

## Overview of Legal Principles

The development of legal principles is the result of the interplay of legislatures that enact laws, executive branches that enforce them and courts that interpret them. The first level of courts are trial courts, where cases are tried and decided. Appeals courts generally hear arguments by parties who feel that lower courts have made errors of law which require reversal of the lower court decision. The federal and most state court systems have two levels of appeals courts (an Appeals Court and a Supreme Court, although terminology varies among jurisdictions). The highest court in the land is the US Supreme Court, which is the final arbiter of questions of Federal and Constitutional Law.

Cases decided in state courts set the law only for the state in which the case is decided. Although state decisions may ultimately influence one another, no state is required to abide by the precedent of a different state's courts. For instance, the Tarasoff case discussed below set standards in California for a mental health professional's duty to protect a third party from the danger posed by a client. Although that case only applied to practice in California, it has had a great influence on legal and clinical practice in other states. Similarly, federal Appeals Courts set precedent only for the Circuits in which they sit. Only when the US Supreme Court has ruled on a matter of law are all other state and federal courts required to follow the precedent.

Each state also has a constitution that may be more protective of individuals' rights or more limiting of the states' power than the federal constitution. State courts can make decisions interpreting their own constitutions or the federal constitution. While federal

Appeals Courts and ultimately the US Supreme Court can overrule a state court's interpretation of the federal constitution, the state supreme court has the final word on the state's constitution, so long as the state constitution does not violate the federal constitution. (For instance, a state constitution may provide greater protection against police searches than the federal constitution, but not less.)

The specific legal rights and principles with which we will concern ourselves are found in the amendments to the US Constitution. Of particular interest to psychiatry are the following constitutional amendments: the First Amendment, which embodies the right to freedom of speech and religion; the Third and Fourth Amendments, which have been interpreted as implying a right to privacy; the Fifth Amendment, which grants the right to remain silent in a criminal case; the Sixth Amendment, which discusses the rights of defendants to fair and speedy trials; the Eighth Amendment, which proscribes cruel and unusual punishment; and the Fourteenth Amendment, which embodies the "due process" and "equal protection of the law" clauses (Table 6.1).

## Rights and Responsibilities

### Right to Treatment

Although the US Supreme Court has expounded no national, constitutionally based right to treatment, there has been a substantial amount of activity in this area since Birnbaum published "The Right to Treatment" in 1960. At the time the article was published, it was common for psychiatric patients to spend decades in hospitals, at times involuntarily, while receiving little treatment or only custodial care. The article attempted to upgrade the quality of care in hospitals by creating a hospitalization-treatment quid pro quo. Birnbaum (1965) later criticized state hospital conditions, declaring that "Personally, I should like to state that as a doctor I often find it repugnant to use the term 'patient' to describe persons in certain mental hospitals". He instead argued that "inmate" was a better term if no treatment were given. Birnbaum's landmark articles generated interest in this key area of mental health policy.

Birnbaum's quid pro quo rationale was endorsed in *Rouse v. Cameron* (1966) decided by Judge Bazelon of the District of Columbia Circuit Court. Rouse was found not guilty by reason of insanity on a misdemeanor charge and was thereafter civilly committed to St Elizabeth's Hospital. He petitioned for his release based on the argument that he was not receiving treatment. Judge Bazelon ruled that hospitals must make real efforts to improve patients' conditions and that lack of resources was not an adequate defense. In his decision he wrote, "The hospital need not show that the treatment will cure or improve him but only that there is a bona fide effort to do so".

**Table 6.1 US Constitutional Amendments Relevant to the Practice of Psychiatry**

<b>First Amendment</b>
Congress shall make no law respecting an establishment of religion, or prohibiting the free exercise thereof; or abridging the freedom of speech, or of the press; or the right of the people to peaceable assemble, and to petition the Government for a redress of Grievances.
<b>Fourth Amendment</b>
The right of the people to be secure in their persons, houses, papers and effects. Against unreasonable searches and seizures, shall not be violated, and no Warrants shall issue, but upon probable cause, supported by Oath or affirmation, and particularly describing the place to be searched, and the persons or things to be seized.
<b>Fifth Amendment</b>
No person shall be held to answer for a capital, or otherwise infamous crime, unless on a presentment or indictment of a Grand Jury. Except in cases arising in the land or naval forces, or in the Militia, when in actual service in time of War or public danger; nor shall any person be subject for the same offence to be twice put in jeopardy of life or limb; nor shall be compelled in any criminal case to be a witness against himself, nor be deprived of life, liberty, or property, without due process of law; nor shall private property be taken for public use, without just compensation.
<b>Sixth Amendment</b>
In all criminal prosecutions, the accused shall enjoy the right to a speedy and public trial, by an impartial jury of the State and district wherein the crime shall have been committed, which district shall have been previously ascertained by law, and to be informed of the nature and cause of the accusation; to be confronted with the witnesses against him: to have compulsory process for obtaining witnesses in his favor, and to have the Assistance of Counsel for his defense.
<b>Eighth Amendment</b>
Excessive bail shall not be required, nor excessive fines imposed, nor cruel and unusual punishments inflicted.
<b>Fourteenth Amendment</b>
Section 1. All persons born or naturalized in the United States, and subject to the jurisdiction thereof, are citizens of the United States and of the State wherein they reside. No State shall make or enforce any law which shall abridge the privileges or immunities of citizens of the United States, or shall any state deprive any person of life, liberty, or property, without due process of law; nor deny to any person within its jurisdiction the equal protection of the laws.

The case of *Wyatt v. Stickney* (1972), a class action suit against an Alabama hospital with poor conditions for patients, led to definitions of humane environment, which have been incorporated into a patient's bill of rights in many states. Chief Judge Johnson wrote for the US District Court, "[Involuntarily committed patients] unquestionably have a constitutional right to receive such individual treatment as will give each of them a realistic opportunity to be cured or to improve his or her mental condition". Although this case was not heard by the US Supreme Court, it did have far-reaching social consequences for institutions in that it prompted scrutiny of the services they provide.

It was not until 1982, in the case of *Youngberg v. Romeo* (1982), that the Court held that a person who is involuntarily confined has a right to "minimally adequate training". Romeo was a profoundly retarded man who suffered injuries "on at least 63 occasions ... by his own violence and by the reactions of other residents to him" while he was an inpatient at Pennhurst State Hospital in Pennsylvania. His mother sued, arguing that Romeo's Eighth and Fourteenth Amendment rights were being violated. The US Supreme Court agreed that Romeo had "constitutionally protected liberty interests under the Due Process Clause of the Fourteenth Amendment to reasonably safe conditions of confinement, freedom from unreasonable bodily restraints, and such minimally adequate training as reasonably may be required by these interests". "Minimally adequate training" required the exercise of professional judgment, which was held to be presumptively valid and to which "courts must show deference".

Most of the right to treatment cases attacked institutional standards of care, and were based on efforts to expand the scope of constitutional rights of inpatients. As will be seen below, current litigation seeking to establish rights to treatment in the community focuses largely on the statutory rights afforded by such anti-discrimination statutes as the Americans with Disabilities Act (ADA).

### Right to Refuse Treatment

Patients with little or no insight into the nature of their psychiatric illness often refuse treatment. A compelling set of ethical and legal questions arises when a person's stated choice (not to receive treatment) appears to conflict with medical prediction that the person's insight and mental status would probably improve with treatment. In the past, a general assumption that mentally ill patients were, by definition, incompetent, led society to grant psychiatrists a great deal of autonomy in selecting and administering treatments to patients. With the consumer activism of the 1960s and 1970s and the accompanying development of patients' rights, however, psychiatrists and legal authorities have come to see that involuntarily committed patients are not always globally incompetent, and efforts to support patients' rights to refuse treatment have increased.

Although the US Supreme Court has not declared a federal right to refuse treatment, federal Appeals Courts and most state courts have found such rights in the federal or state constitutions, citing the due process clause of the Fourteenth

Amendment, within the right to privacy, bodily integrity, or personal security.

Appelbaum (1988) has described two broad models of treatment refusal. The “rights-driven” model seeks to maximize patient autonomy. It is based on the principle that competent adults have the right to reject treatment, even if the rejection of such treatment may result in harm or even death. States that adopt this model focus on the patient’s competence to make the decision and often have considerable judicial procedures protecting patients. The laws of these states typically remove decision-making power from the psychiatrist and vest it in a guardian or the court. In these states the guardian or court decides what the patient would want if he or she were competent (the “substituted judgment” standard). The substituted judgment doctrine requires a challenging decision: it means that the judicial decision-maker must decide, based not on his or her own values and interests, or even on what may objectively be in the patient’s best interests, but instead on what the patient would decide if he or she were competent.

The “treatment-driven” model tends to view treatment as an essential element of commitment to a hospital. States with this model tend to give psychiatrists more autonomy in making decisions for patients. Procedural review is done primarily by psychiatrists and is usually focused on whether the treatment is appropriate to the patients’ conditions. A series of cases emanating from Massachusetts is emblematic of the rights-driven model. In the matter of *Guardianship of Richard Roe III* (1981), the court noted on involuntary psychiatric medication for psychiatric outpatients, stating, “If an incompetent individual refuses antipsychotic drugs, those charged with his protection must seek judicial determination of substituted judgment”.

A later Massachusetts case, *Rogers v. Commissioner of Mental Health* (1983), applied this rationale to involuntary inpatients. Incompetent patients at Boston State Hospital were being given antipsychotic medication without the opportunity to give informed consent. The Rogers case upholds the right of committed mentally ill patients to make treatment decisions unless they have been adjudicated incompetent by a court. The Rogers court also affirmed the holding that treatment with antipsychotic medication constituted extraordinary treatment, and that authority to administer such medication to an incompetent individual required the exercise of the individual’s substituted judgment. The court outlined six factors that a judge must assess when determining whether a patient should be permitted to refuse treatment: 1) the patient’s previously expressed preference; 2) the patient’s religious convictions; 3) the impact on family of the patient’s preference; 4) probable side effects; 5) prognosis with treatment; and 6) prognosis without treatment. Several cases illustrate the treatment-driven model. *Rennie v. Klein* (1983), decided in the Third Circuit of the US Court of Appeals, held that New Jersey’s procedures for reviewing the administration of antipsychotics to an unwilling patient were consistent with due process: the “decision to administer such drugs against a patient’s will must be based on accepted professional judgment”. Rather than have the courts superimpose procedural safeguards, treatment-driven model cases defer to medical judgment. The Rennie decision relied on the US Supreme Court’s deference to professional judgment in *Youngberg v. Romeo* (1982).

## Liberty and Civil Commitment

Although it is generally agreed that patients have a right to be treated in the least restrictive setting, there are times when a person’s mental illness is such that he or she must be hospitalized

involuntarily. Each state has different provisions for short-term emergency commitment. Many states have removed this process from the judicial setting; some states, however, require a probable cause hearing before even an emergency commitment. The purpose of such a hearing is to determine whether there is probable cause to believe that the person meets the legal criteria for involuntary hospitalization. If the patient is hospitalized after such a hearing, it is generally for a short period of time for evaluation; if it is determined that the patient needs longer involuntary hospitalization, then the statutory procedures for long-term commitment must be followed.

In the case of *O’Connor v. Donaldson* (1975), the US Supreme Court set a minimum below which states cannot set their standards for civil commitment. The Court wrote: “The state cannot constitutionally confine without more, a nondangerous, mentally ill person who is capable of surviving safely by himself or with the help of family or friends”. While the Court did not state what it meant by “more”, most states now require a finding of dangerousness in addition to mental illness.

In *Addington v. Texas* (1979), the US Supreme Court recognized the substantial liberty interest involved in a commitment, and set the minimum standard of proof for commitment cases as “clear and convincing”. The court ruled: “The individual’s liberty interest in the outcome of a civil commitment proceeding is of such weight and gravity, compared with the state’s interests in providing care to its citizens who are unable, because of emotional disorders, to care for themselves... that due process requires the State to justify commitment by proof more substantial than mere preponderance of the evidence.... The reasonable-doubt standard is inappropriate in civil commitment proceedings because, given the uncertainty of psychiatric diagnosis, it may impose a burden the state cannot meet and thereby erect an unreasonable barrier to needed medical treatment”. (A few states do interpret their own constitutions to require proof beyond a reasonable doubt.)

The standards for long-term commitment vary from state to state, but they all rely on two broad principles of state power. One is the *parens patriae* power; the other, the police power. *Parens patriae*, translated from Latin as “father of the country”, historically referred to the sovereign’s power to make decisions for the subjects. A more contemporary translation is “state as parent”, which refers to the government’s interest in, and responsibility to act for, individuals who are unable to care for themselves. *Parens patriae* is used as a rationale for commitment when a person is unable to care for herself or himself as a result of a mental illness or when he or she poses a danger to self. The police power stems from the state’s interest in maintaining public safety. The commitment criterion of “dangerousness to others” is derived from the police power. Over time, the trend in legislation and in court action has been more toward the dangerousness standard and less toward disability. Under all current statutes, a finding of mental illness is a prerequisite to commitment Table 6.2.

The notion of dangerousness to others or to self is a problematical one for psychiatrists, given that prediction of harm is an inexact science. Complicating the picture is the fact that states also require different levels of proof that people are dangerous to themselves. Some states require imminent harm, while others are more tolerant of general predictions of future dangerousness based on a patient’s pattern of treatment noncompliance and decompensation.

Finally, many states require a finding that hospitalization is the least restrictive method to prevent the harm the patient

**Table 6.2 Principles Underlying Involuntary Commitment**

Parens Patriae	<ul style="list-style-type: none"> <li>• State as parent: acts for those who cannot</li> <li>• “Unable to care for self” and “danger to self” criteria</li> </ul>
Police Power	<ul style="list-style-type: none"> <li>• State as protector: acts to preserve public safety</li> <li>• “Danger to others” criterion</li> </ul>

faces. In *Lake v. Cameron* (1966), the District of Columbia Court of Appeals held that a 60-year-old demented homeless woman could not be involuntarily hospitalized if there were other alternatives. This case is most famous for the concept of “least restrictive alternative”, as it focused on the place of confinement as well as the fact of confinement.

The issues underlying the threshold for commitment are fundamentally social, not psychiatric. They entail a balancing of rights and liberty interests with needs for treatment and safety. This balance has historically shifted with changes in the political and social climate, and continues to be a source of debate in both the legal and mental health fields.

In 1985, the APA developed a Model Law for Commitment, which generated considerable debate in the profession: “[I]t was conceived in response to the... ‘libertarian model,’ which many mental health professionals and growing numbers of families believed was unworkable, unrealistic and inhumane” (Stone, 1985). Stone added that “the liberty of psychotic persons to sleep in the streets of America is hardly a cherished freedom” and advocated for greater discretion for psychiatric commitment as well as greater resources for treatment once the patient is hospitalized.

## Outpatient Commitment

Progress in the treatment of severe and chronic mental illness often depends upon the patient’s compliance with medication and other treatment regimens in the community. This has been a source of challenge and frustration for psychiatrists who treat such patients. In recent years there has been a growth of interest in the possibility that outpatient commitment may offer a way to ensure that those who most need treatment will in fact receive it. In principle, an outpatient commitment law allows the same sort of treatment options as already exist with inpatient commitment: a patient may be deprived of liberty and, if found to be incompetent to make medication decisions, may be made to take medication against his will. While inpatient commitment is justified when a patient represents a danger or cannot care for himself, how does one justify coercing a patient who may be stable, relatively symptom-free and functioning in the community?

Here the legal debate splits into two camps. Those in favor of outpatient commitment make several arguments: 1) the treatments are safe and effective; 2) untreated mental illness may increase the likelihood of violence, homelessness, incarceration and suicide; and, more controversially, 3) patients with severe mental illness frequently lack awareness of their condition, and are therefore not really free when ill (Torrey and Zdanowicz, 2001). Those opposing outpatient commitment counter that: 1) better funded and staffed outpatient programs would provide the kind of outreach which would make coercion unnecessary; 2) the prospect of coercion may actually drive certain patients away

from help; 3) public safety would not be enhanced by outpatient commitment; and 4) even the most ill patient is, in the eyes of the law, still competent to refuse treatment (Allen and Smith, 2001).

At least 41 states permit some form of outpatient commitment, yet the first two randomized trials examining its use (Steadman *et al.*, 2001; Swartz *et al.*, 2001) provided equivocal evidence of efficacy (Appelbaum, 2001). The actual mechanics of apprehending a nondangerous person, taking him/her to some facility, and injecting him/her involuntarily with medication, all because he/she had not followed through on a treatment plan, has proven difficult both to implement and to tolerate in a society which still places great value on maintaining its citizens’ liberty interests. The debate will continue as psychiatrists try to reduce the aggregate suffering imposed on individuals and society by the effects of untreated mental illness.

## Confidentiality and Privilege

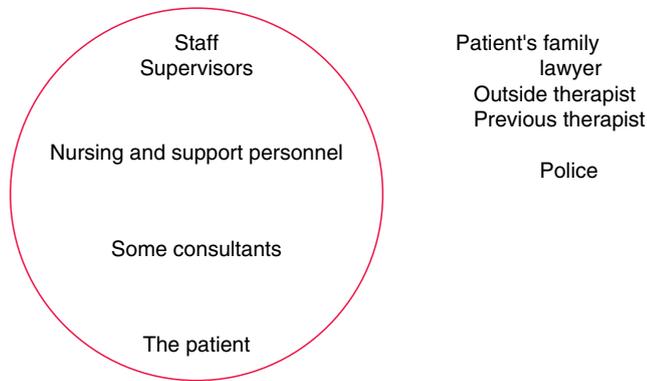

The principles of confidentiality and privilege have a long and still evolving historical connection with the practice of medicine and the role of the physician. The Hippocratic Oath states, “And about whatever I may see or hear in treatment, or even without treatment, in the life of human beings – things that should not ever be blurred out outside – I will remain silent, holding such things to be unutterable [sacred, not to be divulged]” (Von Staden, 1996). The elegant simplicity of this statement of principle is now pitted against conflicting legal demands and societal values. The *Tarasoff* case (discussed below) and its progeny, the increasing use of subpoenas for psychiatric records, the complexity of interfacing with managed care, and confidentiality guidelines related to human immunodeficiency virus infection (HIV) are just some of the issues that complicate the psychiatrists’ oath of confidentiality.

## Confidentiality

In the APA’s *Principles of Medical Ethics with Annotations Especially Applicable to Psychiatry* (1993), Section 4, Annotation 1 reads, “Confidentiality is essential to psychiatric treatment. This is based in part on the special nature of psychiatric therapy as well as on the traditional ethical relationship between physician and patient”. The constitutional right of privacy has been discussed elsewhere in this chapter. Confidentiality is defined as the clinician’s obligation to keep information learned in that relationship unavailable to third parties (Appelbaum and Gutheil, 2000; Gutheil, 1994, pp. 1–13).

Appelbaum and Gutheil (2000) looked at practice in psychiatric facilities, and devised the concept of a “circle of confidentiality” (Figure 6.1). Within the circle, information about the patient is shared without the patient’s consent. For instance, for a hospitalized patient, the resident psychiatrist, the psychiatrist’s supervisor, the staff and essential consultants are considered to be within the circle of confidentiality. The patient’s family, the patient’s attorney, the patient’s outside psychiatrist, the patient’s previous psychiatrist and the police are outside the circle. As Appelbaum and Gutheil note, although the patient is inside the circle, the patient may speak to anyone outside the circle without restriction.

The duty of confidentiality is sometimes understood in terms of the treatment contract between the patient and psychiatrist. There is agreement between the legal system and the psychiatric profession that confidentiality is not an absolute value. There are several major exceptions to the obligation of

**Figure 6.1** *The circle of confidentiality.* Reprinted with permission from Appelbaum PS and Gutheil TG (2000) *Clinical Handbook of Psychiatry and the Law*, Baltimore Psychiatric press. Washington DC, pp. 1–29. Copyright, Lippincott, Williams & Wilkins.

confidentiality, the most common of which is when the patient consents to information being released. Psychiatrists and their patients should be aware of the implications of releasing information to insurance companies, family members, employers and so forth and should work collaboratively in making these decisions (Table 6.3).

As a rule, the psychiatrist should get the patient's consent in writing and, optimally, the patient should read any information that leaves the office before it is released.

The second exception is based on the duty to protect, wherein the value of safety is given priority over the value of confidentiality. This is discussed later in the chapter.

The third set of exceptions includes reporting statutes, which mandate physician reporting of certain conditions. All states have such laws in one form or another, and generally include incidents of infectious diseases, child abuse and elder abuse. If they are following any of these statutes in good faith, psychiatrists run little risk of liability. See the discussion of child abuse reporting, below.

The fourth set of exceptions includes emergencies. For instance, when a psychiatrist is evaluating a patient in an emergency department and the patient is grossly psychotic and unwilling to participate in the interview, the psychiatrist is presented with the dilemma of whether to contact family members or prior treaters without the expressed written consent of the patient. This involves a risk–benefit assessment that the evaluating psychiatrist must make. Psychiatrists must be aware of their states' standards concerning emergency breach of confidentiality; one state may require an identifiable harm to be prevented, while another may permit breach when it is necessary in the clinician's judgment to gather the relevant information to make a proper diagnosis or disposition for the patient.

**Table 6.3** Major Exceptions to Confidentiality

- Patient consents to release of information
- Duty to protect
- Emergencies
- Mandatory reporting statutes
- Court-ordered evaluations
- Patient initiates litigation

Medical insurance has brought its own challenges to the issue of confidentiality. Insurance companies may ask mental health providers to sign a contract agreeing to release information to the insurer. Patients may ultimately have to decide which they value more: their privacy or the benefits obtained through the managed health company. Mental health providers who are negotiating contracts with insurers should be mindful of any obligation to provide confidential information without the patient's consent.

Appelbaum and Gutheil (1991) state that psychiatrists in the position of having to breach confidentiality should observe certain basic principles. First, they should alert patients, whenever possible, of their intention to breach confidentiality before doing so. Secondly, psychiatrists should use a hierarchy of confidentiality. Psychiatrists do not need to jump to breach confidentiality in all situations where it is necessary to communicate confidential information. They often have time to discuss issues with a patient, to consider alternatives and thus avoid such confrontations. Finally, Appelbaum and Gutheil state that psychiatrists should bear in mind that the alliance is based on the “healthy side” of the patient against the patient's illness. They suggested that when the patient is experiencing impulses to harm another person, the psychiatrist and the patient should attempt to make the call to warn the person together. The healthy side of the patient is thus supported actively by the psychiatrist, as opposed to having the psychiatrist “blow the whistle” on a patient who has become dangerous. These recommendations emphasize the importance of the therapeutic alliance and remind us that confidentiality is an important aspect of that alliance.

### Psychiatrist–Patient Privilege

Privilege is defined as the patient's right to prevent testimony by a psychiatrist in a court setting (Gutheil, 1994; Appelbaum and Gutheil, 1991). It rests on two primary justifications: 1) it protects the patient's interests in the privacy of treatment matters; and 2) it may encourage patients to speak openly with their psychiatrists. The scope of privilege is generally limited to the patient's communications with the psychiatrist. Observations of the patient's demeanor, or his or her conduct or even words in a public setting may not be covered within the privilege.

Privilege is a right belonging to the patient and may be waived by the patient. Although the privilege does not belong to the psychiatrist, he or she may have a duty to assert it in legal proceedings, unless and until one of the exceptions to privilege applies. In the absence of a release or waiver of privilege by the patient, psychiatrists should consult with legal counsel if they are called to testify about their communications with a patient.

Exceptions to the doctrine of privilege vary from state to state and include situations when a patient has introduced his or her mental state into litigation to which the patient is a party. In some states, privilege does not apply in competence to stand trial, or criminal responsibility evaluations. There are often exceptions in cases of child custody, involuntary commitment proceedings, will contests, or malpractice claims filed by the patient against a psychiatrist. Finally, state law may vary on the scope of the exception once it is invoked.

### Informed Consent

Psychiatrists, like all other medical practitioners, face a dilemma: patients come to them for answers and treatment, and they expect the psychiatrist to have those answers; however, treatment of mental illness is an uncertain process, and is not without risks. In order to give informed consent to treatment, patients must be

given sufficient information concerning the risks and benefits of the proposed treatment; where outcomes are uncertain, they must also be informed of that uncertainty. The doctrine of informed consent has evolved considerably in the past several decades. The need to obtain a patient's consent for treatment is grounded in the legal theory of battery, which is defined as an intentional touching of a person without that person's consent. Provision of medical treatment is considered an intentional touching; if it is provided without the patient's consent (and without other exceptions, such as provision of emergency medical care), then it is a battery. Only after obtaining consent from a competent person may the physician treat the patient without risking liability for the tort of battery. As medical treatment has become more complex, and as concern for patients' rights has grown, the notion of informed consent has evolved to require provision of ever more information to assist patients in making informed medical decisions.

Courts began setting modern standards for informed consent in the 1960s. The Kansas Supreme Court held that the quantum of information that a physician was required to provide was that which a "reasonable medical practitioner" would divulge (*Natanson v. Kline*, 1960). In 1972, the US Court of Appeals for the District of Columbia decided the landmark case of *Canterbury v. Spence*, in which the court ruled that the physician had the duty to "advise patient of need for or desirability of any alternative treatment". Although the majority of states determine the sufficiency of disclosure by the standard of that which the reasonable practitioner would deem significant, some states take a more patient centered approach in which the quantum of information is that which "would be regarded as significant by a reasonable person in the patient's position" (*Truman v. Thomas*, 1980).

In general, then, the psychiatrist is obligated to disclose likely material risks of treatment, but not all possible risk, that is, the likelihood and severity of injurious side effects or death. Also, the psychiatrist should explain the need for treatment, and risks and the benefits of receiving or refusing the treatment. Finally, there should be a discussion of possible alternative treatments.

Obtaining informed consent for psychopharmacological treatment of children presents a particular challenge, since many psychoactive medications have not received FDA approval for use with children. Psychiatrists should be as clear as possible when explaining the state of knowledge regarding use of particular medications with children, so that the parent's or guardian's consent is as fully informed as possible.

## Exceptions to Informed Consent

There are four primary exceptions to the general rule that the patient receiving treatment must give informed consent (Table 6.4). The first is a medical emergency. Consent is presumed when a person is suffering from an emergent situation that requires treatment, but is unable to give consent. Thus, for example, when a di-

abetic patient is in a coma and consent cannot be obtained before giving the patient insulin, the treating physician may rely on presumed consent for treatment as a defense to a claim of battery. In psychiatry, the definition of an emergency has been somewhat more ambiguous. Because there is no national standard of what constitutes a psychiatric emergency, clinicians should know the definitions (if any) in their state. They should consider how emergent the situation is, document their assessment, and note that it was not possible to gain the patient's informed consent at the time. Intervention in a psychiatric emergency, especially administration of medication, is often not considered treatment in the same sense as emergency treatment of a traditional medical condition. It is for this reason that many states regulate administration of emergency psychiatric medications as restraint, rather than as treatment.

Incompetence is the second exception to the need to obtain informed consent from a patient. An incompetent person, by definition, is incapable of giving informed consent; it can be granted only by that person's guardian, or other entity charged under state law with the authority to give consent. (It is thus not truly an exception to the need for informed consent, but a situation in which the consent is obtained from a surrogate.) Even incompetent patients should be engaged in the making of treatment decisions, to the extent of their ability, and gaining their assent to treatment is important, even if they do not have the legal capacity to render informed consent. All states have procedures by which a person can be declared incompetent; such a declaration usually requires a judicial finding, though some states have administrative proceedings for resolving treatment issues that do not require judicial intervention.

The third exception to informed consent arises from the concept of therapeutic privilege. Psychiatrists use privilege when they withhold information in the belief that giving a patient all of the information necessary to make a decision would harm the patient. Invocation of therapeutic privilege, rare in medicine, is even rarer in psychiatry, in which sharing information is central to the work of the psychiatrist. Psychiatrists should use this exception to the informed consent doctrine exceedingly sparingly, with extreme caution, and with great thought; here, the psychiatrist is taking a maximally paternalistic posture in presuming what is not useful for a patient to know. The psychiatrist assumes a grave risk of liability if the patient suffers harm, and subsequently proves that a reasonable patient would have wanted to have the withheld information in order to make an informed choice about treatment.

Waiver is the fourth exception in the informed consent doctrine. Competent patients may request that their physicians not give them information, effectively waiving their right to know. This circumstance has become increasingly unusual over time as physicians are less likely to withhold this information and patients less likely to request such a waiver.

## Consent to the Treatment of Minors

Minors are considered to be incompetent for almost all purposes, including the right to make medical decisions. Each state has its own definition of the age that minors must attain to consent to different treatments, and the age requirements may vary with the type of treatment. For instance, a state may have a lower age of consent for treatment of sexually transmitted diseases or mental illness than for traditional medical treatment. Psychiatrists must become familiar with the law of the state or states in which they practice.

**Table 6.4** Exceptions to Informed Consent

- Emergencies
- Therapeutic privilege
- Incompetence
- Waiver

Psychiatrists who work in schools must obtain the consent of parents before initiating ongoing treatment. An emergency evaluation of a student – performed without such consent – is permissible for the most part under the doctrine of emergencies and must be documented as such (see earlier discussion). Psychiatrists who work in school settings also have to work with parents who are separated or divorced. Psychiatrists are obligated to determine which parent has legal custody and to obtain the consent of that parent for the treatment of the child; documented proof of custody must be obtained. Most states have laws by which minors may become emancipated, and therefore are deemed competent to make their own decisions. The conditions of emancipation typically include marriage, becoming a parent, entry into the armed services, and sometimes a demonstrated ability of a minor to manage his or her own financial affairs and to live on his or her own.

## Medicolegal Aspects of Clinical Practice

### Malpractice and Risk Management

A lawsuit in which a plaintiff sues a defendant for damages resulting from some act of negligence is called a tort (which is characterized as a civil, as opposed to a criminal, wrong). A malpractice suit is a type of negligence case; it shares with all negligence cases four broad elements – the “four Ds” – which must be proved if the plaintiff is to be awarded damages (Table 6.5).

The first element involves duty. A psychiatrist in private practice has no duty to treat or care for a patient unless he or she has made an agreement to do so. Once the psychiatrist agrees to treat the patient, however, the psychiatrist is legally and ethically obligated to treat the patient until treatment is properly terminated.

Once the psychiatrist–patient relationship is established, the psychiatrist is obligated to provide treatment at the standard of care. Since the duty comes into being when the relationship is established, psychiatrists need to be mindful of whether they are in fact entering into a psychiatrist–patient relationship. Commonly, psychiatrists in private practice see patients for a one-time consultation and then decide whether they wish to provide treatment. The psychiatrist should make it clear at the time of the initial contact that the first appointment is an opportunity for the psychiatrist and patient to see if their relationship is going to be a useful one. If this is not clearly spelled out and agreed to, it might be argued that the psychiatrist assumed a duty to provide care at the initial consultation. The second element of malpractice is negligence (or dereliction of duty). The test of negligence is whether the psychiatrist’s actions deviated from the standard of care practiced by other professionals of the same level of training.

The third element that needs to be demonstrated is harm or damage. Once the plaintiff has proven that the psychiatrist has a duty to the patient and has performed in a derelict manner, there must be proof that the patient has suffered harm. Even a grossly

negligent act that results in no harm will not result in a finding of liability for malpractice.

The fourth factor is direct or proximate cause. The damage that the patient has suffered must directly result from the dereliction of duty by the psychiatrist. Without this connection, a claim of malpractice will not be successful.

### Third Party Payers and the Psychiatrist

The increasing role that insurers play in determining the type of treatment patients receive has increased the complexity of the psychiatric–legal interface. A major public policy issue in this area is whether, and to what extent, insurance companies may be held responsible when a denial of coverage results in harm to a patient. Health care providers are faced with difficult legal and ethical decisions when their professional judgment calls for provision of a particular service in the face of an insurance company denial. The law in this area is evolving; whereas early cases seemed to cloak managed care payers with a great deal of protection, later cases and some statutory changes are increasing their exposure.

The 1987 case, *Wickline v. the State of California*, illustrates the relationship between the treating physician and the third party payer in a relatively early stage of the development of this area of law. The message of the case is that a denial of coverage does not obviate a physician’s duty to render treatment to the appropriate standard of care. Where coverage is denied, physicians are nonetheless obligated to exercise their medical judgment, and, where necessary, to challenge the denial through whatever mechanisms are available.

Three years later, the same California court made it clear that insurance companies may indeed share liability with physicians when the denial of benefits results in harm to the patient. In the case of *Wilson v. Blue Cross of California* (1990), the patient, Wilson, was admitted to a hospital in Los Angeles, suffering from depression, substance dependence and anorexia. His treating physician determined that he required 3 or 4 weeks of inpatient care, but on his 10th day in the hospital his insurance company stated that it would not pay for any further hospital care. When the family made it clear that they could not afford to pay for the hospitalization, the patient was discharged; 20 days later he committed suicide. Although the treating physician did not appeal the denial of coverage, he later testified that he was reasonably sure that Wilson would not have committed suicide had he been permitted to remain in the hospital. The court ruled that the insurance company’s denial of coverage might have been a proximate cause of Wilson’s suicide, and it permitted the case to go to trial where the plaintiff would have had to prove the elements of negligence to a jury. The intersection of the demands of confidentiality with those of managed care presents a second major area of complexity. At the beginning of therapy, the psychiatrist should outline the scope of utilization review and should obtain the consent of the patient before releasing any information to the reviewing companies. Once a patient gives consent for a psychiatrist to speak to a utilization review committee, the psychiatrist should give only the minimal amount of information necessary to facilitate the utilization review decision. Patients should also be made aware of the possibility that payment for recommended services may be denied by the insurance company. The treatment agreement between the patient and psychiatrist should make clear the patient’s financial responsibilities in the event of such a denial. However, a psychiatrist may face liability for failure to provide,

**Table 6.5** The Four Ds of Malpractice

- Dereliction of
- Duty
- Directly causing
- Damage

or arrange for, necessary care in the community, just as in the hospital setting, even when coverage is denied.

Finally, there is a potential for conflict and liability when health care providers sign contracts with managed care companies. Whether the contract is based on a capitated scale or fee for service, providers often have a financial incentive to limit the care they provide (just as they have a financial incentive to inflate costs under traditional indemnity arrangements). In addition, some managed care companies are making an effort to transfer their financial liability for treatment denials to their psychiatrists by having them sign “hold harmless” or “indemnification” agreements. Psychiatrists must be aware that such arrangements may have an impact on their relationships with their patients, and must guard against the possibility that their clinical judgment may be influenced thereby.

### Liability for Supervising Other Professionals

Psychiatrists work in a variety of settings and interact in many different ways with other mental health professionals. One aspect of this interaction is the liability potential that psychiatrists undertake in each of these relationships. The APA publication entitled “Guidelines for psychiatrists in consultative, supervisory, or collaborative relationships with nonmedical therapists” (1980) outlines the typical consultative relationships and their corresponding degree of responsibility. Broadly, the degree of liability correlates with the extent of authority to make (as opposed to recommend) treatment decisions (Table 6.6).

Supervisory relationships are relationships in which the psychiatrist is hierarchically and legally responsible for the overall care of the patient, and will be held responsible for the treatment provided by those he or she supervises. The American Psychiatric Association (1980) guidelines state that:

In a supervisory relationship the psychiatrist retains direct responsibility for patient care and gives professional direction and active guidance to the therapist. In this relationship the non-medical therapist may be an employee of an organized health care setting or of the psychiatrist. The psychiatrist remains ethically and medically responsible for the patient’s care as long as the treatment continues under his or her supervision. The patient should be fully informed of the existence and nature of, and any changes in, the supervisory relationship.

Consultative relationships are different in terms of the level of responsibility and liability undertaken. Consultative advice is given on a “take it or leave it” basis. Consultants are outside the decision-making chain of command; they do not make

treatment decisions, and do not have hiring and firing authority. As such, they generally are not held liable for treatment decisions (though psychiatrists practicing as consultants should be aware of any unusual legal provisions in the state in which they practice). The American Psychiatric Association (1980) guidelines state that in this type of relationship the psychiatrist does not assume responsibility for the patient’s care. The psychiatrist evaluates the information provided by the therapist and offers a medical opinion which the therapist may or may not accept. Consultation is not a one-way process and psychiatrists do and should seek appropriate consultation from members of other disciplines in order to provide more comprehensive services to patients.

### Risk Management Techniques

There is consensus among risk management experts that various strategies can reduce medico-legal liability. The clinical strategies of obtaining consultation on difficult cases, documenting the rationale behind critical decisions, and using informed consent to build rapport are valuable risk management techniques. In documentation, “thinking for the record” is advocated by Gutheil. The psychiatrist thus demonstrates the use of judgment and ongoing risk benefit assessments. Institutional strategies include regular quality assurance monitoring, training in documentation, a system for working with patients and families on adverse effects, and providing access to expert consultation.

In psychiatry, several areas deserve special mention. Suicide and attempted suicide represent one of the most common and expensive sources of lawsuits in psychiatry (Slawson, 1989). Psychiatrists should assess the level of suicidality and the ability of patients to monitor and report their suicidality (Gutheil *et al.*, 1986) and plan an appropriate strategy based on that assessment. In lawsuits involving suicide, the patients are more commonly portrayed as the victims, rather than agents in their own deaths. The psychiatrist who both fosters and documents active collaboration with the patient demonstrates good risk management practice as well as clinical skill. Prescribing medications also raises psychiatrists’ liability risk. Solid documentation of history, examinations, laboratory tests, indications for a medication and risk assessment are essential to reduce liability. Consultation with a colleague should be sought for difficult cases.

### Duty to Warn, Duty to Protect

When a psychotherapist determines (or, pursuant to the standards of the profession, should determine) that his/her patient represents a serious danger of violence to another, he/she incurs an obligation to use reasonable care to protect the intended victim against such danger. The discharge of such duty, depending on the nature of the case, may call for the therapist to warn the intended victim or others likely to appraise the victim of the danger, to notify the police, or to take whatever other steps are reasonably necessary under the circumstances.

This is the so-called Tarasoff principle, established by California Judge Tobrinen in 1976 in the case of *Tarasoff v. Regents* (1976). It has generated controversy, spawned lawsuits, and initiated a fundamental reexamination of the psychiatrist’s role *vis-à-vis* members of the public.

The *Tarasoff* case involved the tragic death of a University of California student, Tatiana Tarasoff, who was murdered by a fellow student, Prosenjit Poddar. Poddar was an outpatient at the campus mental health clinic. He stated to his psychologist that he intended to kill Tarasoff. The therapist completed

**Table 6.6 Psychiatrists’ Relationships with Nonmedical Therapists**

Supervisory	<ul style="list-style-type: none"> <li>● Psychiatrist has treatment responsibility</li> <li>● Psychiatrist may hire or fire</li> <li>● Psychiatrist has final authority</li> </ul>
Collaborative	<ul style="list-style-type: none"> <li>● Responsibility shared between parties</li> <li>● Delineation of responsibilities required</li> </ul>
Consultative	<ul style="list-style-type: none"> <li>● Consultee may take advice or not</li> <li>● Consultant is not responsible for supervision</li> <li>● Consultant has no hire or fire authority</li> </ul>

paperwork to have Poddar committed for 72-hour emergency psychiatric detention. The local police detained Poddar, but released him when he stated that he would “stay away from that girl”. Two months later he successfully carried out his threat to kill Tarasoff.

This case, as well as subsequent cases and legislation in other states, created new clinical and ethical dilemmas for psychiatrists, as they now must balance confidentiality with the safety of third parties in outpatient settings as well. At what point is the inherently trusting nature of the psychiatrist–patient relationship impaired by the legally driven obligation to report threats of harm? When should a psychiatrist report a patient’s vague statement wishing to harm a third party? How should the patient’s violent history be weighed in the assessment of whether to violate confidentiality? Does the circle of responsibility include only named third parties, or does it extend to groups of reasonably identifiable potential victims? Is a warning sufficient? Although these questions are ultimately matters of clinical judgment, psychiatrists need to know whether their states have established specific guidelines for settling them.

### Criminal Law and Psychiatry

The psychiatrist’s role in the courtroom is substantially different from that in the clinical setting (Rappeport, 1982). In criminal cases, psychiatrists are commonly called on to evaluate defendants’ competence to stand trial or (less commonly) criminal responsibility. In perhaps the most challenging of situations, psychiatrists are faced with the ethically challenging task of evaluating defendants’ competence to understand the death penalty.

### The Psychiatrist as Expert Witness

Psychiatrists may work in forensic settings as agents of the court, providing impartial evaluations for the judge, or may function as experts for the defense or prosecution. As opposed to fact witnesses, who can testify only as to facts that they have observed, expert witnesses may review records, conduct tests, perform evaluations or other research, and provide opinions (such as diagnoses) in court. Expert witnesses, by definition, are familiar with a body of professional knowledge that is not well known to the layperson (Table 6.7).

When asked to serve as an expert witness, the psychiatrist should have a clear understanding of the legal question or standard being addressed. The expert witness should inform the client that patient–psychiatrist confidentiality is not to be expected and that the information being elicited will be presented to the court to help the judge or jury make a decision. In general, attorneys attempt to establish the credibility of their experts by presenting their qualifications to the court, either by testimony, or by admitting the expert’s resumé. Psychiatrists who offer themselves as expert witnesses should be prepared to have their credentials challenged by the attorney for the opposing side. Good expert

witnesses take these challenges in stride. They respond to questions calmly, without becoming defensive or arrogant. Good expert testimony is given in understandable, jargon-free language, with short, concise answers. Expert testimony is a challenging and difficult professional task.

### Competence to Stand Trial Evaluations

In order for a criminal case to proceed, the defendant must be competent to stand trial. This is a constitutional standard that has its roots in old English law. Although specific standards of competence are determined on a state-by-state basis, the federal standard has provided the basis for each state’s law. The test is “whether [the defendant] has sufficient present ability to consult with his lawyer with a reasonable degree of rational understanding and whether he has a rational as well as a factual understanding of the proceedings against him” (*Dusky v. United States*, 1960).” The legal standard is not an exacting one. Only a small proportion of criminal defendants are referred for competency evaluations.

Although there is no universally accepted clinical standard for assessing competence, the McGarry (McGarry *et al.*, 1973) criteria have been empirically validated and are the most commonly used sources of evaluation. This standard encourages the psychiatrist to assess 13 different areas of functioning, including the patient’s behavior, ability to relate to an attorney, ability to plan a legal strategy, and motivation and capacity to testify, in addition to the patient’s understanding of the charges, possible consequences, and likely outcomes.

Psychiatrists must remember that when they are conducting evaluations on behalf of the court, they are agents of the court; the usual rules of the psychiatrist–patient relationship (including confidentiality and privilege) are thereby waived. Those being examined must be informed of these different ground rules, in accordance with the requirements of the particular state. Since the defendant’s understanding of his or her waiver of confidentiality is often an issue, the evaluator should carefully document the defendant’s response to the information, using direct quotes, when possible. States have different requirements in cases where the patient appears incompetent to give informed consent for a “stand trial” evaluation. The psychiatrist needs to be aware of these requirements, and to be prepared to proceed accordingly (some states permit the evaluation to proceed; others might require further hearings). The fate of defendants found incompetent to stand trial was addressed in *Jackson v. Indiana* (1972). Jackson was mentally retarded, deaf and mute; he was charged with two counts of petty larceny. The psychiatrist who evaluated Jackson concluded that he was almost completely unable to communicate; in addition to his lack of hearing, his mental deficiency left him unable to understand the nature of the charges against him or to participate in his defense. Based on this evidence, the trial court found that Jackson “lacked comprehension sufficient to make his defense” and ordered him committed to the Indiana Department of Mental Health until that department could certify to the court that he was “sane”.

Since it was clear that Jackson would never become “sane”, (that is, competent to stand trial), his commitment essentially amounted to imposition of a life sentence, without his ever being convicted of a crime. The court held that this outcome violated Jackson’s Fourteenth Amendment right to due process and that a defendant cannot be committed indefinitely just because he is incompetent to stand trial. His commitment must be for a purpose permitted under state law (and the Constitution).

**Table 6.7 The Psychiatrist as Expert Witness**

Fact Witness	Expert Witness
<ul style="list-style-type: none"> <li>• No specialized knowledge</li> <li>• No special fee</li> <li>• Does not offer opinion</li> </ul>	<ul style="list-style-type: none"> <li>• Has special knowledge base</li> <li>• May offer opinions</li> <li>• Receives compensation</li> </ul>

Thus, if the defendant may reasonably be restored to competence with treatment, he may be committed for that purpose. If it is unlikely that the defendant will be restored to competence (as in Jackson's case), then his commitment must meet other legitimate state purposes, such as prevention of harm under civil commitment standards. If the defendant does not meet the criteria for such a commitment, he must be released.

## Insanity Defense

There is an important distinction between a finding of incompetence to stand trial and a finding of not guilty by reason of insanity (NGRI). The former means that defendants do not have a chance to defend themselves until competence is restored. The latter is a not guilty finding, based on the defendant's inability to have formed the state of mind requisite for a criminal conviction. It is not a matter of restoration or recovery from mental illness; once a defendant is found NGRI, the criminal case is permanently resolved. Criminal responsibility and competency evaluations are often requested together, but they are separate and distinct.

In order to be convicted, a defendant must be shown both to be guilty of committing an illegal act (*actus reus*) and to have had the intention of committing the crime (*mens rea*). Criminal responsibility evaluations focus on the *mens rea* component of criminal acts. The psychiatrist involved in an insanity defense is presented with a more challenging assignment than that of the competence to stand trial evaluation. Assessing a patient's mental state retrospectively is a task fraught with difficulties. The defendant may forget, lie, or "fill in" details of the events. For this reason, this evaluation typically involves more collateral investigation, such as reviewing the prosecutor's file including police, witness, victim and perhaps even autopsy reports, in addition to standard history such as past psychiatric records. The clinical interview should include the confidentiality warning, a detailed present-day mental status examination, and direct queries into the defendant's recollected mental state and in-depth recall of the crime. This detective work, together with careful questioning, as well as psychological or neurological assessment when indicated, is necessary to enable the psychiatrist to present as clear a picture as possible of the defendant's state of mind at the moment of the crime.

The first appellate decision in English law involving the insanity defense was *M'Naghten's* case. In 1843, Daniel M'Naghten shot and killed Edward Drummond, who was secretary to the prime minister. Apparently, M'Naghten was under the delusion that he was being persecuted by the prime minister as well as other people throughout all of England. After this case, the standard for criminal responsibility became known as the M'Naghten rule: "To establish a defense on the grounds of insanity it must be conclusively proved that, at the time of committing the act, the party accused was laboring under such a defect of reason, from the disease of the mind, as to not know the nature and quality of the act he was doing; or if he did know it that he did not know what he was doing was wrong". This standard allows either a cognitive test (did he know what he was doing?) or a moral test (did he know it was wrong?). It addresses itself to the specific criminal act, as opposed to assessing the defendant from the perspective of a broad-reaching sense of right and wrong.

The American Law Institute standard provides: "A person is not responsible for criminal conduct if at the time of such conduct as a result of a mental disease or defect he lacks substantial capacity either to appreciate the wrongfulness of his conduct or

to conform his conduct to the requirements of the law" (Model Penal Code, 1955). This test incorporates the cognitive component of the M'Naghten rule but, by use of the terms "mental disease or defect", allows for the possibility that conditions other than psychotic illnesses (such as impulse disorders) may result in a lack of criminal responsibility. Contrary to public perception, a successful insanity defense does not usually result in freedom. In fact, when a defendant is found not guilty by reason of insanity, he or she may face years of confinement in a hospital setting. As Elliot and colleagues (1993) note:

Acquittals by reason of insanity are unlike acquittals in criminal law. The criminal defendant who wins an outright acquittal is free of state control and may simply walk away from the court house after the trial. But the defendant found [NGRI] typically remains confined....

The hurdles to commitment are typically much lower and the barriers to release much higher. Especially when charged with misdemeanors, insanity acquittees generally remain hospitalized far longer than ordinary civil acquittees and may remain confined for periods greater than the maximum sentence that would have been possible on conviction of the criminal charges.

## Civil Litigation

### Tort Liability

The tort system is designed to compensate individuals or groups who are injured by the acts of other individuals or entities, including corporations and sometimes government agencies. As in malpractice cases (which are a category of tort), the four Ds (**dereliction of a duty, directly causing damage**) are the standard by which tort liability is assessed. Unlike most criminal cases, where the conduct of the victim is not relevant to the defendant's guilt, the injured party's (or plaintiff's) conduct is often a factor in determining the legal result. Thus, in a motor vehicle case, if the plaintiff was also operating his or her vehicle negligently, and thus contributed to the accident, the defendant's liability will be reduced in proportion to the plaintiff's comparative negligence. Where a party's mental state is at issue, or where there are claims for emotional damages, psychiatrists may be called upon to conduct evaluations and testify.

Psychiatrists performing an evaluation for psychic harm must evaluate the person's mental state before and after the act. For instance, if a person had a preexisting history of affective disorder and had recurrent episodes after an injury, that would be noteworthy for a psychic harm report. The question would be whether the traumatic event exacerbated the preexisting condition. Not unlike criminal responsibility evaluations, these assessments may rely heavily on collateral documentation of the event and interviews with other witnesses. Emotional injury evaluations often focus heavily on functional deficits that the plaintiff may be exhibiting, since damages are related to loss of function; it is not sufficient to simply meet diagnostic criteria for mental illness. As in all such evaluations, especially where the subject is aware of the consequences of the process, malingering should always be considered.

### Disability

Psychiatrists may perform disability evaluations for both workers' compensation and Social Security disability claims. Workers' compensation is an alternative system of compensation that does

not involve the complexity of the tort system. Workers' compensation, which is paid when a disabling injury occurs in the course of employment, is an exclusive remedy based on the worker's prior salary and the degree and duration of disability. In general, there are no awards for pain and suffering as there are in tort cases. In this system, evaluations focus on functional limitations and require assessment of credibility, as well as corroboration of the person's prior mental state and its connection to the work environment.

Since workers' compensation systems are created by legislatures, it is important to know the statutory definitions of the conditions under evaluation; this is particularly true for mental disability. The typical categories of mental disability are as follows: 1) physical trauma causing mental injury; 2) mental injury causing physical effects; and 3) mental stress causing mental injury.

Social Security Disability Insurance was established in 1956 for people who had contributed to the fund while working. Supplemental Security Income was developed in 1972 to establish federal matching payment for state benefit programs for the disabled, regardless of work history. The Social Security disability programs use definitions of mental disorders that resemble, but are not identical with, those of the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (DSM-IV) (American Psychiatric Association, 1994). The evaluating clinician must determine whether a qualifying condition exists, and assess the degree of disability it produces, as measured against standards of the American Medical Association's guidelines (Linda *et al.*, 2001).

### Competence, Capacity and Guardianship

Competence is best understood as a legal term referring to an individual's capacity to make informed decisions. Adult individuals are presumed to be legally competent, unless and until there is a court finding of incompetence. A finding of incompetence means that a physical or mental illness has caused a defect in cognition or judgment, regarding the specific area in question, such that the individual lacks the capacity to make informed decisions. When a court determines that an individual is incompetent, a guardian may be appointed to make decisions for that person.

Competence is often used as a general term, but it should be defined specifically. With the advent of modern psychopharmacology, competence in severely mentally ill patients is often related to medication compliance. Even floridly psychotic patients may become competent after they are stabilized on medications. Since the legal decision-making for incompetent patients often involves determining what the individual would want if he or she were competent to choose, it is important that the psychiatrist assess the person's capacity when he/she is doing clinically well, in addition to when he/she is doing poorly.

Assessing a patient's capacity to give consent is based on several general principles (Appelbaum and Grisso, 1988). The patient must be able to 1) communicate choices, 2) understand the relevant information, 3) appreciate the situation and its consequences, and 4) manipulate the information rationally (Table 6.8).

There is general agreement that the standard for judging competence also varies with the presented task. For instance the standard for competence to consent to take an experimental drug is higher than for taking an aspirin. The greater the risk in the

**Table 6.8 Assessment of Capacity**

- Ability to communicate choices
- Understand relevant information
- Appreciate the situation and its consequences
- Rationally manipulate information

intervention, the more the psychiatrist needs to be clear about the four elements noted in the preceding paragraph.

Several other competencies require attention in civil matters. For example, testamentary capacity (the capacity to make a will) may be challenged by disgruntled and disinherited parties. For this reason, some people obtain an evaluation of their capacity to make a will before their death. Testamentary capacity requires that individuals understand 1) the nature of a will, 2) the extent of their assets, 3) the identity of their natural heirs, and 4) that they should not be under undue influence. Decision-making can be based on either the "best interests" standard or the "substituted judgment" model. The best interests model is a paternalistic approach that assumes that decision-makers know what is in the patient's best interests, and that they will act accordingly. It is a value laden paradigm that requires guardians to be aware of their own value systems, and to be on guard against the risk that their values may conflict with those that might apply to the patient. Perhaps more onerous, but more individualized, is the substituted judgment model, discussed briefly above in the section on informed consent. Here, the guardian attempts to act in the manner the person would want under the circumstances. This is a difficult task. When an individual has never considered a possibility, such as being in a coma, it cannot be known with certainty what the individual's wishes would be. While it might be generally agreed that individualized decision-making is a preferable model, it is easy to see why the relative comfort of the best interest approach makes this model the one that is most widely applied.

### Special Issues

#### Child Abuse Reporting

Kempe and colleagues in a 1962 paper, "The Battered Child Syndrome", began an awareness of child abuse and neglect that continues to grow. Before this seminal paper, many psychiatrists considered children's allegations of sexual and physical abuse to be fantasy that was to be interpreted and not acted on. Child abuse is now recognized to be widespread, and for the individual child, a potentially devastating reality.

All states place an affirmative duty on the professional to report suspicions of abuse. Even though many adult psychiatrists receive relatively little training in child psychiatry and in child development, all psychiatrists are mandated reporters of suspicions of child abuse and neglect. Psychiatrists who treat patients with alcoholism, serious mental illness, and a history of abuse are working with populations who have increased risk of child abuse. While pediatricians file the majority of child abuse reports, psychiatrists may be called to consult in cases requiring additional clinical judgment.

Neglect is a most difficult form of abuse to identify. Although the laws are written to encourage reporting in the "gray" cases, clinicians must still exercise a level of clinical

judgment. One person's view of neglect may be another person's view of bad parenting. Clearly, a child who is malnourished is being neglected. A child who is left alone for a significant period may have been neglected, but this depends on the age and developmental stage of the child. Clinicians must also guard against cultural or racial bias. Hampton and Newberger (1985) studied child abuse reporting and noted that physicians are more likely to file child abuse reports involving people who are of a different race or class than themselves. Psychiatrists also worry about the damage a report will do to the alliance between the psychiatrist and the patient. Clinical experience demonstrates that, in most cases, an explanation of the practitioner's legal obligation to file a report maximizes the potential to maintain the clinical alliance. That reassurance aside, psychiatrists must be aware that the legal obligation to report supersedes the value of the alliance.

A child abuse report is usually made to the state's child welfare agency, sometimes called the "Department of Social Services" or "Children and Family Services". Most commonly, the call is screened in or out over the phone and, if screened in, then the agency begins an investigation into the allegations. If the report is substantiated the child may be taken out of the home, and the parents may eventually lose custody. Less draconian measures often include mandatory treatment of psychiatric or substance abuse disorders for both parents and children. These are painful clinical realities, but psychiatrists should not hesitate to file a child abuse report when, in their judgment, they have reason to believe a child is suffering from either abuse or neglect.

### Elder or Disabled Abuse Reporting

Over 40 states have also enacted statutes mandating reporting of abuse or neglect of elderly or disabled individuals. These statutes often mirror the state's child abuse reporting laws, though they may contain broader exceptions to mandated reporting in certain circumstances. The remaining states provide legal immunity for professionals who voluntarily report abuse or neglect of the aged or disabled.

### Child Custody Evaluations

Divorce has an impact on all children, but where the parents are unable to agree, especially around custody, children face more stress. Psychiatrists have responded to this burgeoning need by developing expertise in the clinical issues that surround custody decisions. A number of psychiatrists offer consultation and mediation services to divorcing couples who wish to resolve custody issues between themselves. However, when custody disputes become adversarial, formal child custody assessments are often ordered by the court. These assessments present unique clinical, legal and ethical challenges. The APA has written recommendations for conducting child custody evaluations (Child Custody Consultation, 1982).

Psychiatrists performing a child custody evaluation should have training in child work or at least have a child psychiatrist with whom to confer. As with forensic evaluations, the parents (and where appropriate, the child) should be informed that the usual rules of confidentiality and privilege will not apply.

In conducting custody evaluations, it is important to know the legal standard which the court will apply. The standard adopted in many states provides that judges making custody decisions shall "consider all relevant factors including 1) the wishes of the child's parents as to his custody, 2) the wishes of the child as to his custodian, 3) the interaction and interrelationship of the child with his parent or parents, his siblings, and any other

persons who may significantly affect the child's best interest, 4) the child's adjustment to his home, school, and community, and 5) the mental and physical health of all individuals involved. The court shall not consider conduct of a proposed custodian that does not affect his relationship to the child" (Child Custody Consultation, 1982). The judge is required to balance these factors against the legal standard, which in most states is a "best interests of the child" standard. The psychiatrist should thus conduct the evaluation in such a way as to provide information that will assist the judge in weighing the relevant factors.

### The Americans with Disabilities Act and the Olmstead Case

In 1990, Congress enacted the Americans with Disabilities Act (ADA), with the goal of eliminating discrimination against individuals with disabilities. The Act is divided into four major sections, which prohibit discrimination in employment (Title I), public services provided by government entities (Title II), public accommodations provided by private entities (Title III) and telecommunications (Title IV).

Although discrimination in employment has been the focus of most ADA enforcement activity, advocates for the mentally ill have been litigating under Title II of the ADA, arguing that institutionalization of individuals with mental disabilities who could be appropriately treated in a less restrictive setting constitutes illegal discrimination by the state. The issue came to a head in the case of *Olmstead v. L.C.*, decided by the US Supreme Court in 1999.

Title II of the ADA states that "no qualified individual with a disability" shall be discriminated against by a public entity (such as a state) in the provision of services, programs, or activities. In order to enable such individuals to participate on a par with nondisabled individuals, public entities are required to make "reasonable accommodations" in the operation of services, programs, or activities. The federal Court of Appeals noted that when "treating professionals find that a community-based placement is appropriate [for an individual with a disability], the ADA imposes a duty to provide treatment in a community setting – the most integrated setting appropriate to that [individual's] needs". The US Supreme Court agreed, ruling that "unjustified isolation is properly regarded as discrimination based on disability".

For psychiatrists who practice in state institutions, the case is significant for the importance placed on clinical judgment about whether the patient can be adequately treated in a community setting. It is this judgment that triggers the right to community placement under the ADA, according to the Supreme Court. Clinicians making these determinations are confronted with a myriad of sometimes conflicting pressures. Is the patient really ready for the community? What kinds of accommodations might be needed in the standard community programs in order to enable the patient to function? Are these accommodations reasonable? What is the role of the clinician in advocating for individual patients versus maximizing scarce resources to benefit the greatest number of patients?

### Psychiatric Ethics

Ethics, from the Greek word *ethikos*, meaning customary, or nature, is the study of standards of conduct and moral judgment. These two definitions summarize the core features of ethics. The term customary speaks to the social component of ethics, while nature emphasizes that the actor's own character is an important

component. Ethics also refers to the system or code of morals of a particular person, religion, group, or profession (*Webster's*, 1980). In recent years, professional ethics have evolved from widely understood principles of etiquette and consideration for dealing with other members of the profession, to sets of rules that govern the relationship between a professional and a client or patient (Kelly, 1998). These modern principles are built upon the most ancient ideal of medical ethics: first do no harm.

Certain basic assumptions form the framework of psychiatric ethics. Society and the medical profession expect the physician to do the following:

- Deliver competent, compassionate, and respectful care.
- Deal honestly with patients and colleagues.
- Act within the bounds of the law.
- Respect the rights and autonomy of the patient.
- Be responsible to the community and society.

## Sources of Psychiatric Ethics

### Law

Ethics and law are closely related, but they are not synonymous (Ellis, 1991). Courts and legislatures attempt to embody ethical principles in their creation and interpretation of law. But not every ethically supportable course of conduct is, or should be, codified in the form of mandatory or prohibitory legal provisions backed up by the government's authority to punish, and not every legal mandate is consistent with medical ethics.

### Religion

It is beyond the scope of this chapter to deal comprehensively with the ethical codes established by the world's various religions. Suffice it to say that many ethical decisions that confront psychiatrists have their roots in religion. Indeed, almost to the end of the 19th century, the treatment of mental disorders was conducted, to a great extent, under the auspices of religious institutions or at least in concert with the prevailing religious ideas of the time. Today's issues include treatment refusal, abortion and end of life decisions, among many others. Psychiatrists must be sensitive to the impact that their own and their patients' religious beliefs have on their understanding of human behavior.

### Professional Associations

One of the hallmark characteristics of a learned profession is its development and adoption of a unique code of ethics to guide its practitioners. The APA has adopted such a code since 1989. Although "psychiatrists are assumed to have the same goals as all physicians", these principles have been revised "with annotations especially applicable to psychiatry". The rationale was that "there are special ethical problems in psychiatric practice that differ in coloring and degree from ethical problems in other branches of medical practice" (Table 6.9).

## Potential Consequences of Diagnostic Labels

Diagnoses of mental disorders carry implications that are different from diagnoses of purely somatic illnesses, in part because of the societal stigma attached to mental illness. This stigma has ancient roots. Humankind attaches great power to the mind but finds it deeply mysterious. One of the worst fears is the loss of

control of meaningful communication, decision-making ability and intellectual capacity (Trad, 1991). Even accepting the medical model that grants validity to the diagnosis of mental disorders, the psychiatrist still faces ethical tensions in making such diagnoses.

Because confidentiality is not absolute, a patient's diagnosis is available to many parties, with practical consequences. Opportunities to obtain employment or insurance may be constrained by the documented presence of a psychiatric illness. Conversely, such a diagnosis may make tangible assistance and subsidies available based on the psychiatrist's assessment of the patient's disability. The clinician performing an evaluation is obliged to pay attention to any internal prejudices about patients' entitlements and to perform the assessment as fairly as possible. Another realm of prejudice that can enter the diagnostic arena relates to cultural perceptions of behavior. Although there is abundant statistical validity to the diagnostic schema of the DSM-IV, its validity is based on the norms of the majority culture. Patients who are members of cultural minority groups may express distress in ways that are inappropriately labeled as diagnosable psychopathology (Siantz, 1993).

## Ethics and Patient–Therapist Boundaries

There are abundant clinical reasons for maintaining clear and predictable boundaries in the patient's relationship to the psychiatrist. Among other justifications, a clear therapeutic framework makes the psychotherapeutic environment one in which the patient can feel safe to disclose sensitive information without fear of punishment, and in which the care received is not dependent on the patient's meeting the needs or earning the approval of the caregiver.

Maintaining the principles of respect, honesty and autonomy of patients, all major organizations of medical and mental health professionals specifically condemn sexual contact between physicians or therapists and their patients, regardless of the form or intensity of the psychiatric treatment being provided. The ethical background for this blanket prohibition stems from the nature of the therapeutic relationship. Although many of the features of the psychiatrist–patient relationship are the same as those that exist with any other physician, there are some specific facets of the psychiatric alliance that lend the issue particular distinction.

The patient enters the relationship in pain and is therefore vulnerable. Not infrequently, issues of unresolved feelings about sexuality, intimacy and dependence may be part of the problem brought to the psychiatrist. The psychiatrist is seen by society, and usually by the patient, as possessing education, authority and experience. Therefore, there is an imbalance of power in the relationship from the beginning. Because the patient has brought his or her problem to the trusted psychiatrist with the expectation of assistance, courts and society have maintained that the therapeutic alliance constitutes a fiduciary relationship, wherein the psychiatrist is obliged to act scrupulously in the patient's best interests, eschewing any personal advantage (Carr and Robinson, 1990; Strasburger *et al.*, 1992).

This absolute prohibition, however, has not yielded absolute abstinence. Numerous surveys conducted from the mid-1970s through the late 1980s found that 7 to 10% of male therapists and 2 to 3% of female therapists admitted to erotic contact with patients (Strasburger *et al.*, 1992). Rarely does sexual contact with patients occur in isolation. Rather, it usually represents the last in a series of steps eroding the professional and clinical boundaries of therapy. The earlier steps may include extending

**Table 6.9 Ethical Principles for Psychiatric Practice**

Principles of Medical Ethics: American Medical Association	Annotations Especially Applicable to Psychiatry: American Psychiatric Association
<p>“A physician shall be dedicated to providing competent medical service with compassion and respect for human dignity.”</p>	<ol style="list-style-type: none"> <li>1. The psychiatrist shall be vigilant about the boundaries of the doctor–patient relationship.</li> <li>2. A psychiatrist should not be party to any discriminatory policy.</li> <li>3. It is ethical for a physician to cooperate with peer review.</li> <li>4. A psychiatrist should not be a participant in a legally authorized execution.</li> </ol>
<p>“A physician shall deal honestly with patients and colleagues, and strive to expose those physicians deficient in character or competence, or who engage in fraud or deception.”</p>	<ol style="list-style-type: none"> <li>1. Sexual activity with a current or former patient is unethical.</li> <li>2. The psychiatrist should not exploit information furnished by the patient, and should not influence a patient in any way not directly relevant to the treatment goals.</li> <li>3. A psychiatrist should not practice outside his/her area of professional competence.</li> <li>4. When patient welfare is jeopardized by the mental illness of a psychiatrist, it is encouraged for other psychiatrists to intercede.</li> <li>5. The treatment contract should be explicitly established.</li> <li>6. It is ethical to charge for missed appointments within the terms of the treatment contract.</li> <li>7. Fee-splitting arrangements for administration or supervision are not acceptable.</li> </ol>
<p>“A physician shall respect the law and also recognize a responsibility to seek changes in those requirements which are contrary to the best interests of the patient.”</p>	<ol style="list-style-type: none"> <li>1. The right to protest social injustices, which may violate certain laws, may not be professionally unethical.</li> <li>2. sessions beyond the usual time, scheduling a patient for an hour when no one else is in the office or clinic, meeting the patient for meals or elsewhere outside the treatment setting, and accepting invitations that place the therapist and patient in intimate social situations. Such compromises erode the structure that is necessary for therapy to be a healing process and pave the way for a destructive relationship. After the termination of therapy. Most maintain, that the fiduciary obligation does not end; that transference, despite the most intense and successful analysis, never disappears; that the therapist always maintains the power of confidences divulged in the treatment; and that a therapist who begins

any therapy without having first excluded the possibility of any future sexual contact with the patient may be seen as lying in wait for the opportunity to exploit (Murphy, 1992). The consensus of practitioners and ethicists remains that, “Once a patient, always a patient”.

### Ethics of Psychiatric Research

The conduct of psychiatric research often presents a paradox with troubling ethical ramifications. In many circumstances, particularly in clinical investigations, worthwhile research that

is primarily intended to benefit individuals with mental illnesses as a group demands that the human subjects taking part in the protocols themselves be drawn from the ranks of the mentally ill community. The central dilemma, of course, is that the very psychiatric illness that makes an individual a desirable, even necessary, subject for a particular research project may compromise that individual's own capacity to give voluntary, informed and competent consent to research participation. No subjects may be involved in research unless legally effective informed consent has been obtained and it is clear that undue influence and coercion are eliminated. The best research asks a specific and relevant question that will advance the field of knowledge, has a hypothesis, and has an investigator who has thoughtfully considered the risks of the study for subjects and the process for obtaining informed consent. The investigator presents the study to an Institutional Review Boards (IRB) which is comprised of institutionally-appointed assessors of risk and informed consent. IRBs have membership from the consumer community, the scientific community and others. IRBs are free to reject research, to amend the informed consent procedure, and to demand additional protections for the subjects. Although IRBs are a legally mandated check, which can also provide resources on the ethics of research, the responsibility for conducting ethical research lies with the investigator.

### Ethics and Suicide

Much has been written about the ethics of suicide (Heyd and Bloch, 1991), and a number of philosophers, as well as physicians, have argued that suicide may be rational under some circumstances. Although US society no longer criminalizes attempted suicide, neither does it condone it. Thus, the strong current weight of ethical opinion, based on a commitment to the sanctity of life, is that usually psychiatrists ought to intervene to prevent or disrupt suicide attempts by patients. Further, according to this view, the psychiatrist's duty to intervene may justify a breach of the ordinary obligation of confidentiality (see earlier discussion) and initiation of involuntary commitment and forced treatment proceedings because of the patient's danger to self. Yet the obligation to respect the patient's autonomy requires the psychiatrist to ask whether the intent to commit suicide in a particular case is sick and justifying – even mandating – intervention or whether it is a rational decision with which the physician has no ethical justification to interfere.

In a related vein, much debate has emerged in the past few years surrounding the ethical permissibility of physician-assisted suicide (Quill, 1991). Advocates for permissibility cite unbearable pain as a justification and submit that a regimen of procedural safeguards could adequately ensure against abuse (Quill, 1993). Among these safeguards would be the presence of a terminal or disabling condition from which there is no reasonable likelihood of recovery, the existence of an ongoing physician–patient relationship, a patient capable of making decisions, and repeated and unequivocal requests by the patient for the physician's assistance in hastening death.

### Ethical Dimensions of Health System Changes

The US health care system, including its mental health components, exists in a tremendous state of turbulence and flux

at the beginning of the 21st century. The continuing quest for simultaneous achievement of the three goals of quality, accessibility and affordability continues to frustrate health policy-makers in both public and private sectors. This quest has resulted in dramatic changes in the structure of our health care delivery system, with the growing replacement of fee-for-service professionals and institutions by large managed care networks. These structural and operational changes are radically altering the financial incentives that influence provider behavior by rewarding cost containment, rather than generous provision of services.

The proper ethical stance of the psychiatrist in a changing health system is not clear, but the psychiatrist ought to be clear whether he/she is acting as a doctor or citizen. Doctors ethically and zealously advocate for getting whatever they feel is in the best interests for their patients. This may be done without regard for the bigger picture of resource allocation. For the doctor, the patient comes first.

As citizens, however, psychiatrists also have a responsibility. Society makes determinations of how big the pool of resources will be, what illnesses are covered under insurance, and how much a clinician will be paid. Psychiatrists have a unique perspective and expertise on the consequences of these decisions, and in their citizen and public policy role will do well to participate in the difficult and ethically challenging work of creating and influencing policy decisions affecting their patients, profession and society.

### Conclusion

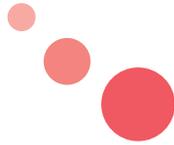

Psychiatrists can anticipate further developments in the clinical/legal interface, and that ethical challenges will be a core element of the work. This chapter has attempted to outline the most relevant legal and ethical issues and principles facing psychiatrists today. Many of these principles, such as society's value of individual liberty, are stable, and will endure throughout the entire careers of today's students. Others are in flux, such as the balance between confidentiality and public safety. Still others have yet to be identified and are unforeseen. As psychiatrists try to implement the ancient ethical principle, "first do no harm", in today's complex legal, social and financial environment, continued education and reflection in all these areas will be required of all of us.

PART  
Two

# A Developmental Perspective on Normal Domains of Mental and Behavioral Function

---

# A Psychiatric Perspective on Human Development

The miracle of human development has always fascinated physicians. Psychiatrists and pediatricians have formally studied developmental processes and used the knowledge gained from these investigations to create more effective strategies for care of patients. With the evolution of the specialty of geriatrics, interest in the developmental changes that occur after having achieved full maturation has further expanded the scope of investigations. With better understanding of the changes that predictably occur in the last half of life, it has become possible to link more effectively early precursors of illnesses to the later expression of developmental delays and deviations.

There are two classical approaches to the study of human development: the stage model and the longitudinal lines of development model. Each has distinct advantages and disadvantages. The more traditional approach is to examine each stage of development. Consequently, the unfolding of the many new capabilities of the infant is reviewed chronologically so the child as a whole can be better understood. Thinking about development as a series of stages is a particularly useful approach for clinicians. In this regard, it is traditional to address the development of 1) infants, 2) preschool children, 3) school-age children, 4) adolescents, and 5) adults. Sometimes it is helpful to distinguish phases within these groups. For example, it is common to describe adolescence as being comprised of early, middle, and late phases as illustrated in Table 7.1.

An alternative strategy used to teach development is to choose a particular aspect of human development and track it

from birth until death. This is a helpful strategy for understanding the process of development and is useful for researchers who are searching for the antecedents of characteristics that occur during later developmental periods. However, accurately charting these lines of development has proved to be difficult. Clearly, it is not feasible for a single investigator to study the extensive changes that occur over the lifespan. In the rare longitudinal studies that span at least 10 years, it is usually necessary for a series of principal investigators to work sequentially in order to achieve continuity. Consequently, most investigators become specialists in narrow age ranges of the developmental process and must work collaboratively with colleagues to link together the transitions from infancy to childhood or adolescence to the adult years.

## Theories and Models of Development

### Theories of Development

Theories are important to the study of development for a number of reasons. They organize and prioritize large amounts of data regarding infant development, indicating which are the most salient and why. Often, they also explain the importance of the early years for subsequent development, indicating how developmental issues are related to broader issues of the lifespan. Generally, they move beyond mere descriptions of behavior and attempt to explain why individuals are motivated to behave in certain ways at certain times. Finally, they may generate meaningful and testable hypotheses for empirical research.

On the other hand, theories have inherent liabilities. A selective focus on one theory may obscure others of equal or greater value. Theories also inevitably lead to oversimplification of complex processes and events. They may create biases that affect how we interpret observations and how we make inferences from these observations. The history of psychology is filled with examples of adherence to a particular point of view, making it impossible to see disconfirming information. All of these factors warrant caution about the uncritical use of theories to understand development. A useful theory is one which is developmental, integrative, contextualist, constructionist and perspectivist in nature, discounting its own absolute claim to truth and integrating as many relevant approaches as possible. An integrative developmental theory accounts for the dynamic interactions of biology (including neuroanatomy, genetics, neurotransmitters, etc.), relationships (including parental, sibling, peer and wider social

**Table 7.1 Phases of Adolescence**

Phase	Age (Years)	Characteristic
Early	11–13	Growth spurt, development of secondary sex characteristics, beginning of social separation from parents and family, greater affinity with peers
Middle	14–16	Consolidation of sense of self, increased sexual experimentation, decreased sense of threat from adults
Late	17–19	Concerns about entering adult life – work, independence, intimacy

**Table 7.2** Some Developmental Theories and the First 3 Years of Life

Theorist	Type and Focus of Theory	Stages or Phases
Sigmund Freud (1940)	Psychoanalytic drive theory (psychosexual stages)	Oral (birth–18 mo) Anal (18–36 mo)
Jean Piaget (1952)	Cognitive	Sensory–motor intelligence (first 2 yr) Modification of reflexes (birth–1 mo) Primary circular reactions (1–4 mo) Secondary circular reactions (4–10 mo) Coordination of secondary schemas (10–12 mo) Tertiary circular reactions (12–18 mo) Representational thinking (18–24 mo) Preoperational intelligence (2–6 yr)
Erik Erikson (1951)	Psychoanalytic theory (psychosocial stages)	Trust vs. mistrust (birth–18 mo) Autonomy vs. shame or doubt (18–36 mo)
Margaret Mahler (1975)	Psychoanalytic theory (separation and individuation)	Autistic phase (birth–2 mo) Symbiosis (2–4 or 5 mo) Differentiation (4 or 5–8 or 9 mo) Practising Early practising (8 or 9–12 mo) Practising proper (12–18 mo) Rapprochement (18–24 mo) On the way to object constancy (24–36 mo)
John Bowlby (1969, 1973, 1980)	Attachment theory	Phase of limited discrimination (birth–2 mo) Phase of limited preference (2–7 mo) Phase of focused attachment and secure base (7–24 mo) Phase of goal-corrected partnership (24–36 mo)
Daniel Stern (1985)	Psychoanalytic theory (sense of self-development)	Sense of emergent self (birth–2 mo) Sense of core self (2–3 mo) Sense of subjective self (7–9 mo) Sense of verbal self (18–20 mo)

groups), culture (including cultural norms for individual and collective development), and technology (including medication, informatics, etc.) (Wilber, 2000).

Table 7.2 presents a brief summary of some of the major theories of development as they pertain to the first 3 years of life. Although others could have been selected, those presented have been most influential with regard to clinical practice and research on early development. As noted in Table 7.2, the theories vary with regard to their particular focus of development, although most use stages to describe periods of discontinuity.

In this chapter, an overview of five prominent lines of human development is presented so that the reader can quickly obtain a sense of the timetable of normal development. These are 1) biological development, 2) cognitive social development, 3) emotional development, 4) social development, and 5) moral development.

In addition, a longitudinal review of periods of development that are associated with an increased risk for specific psychiatric disturbances is provided.

There has been a scientific preoccupation with defining the relative contributions of genetic endowment and environmental experience on the course of human development. While early behavioralists took the extreme view that children can be shaped almost exclusively by their environments, today evidence supports the view that genes and experience interact continuously over

time in a transactional manner that leads to the unique development of an individual. The study of environmental contributions has steadily improved through the application of more careful methods of assessment and an appreciation of the value of examining the many components of the early experience of children.

However, the most explosive advances in the understanding of human development have been made as specific gene sequences have been identified and linked to physical and behavioral outcomes. In the past decade, the pace of new gene discovery has increased exponentially as a consequence of the success of the Human Genome Project. It is now estimated that human beings have approximately 38 000 to 40 000 genes. Determining the precise number has been elusive as it has been necessary gradually to understand that human genes are more complex than the genes of simpler organisms. Specifically, many human genes produce multiple proteins. We are now learning about the degrees of genomic variability that exist between individuals, as well as beginning to understand how genes interact with each other and how they are regulated by the environment. A key focus of new research is the discovery of how the passage of time and the gradual maturation of the individual affect the expression of genes that have remained silent but potentially ominous from the beginning of fetal development. Future studies of cohorts of infants who are at known genetic risk for a trait or illness may

well identify environmental factors associated with both the expression and the suppression of gene expression.

The concept of studying development longitudinally has its origin in the studies of lives and was well established by Plutarch and popularized by Shakespeare. In many ways, biographers strive to examine the origins of adult traits through consideration of the early experiences of their particular subject. This tradition was adopted by psychoanalysts who searched for the origins of psychopathology through the exposition of a “genetic formulation”. The choice of the word “genetic” to modify a conceptual formulation based on the experience of the individual is somewhat ironic. The term has largely been abandoned, as these formulations had little to do with the function of individual genes. Nonetheless, this focus on the influence of early experience on development may well have been a foreshadowing of the importance of intense early experience on gene expression. In all likelihood, the genetic formulations of the future will focus on how experience regulates gene expression at the molecular level.

The concept of parallel yet interacting lines of development was popularized by Anna Freud (1946) who created a classical monograph that articulated nine lines of development that were well described through adolescence. Although some of these conceptual lines have been abandoned, the overarching principle of a line of development has proven to have heuristic value. Table 7.3 lists four relevant developmental lines.

Other psychoanalysts have built on her model to create parallel lines extending into adulthood. Erikson (1963) further elaborated the evolution of domains of function in the creation of his epigenetic stage model, as presented in Figure 7.1. His paradigm continues to have a strong influence on psychiatric theory,

as is well illustrated by Vaillant’s work who has extended the Eriksonian model by proposing two additional phases of the adult life-cycle, career-consolidation vs. self-absorption and keeper of the meaning vs. rigidity. The former acknowledges the importance of achieving a stable career identity in addition to the achievement of identity within one’s family of origin. The latter describes further Erikson’s concept of generativity beyond assuming sustained responsibility for building the community and for the growth, well-being and leadership of others. “Keeper of the meaning” and its virtue, wisdom, involve a nonpartisan and less personal approach to others and is to be distinguished from the tasks of a generative coach, partisan parent, or mentor from the tasks of a Supreme Court judge or chair of a historical society.

Although lines of development are attractive conceptually, they are a deceptively simplistic representation of the complex evolution of personality. The concept of “decalage” was put forward by Piaget (1952) to refer to a disengagement in the normal evolution of the parallel development of specific cognitive abilities. However, decalage is equally salient in the conceptualization of major distortions in emotional or social development. In this chapter, five broad lines of development are reviewed as they evolve over the course of the lifespan, and developmental timelines for each line are included.

## Biological Development

### Genetic Considerations

The genes that an individual possesses contain all of the information required to define the individual. Some genes have strong pen-

**Table 7.3 Kohlberg’s Stages of Moral Development**

Preconventional: Emphasis on avoiding punishments and getting rewards	Stage 1 Might makes right (punishment and obedience orientation)	Children at this stage are egocentric and experience difficulty with perspective taking when considering moral dilemmas. Motives and intentions are ignored when judging the goodness or badness of a behavior.
	Stage 2 Look out for number one (instrument and relativist orientation)	Recognition that others have different points of view occurs at this stage, but this understanding is still somewhat limited. Action is viewed as right if it satisfies one’s needs. The reason to be nice to people is so they will be nice to you.
Conventional: Emphasis on social rules and conformity to social norms	Stage 3 “Good girl” and “nice boy”	Approval is more important than any specific reward. The individual has newly acquired abilities for mutual perspective taking. In this stage, a person can anticipate what another person is feeling and knows that other people also have this ability.
	Stage 4 Law and order	The individual can now take into consideration societal laws when deciding a course of action. A behavior is considered right if it involves obeying rules established by authority.
Postconventional: Emphasis on moral principles and values	Stage 5 Social contract, legalistic	Rules are regarded as more flexible, with the aim of furthering human values. They are not absolute. This stage emphasizes fair procedures for interpreting and changing the law when the law is destructive or unethical. Ethics are considered when evaluating laws.
	Stage 6 Universal ethical principles	At this stage, there is the recognition that some principles and values (i.e., “life is sacred”) transcend laws, and that some moral obligations are valid for humanity.

entrance and express themselves in virtually all environments. This is the traditional view of the influence of genes, which if taken literally leads to the erroneous conclusion that any genetic influence is immutable. It is now clear that many genes have only partial penetrance and that there are both physical and emotional–environmental factors associated with the expression of these genes.

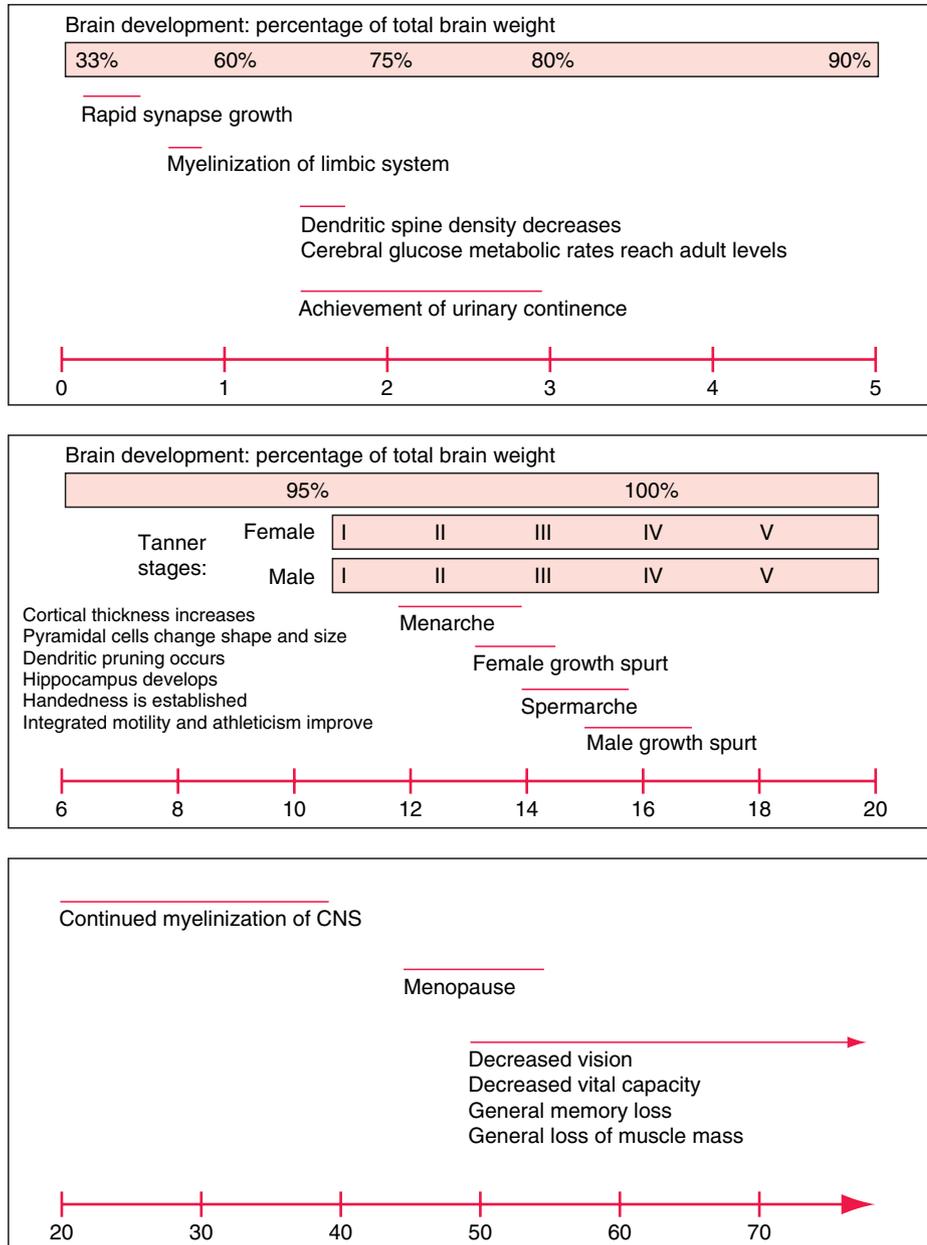

In considering the biological development of an individual, it is apparent that single genes that control such critical functions as physical growth have a high degree of penetrance in a wide range of environments. For example, while malnutrition, maltreatment and medications can retard growth, genes have a powerful impact on adult height. This is demonstrated by the observation that monozygotic twins are nearly identical in adult height. Interestingly, the same is not true of weight, which suggests that a wider range of environmental factors lead to adult variation in weight. In monozygotic twin pairs, adult weight can vary by more than 20%, although the majority of twins are actually much closer in size.

A timeline of biological development over the course of the lifespan is presented in Figure 7.2.

## Neurological Considerations

Brain growth is one of the most basic indicators of neurological development. The brain is already at approximately one-third of its adult size at birth, and it grows rapidly, reaching 60% by approximately 1 year and 90% by 5 years of age. The final 10% of growth occurs during the next 10 years with attainment of full weight by 16 years of age. The processes of myelination, synapse proliferation and synaptic pruning occur in the course of the lifespan, but they are particularly active in the first years of life when the functional structure of the brain is becoming defined. Maximum synaptic density is reached at different development time points in different brain regions. Maximum density in the auditory cortex is achieved by 3 months, whereas maximum density in the middle frontal gyrus is not reached until 15 months of age (Huttenlocher and Dabholkar, 1997). After this point, the density of dendritic spines generally decreases as glucose metabolism becomes fully developed. The establishment of biological rhythms occurs in early infancy and sleep becomes more organized and of shorter nocturnal duration. A stable pattern of temperament cannot be documented in the first months of life, but it gradually

## Biological Development

**Figure 7.2** Timeline (in years) of biological development across the lifespan.

becomes established during the second year. All of the major theories of temperament endorse the idea that temperament is rooted in biological differences (Goldsmith *et al.*, 1987). The most influential view has been that of Thomas and colleagues (1968). In the New York Longitudinal Study which viewed temperament as a child's behavioral style, the "how" of behavior as opposed to its content or motivation. This work addressed dimensions such as activity level, intensity of emotional expression, adaptability to changes in routine and the tendency to approach or avoid novel situations. This work elucidated distinct temperament clusters, the easy, slow to warm-up and difficult child. The difficult child was characterized as having a negative mood, irregular biological rhythms, slower adaptability, intensity of reactions and a negative response to novelty. Difficult children often express early behaviors that are correlated with later school problems, social difficulties and psychiatric disorders. Behavioral inhibition is

a trait that has been reliably identified after 18 months and has been associated with the Hypothalamic-Pituitary-Adrenal (HPA) axis activation and right frontal asymmetry (Fox *et al.*, 2001), the latter being predictive of social wariness at 4 years for boys more so than girls (Henderson *et al.*, 2001). During the preschool period, individual neurons and neural networks are preferentially preserved if they receive stimulation. Motor skills emerge as a reflection of the underlying neuronal development of the central nervous system.

By the age of 7 years, considerable sensory integration has occurred. Handedness has been clearly established, and brain plasticity has decreased. By 10 years of age, limitations in the ability to learn to speak an unaccented second language reflect further changes in the development of the motor linguistic pathways. In the years of adolescence, full brain weight is achieved, but myelination continues well into the fourth decade. As well, the dorsolateral

**Table 7.4 Patterns of Attachment**

Characteristics	Secure Pattern	Avoidant Pattern	Resistant Pattern	Disorganized Pattern
Distress	Open display of distress and need for comfort	Inhibited display of distress	Exaggerated display of distress	Odd or contradictory display of distress
Soothing	Effective soothing; positive greeting	No soothing; avoidance instead of greeting	Ineffective soothing; no positive greeting because of distress	Ineffective soothing; usually no positive greeting; often odd or ambivalent greeting
Anger	Little angry behavior	Displaced anger	Angry, resistant behaviors	No predictable pattern
Stress	Low cortisol secretion	High cortisol secretion	No cortisol data	No cortisol data
Strategy for obtaining comfort	Coherent strategy of seeking comfort directly when needed	Coherent strategy of minimizing distress by displaced attention	Coherent strategy of exaggerating distress to mobilize caregiver	Incoherent strategy or significant lapse in organization of strategy
Parental characteristics	Sensitive, emotionally available caregiving; balanced perspective on childhood relationship experiences	Emotionally restricted caregiving; dismissing of painful relationship experiences and their effects	Inconsistent caregiving; unintegrated emotional response to relationship experiences	No data on caregiving; unresolved losses or traumatic childhood experiences

prefrontal cortex (DLPFC) has a protracted developmental course, given that its functional specificity is not fully determined until puberty. By the end of the fifth decade, there is often evidence of the beginning of decline in specific neuronal functions, with vision and memory being particularly vulnerable. However, integrative capacities may reach a peak during the later decades.

### Endocrinological Considerations

While interesting changes in hormonal development occur in the first years of life, dramatic changes in both physical and emotional functions are triggered by the hormonal shifts associated with puberty that characterize the adolescent years. In girls, estradiol and progesterone production results in the onset of breast development, followed by the onset of pubic hair growth and vaginal elongation. Axillary hair subsequently develops during stage 3 of pubic hair development. Although there is wide variability in different cultural environments, menarche is usually attained 2 years after the onset of breast development and has been reported to occur at an average of 12.8 years of age in population studies (Zacharias *et al.*, 1976), the range is between 10–16 years. Menarche appears to be affected by nutrition, genetic endowment, general health status and environmental factors such as altitude and light. In boys, puberty begins when rising levels of pituitary hormone result in enlargement of the testes and subsequent increases in circulating testosterone. Spermatogenesis occurs after testicular enlargement at approximately 14 years of age. Pubic hair development is triggered by adrenal androgens and occurs in five stages during the course of about 2.5 years. Facial hair tends to develop between 14 and 15 years of age.

Growth hormone and gonadal hormones are both necessary to initiate the adolescent growth spurt. This occurs earlier in girls, usually during Tanner's breast stages 2 and 3, whereas in boys it does not occur until stage 4 of genital development. Both an acceleration of bone growth and a maturation of the skeletal structure as reflected by increased bone density and closing of epiphyses occur during this process.

Sexual function peaks early in the adult years in men but there is only a gradual decline in sexual function as measured by frequency of orgasm from 20 to 70 years. Women have consistent

sexual functioning throughout the childbearing years and frequently become more orgasmic in their 30s. However, decreases in estrogen levels associated with menopause usually occur between 45 and 54 years of age. Men have no comparable menopausal change in hormonal levels.

### Cognitive Development

The study of cognitive development provides a perspective on the evolution of the capacity to think. Increased cognitive abilities are an integral component required for the onset of language. Changes in thinking ultimately shape the course of emotional, social and moral development. Recent investigations of the relation of brain development to cognitive development have attempted to attribute specific developmental changes in central nervous system function with the achievement of new cognitive abilities (Casey *et al.*, 2000; Anderson, 2001).

However, the acquisition of mental abilities has been charted as an independent sequence of mental accomplishments. Piaget established the field of cognitive development, and his stage theory of the evolution of cognitive processes has dominated this field (Piaget and Inhelder, 1969). Although specific aspects of his four primary stages have been modified by subsequent empirical experiments as well as by the development of a greater appreciation of the role of emotions and context in the utilization of cognitive abilities, his careful observations and brilliant deductions have provided the framework on which much of our knowledge of cognitive development has been built. In contrast, Vygotsky (1978) provided a model of early cognitive development that placed greater importance on the influence of culture and language-mediated guidance by adults.

Piaget introduced the concept of "schemas" which he defined as units of cognition. He further described processes that result in schema modification, which begin in infancy as a child assimilates new information and accommodates to novel stimuli. A particularly important Piagetian concept has been that of a decalage within cognitive development, which refers to an unevenness in cognitive development. For example, a child may demonstrate cognitive abilities at the concrete operational stage

of development with regard to conservation of volume and at the same time retain preoperational forms of thinking such as persistent egocentrism. Such an unevenness can also be seen across lines of development. The concept of interlineal decalages is described more fully in the last section of this chapter.

Even newborns have the ability to learn through making associations between different states or experiences. There is evidence that cognitive “prewiring” exists, which allows for the perceptual capacities of infants that are necessary to seek stimulation and interaction with adult caregivers. A key capacity required for these early cognitions is recognition of the invariant features of perceptual stimuli coupled with the ability to translate these invariant features across sensory modalities. Interestingly, infants can differentiate the human voice from other sounds innately without “learning” the complex characteristics of the structure and pitch of speech.

By 2 to 3 weeks of age, cross-modal fluency is demonstrated by the ability of infants to imitate facial expression. This requires the recognition of a visual schema of a facial expression to be linked with a proprioceptive tactile schema of producing a facial expression. By 3 months of age, infants can be classically conditioned, and their interest in stimuli led Piaget to suggest this was a period dominated by attempts to make “interesting spectacles last” (Piaget and Inhelder, 1969).

By 6 months of age, associations between “means” and “ends” have been demonstrated. This is followed by object permanence, which evolves during the second half of the first year. During the second year, infants can infer cause after observing an effect as well as anticipate effects after producing a causal action. A corollary of this new ability is that they are now able correctly to sequence past events.

By the third year of life, children enter the preoperational stage. This form of thinking is more similar to adult cognition, but it incorporates magical explanations and is marked by a tendency to focus on one perceptual attribute at a time (centration). Idiosyncratic cosmological theories are common and are usually dominated by transductive reasoning, which attributes causality based exclusively on temporal or spatial juxtaposition. Throughout the preschool period, attention span and memory are limited while pretend play and fanciful thinking are common. Animism is frequently used and refers to endowing inanimate objects with the qualities of living things. Not surprisingly, children having imaginary friends and talking pets characterize this cognitive period. The preoperational stage is also the time during which explosive language development occurs. This development appears to be made possible by a genetically determined capacity for language. However, language development is clearly enhanced by experiential support and parental communication that is sensitive to the child’s ability to process new words and grammatical structure.

By age 6 or 7 years, children begin to use operational thinking. The child who has attained concrete operational thought has the ability to conserve both volume and quantity as well as being able to appreciate the reversibility of events and ideas. A shift from an egocentric perspective results in a new capacity to appreciate the perspective of others. These new cognitive skills demonstrate an ability to engage in logical dialogue and to develop an appreciation of more complex causal sequences. These new cognitive abilities are clearly required for a child to benefit from the grade school curriculum.

Adolescence results in the development of a new processing capacity that involves the manipulation of ideas and concepts.

Furthermore, the informational fund of knowledge is dramatically expanded and serves as a referent for verification of new data that are assimilated. A final major transition is possible with the development of the ability to reflect on cognition as a process. This is referred to as the development of a metacognitive capacity. Achievement of this capacity allows adolescents to understand and empathize with the divergent perspectives of others to a greater degree than was previously possible. This capacity is necessary for recursive thinking which involves an awareness that others can think about the domain of the adolescent’s own thought. These cognitive skills represent the transition into the final stage of cognitive ability, which is referred to as the use of formal operations. One capacity characteristic of this stage is the ability to understand complex combinatorial systems that require a well-developed sense of reversibilities that include inversion, reciprocity and symmetry. New levels of problem solving are achieved that include the ability to recognize a core problem or core isomorph within a more complex new problem. The adult with formal operational ability can recognize a previously successful solution and use this knowledge to develop a parallel innovative solution to the complex problem. It is important to appreciate that many adults remain at the stage of concrete operations and never develop these more advanced capacities.

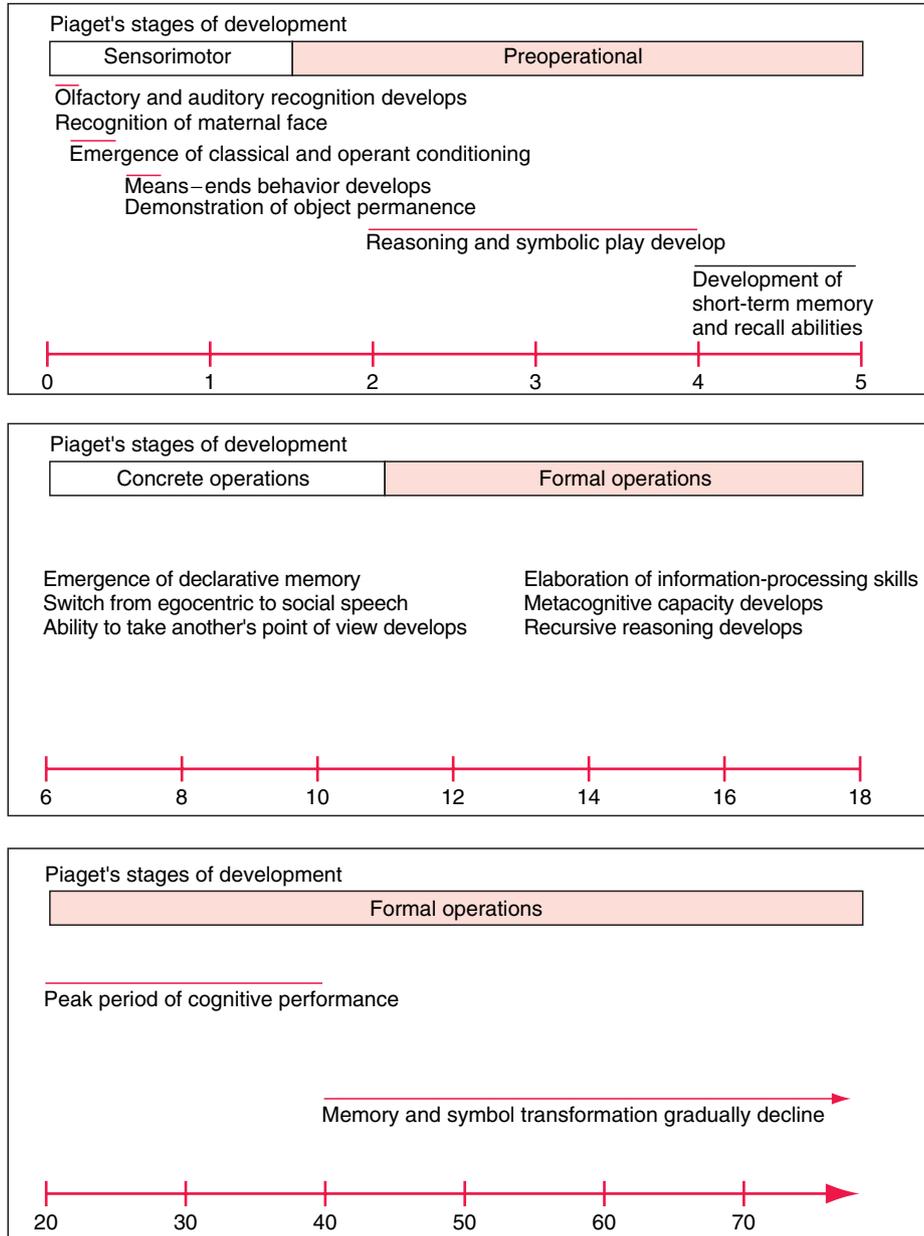

A timeline of cognitive development during the course of the lifespan is presented in Figure 7.3.

## Emotional Development

The emotional state of the newborn is largely assessed by facial expression and accompanying vocalizations. However, the communicative capacity of young infants has become increasingly well appreciated. In the first weeks of life, contentment and distress have been reliably monitored (Lewis, 1994). These primary emotions further differentiate during the first months of life. It is clear from work beginning in the late 1960s and 1970s that the infant is not a passive recipient of external influences, a *tabula rasa* or blank slate. Freud’s idea about a stimulus barrier, which was postulated to protect a young infant from overstimulation, and Mahler *et al.*, (1975) notion that the first 2 months can be conceptualized as a relatively autistic phase of development are no longer supported. By 7 to 9 months, a transition occurs that is based on the earliest attainment of intersubjectivity. At this point, infants begin to understand that their own inner experiences and feelings can be appreciated by other individuals (Trevarthen, 1979; Emde, 1984). This leads to the possibility of developing affect attunement as parents match their own behavior with the behavior of their infant, while experiencing shared internal feeling states. An infant pouting to elicit a parental response evidences the instrumental use of emotions. Social referencing is usually evident by 12 months of age, when infants turn to examine their mothers’ facial expressions at times when they are confronted with potentially fearful situations or objects (Klennert, 1984).

In the second year of life, the *rapprochement* crisis occurs, as infants become aware of their separateness from their primary attachment figure and the limitations of their control on her behavior. After the infant has attained self-cognition, new, more complex emotions of embarrassment and envy emerge that further evolve to feelings of shame, pride and then guilt by the end of the second year. Object constancy, or the ability to reduce anxiety in response to the separation from the primary caretaker, reflects the association of an emotional state with the memory of the sense of internal security provided by the attachment figure.

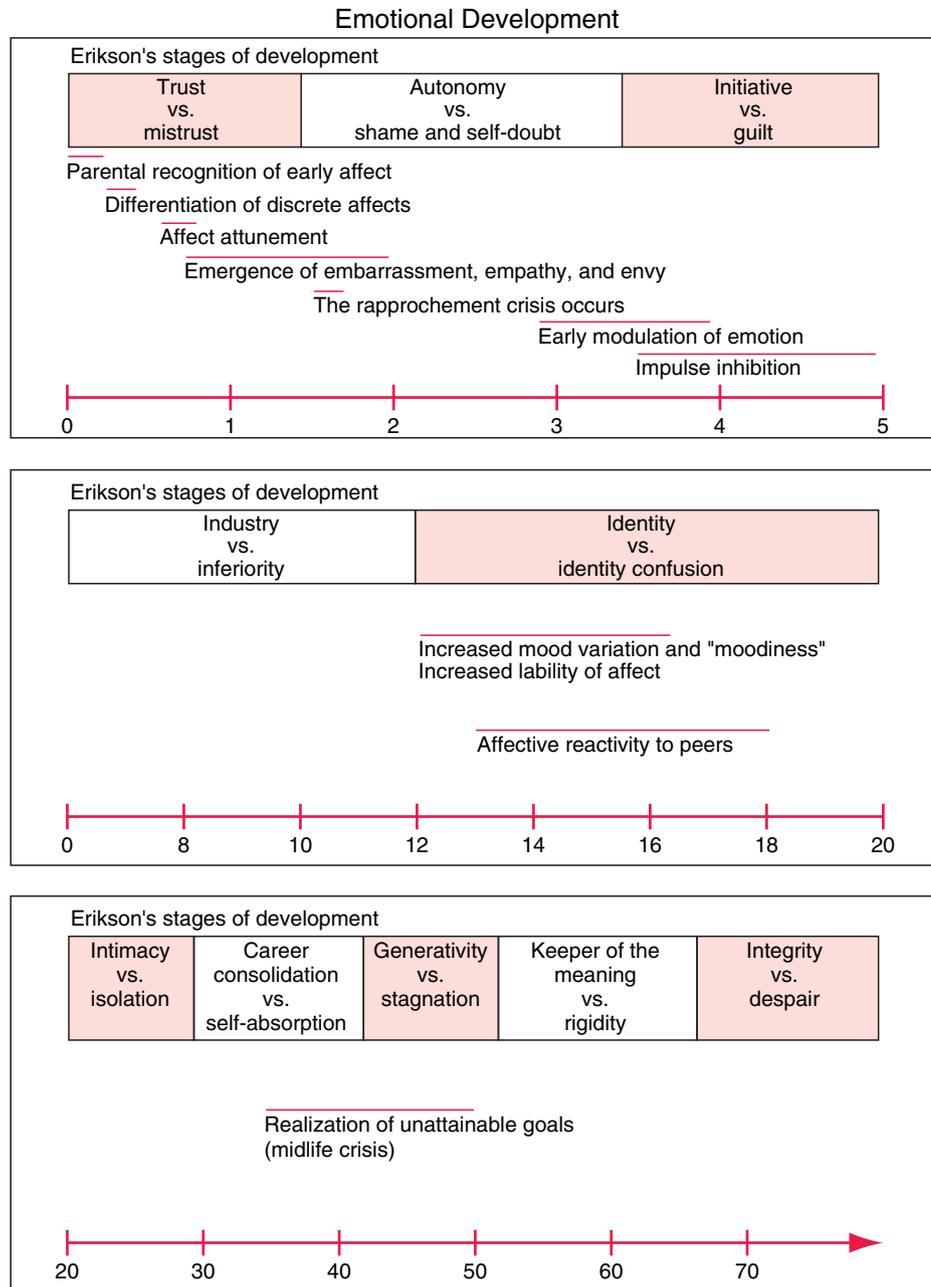

### Cognitive Development

**Figure 7.3** Timeline (in years) of cognitive development across the lifespan.

The role of implicit memory through the experience of synchrony, reciprocity and affect attunement between parent and infant in numerous modalities is substantial in early emotional development and has been related to sense of self and emotional regulation. Affect attunement between mother and infant involves an emotional interchange in which the mother matches her behavior to the infant's behavior. This matching is not merely imitative but involves some aspect of the internal feeling state that is shared. An attuned mother exaggerates her responses which allow the infant to begin to recognize his own emotional response as being separate from that of his mother's. Affective attunement appears to be an essential ingredient of empathy, intimacy, mirroring and other clinical phenomena. Fonagy's (2001) concept of mentalization is predicated on the mother's ability to promote both relatedness and separateness in the infant through

her marked affective responses. Mentalization is the capacity of the infant to ascertain the mental states of the self and of others. It describes a process of the infant's recognition that someone else has a different mind from his own. It is acquired through repeated experiences in judging facial expression, tone of voice and other nonverbal communications. These experiences are encoded in implicit (nondeclarative) memory and in parallel with explicit (declarative) memory which has a temporal dimension. This is a critical accomplishment in that it establishes the basis for secure attachment. Conversely, the failure to mirror the child's affective state often results in disorganized attachment through problematic internalization and therefore less than optimal identity formation and individuation. These infants are at extreme risk for attentional, behavioral and emotional disturbance in early childhood often with enduring consequences in

**Figure 7.4** Timeline (in years) of emotional development across the lifespan.

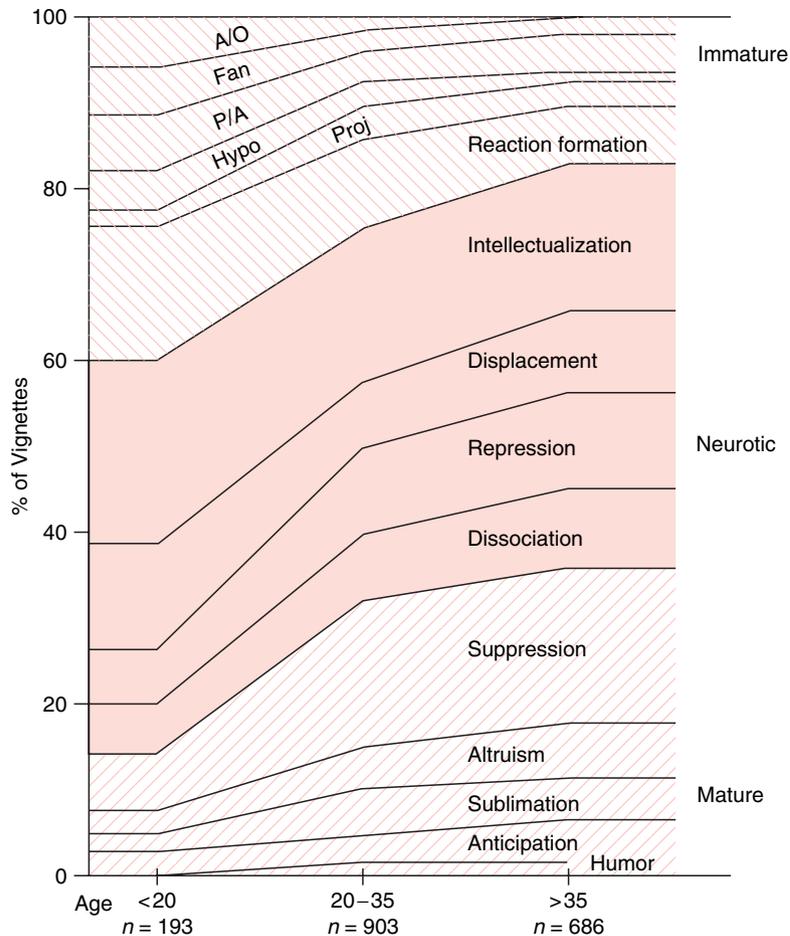

development at later stages of childhood, adolescence, and even adulthood.

During the preschool years, children begin to learn the nature of the relationship between emotions and behaviors. They begin to understand the culturally defined rules associated with affect expression and consequently begin to mask their emotions. This is also the period when the Oedipus impulses are most evident and children must deal with both their conscious attraction to the parent of the opposite sex and their fear of potential retaliation from the same-sex parent.

As children move into the school years, they experience the full range of adult emotions, although there is at least a qualitative sense that during the prepubertal period there is less intense expression of affect. Although sadness is easily recognized from the second year of life, prolonged periods of depressed affect are

rare during this period. However, temperamental styles tend to emerge and, specifically, behavioral inhibition can become more clearly appreciated within the context of increasing social and educational demands (Kagan *et al.*, 1989).

In adolescence, emotions are more intensely displayed. Capacities for abstraction permit adolescents to consider factors outside their own immediate emotional experience and they are, therefore, more emotionally interactive than at any previous period of development. Emotions in adolescence exert an increasingly important role in guiding behavior and become a sustaining motivation for behaviors and mediate relationships with peers and family. During this period, there is an emergence of a greater incidence of affective disorder and anxiety. Similarly, there is a dramatic increase in suicidal behavior that is in part associated with cognitive ability. At this point, there is a greater reflection

**Figure 7.5** Shifts in distribution of defensive vignettes shown by 95 subjects at adolescence, young adulthood, and middle age (A/O indicates acting out; Fan, fantasy; P/A, passive aggression; Hypo, hypochondriasis; Proj, projection). on aspects of existential crisis, which can be experienced from more complex vantage points.

A perspective on the evolution of defense mechanisms as regulators of affect suggests that a hierarchy of more sophisticated and effective defensive strategies emerge throughout adolescence and adulthood (Vaillant, 1993). Figure 7.5 illustrates the evolution of defense mechanisms during adulthood. A timeline of emotional development during the course of the lifespan is presented in Figure 7.5.

### Social Development

It has become widely appreciated that infants are socially interactive from the first days of life. The strong tie that parents feel for their infants has been referred to as the parent–infant bond. Between 7 and 9 months of age, infants develop separation protest and a negative reaction to the approach of a stranger. During the second half of the first year, the attachment of the infant to his or her parents evolves. The primary role of the attachment figure is the provision of a secure base from which the infant can begin to explore a wider social environment (Ainsworth *et al.*, 1978). It is within the context of the attachment relationship that the first Eriksonian state of “basic trust” is achieved.

Attachment is the affectional connection that a baby develops with its primary caregiver, most often the mothering per-

son, which becomes increasingly discriminating and enduring. It is the availability and responsiveness of the mother or other caretaker that is ultimately the most influential in determining the strength and safety of the attachment system. The infant’s attachment behavior is an attempt to bring stability, predictability and consistency to his or her world through drawing the mother closer. There is an extensive literature on and theories about what occurs in the mental life of infants and children during the attachment process. At the risk of over-simplifying, the most intriguing and clinically useful of these theories focuses on the process of internalization. Internalization is the mechanism for building psychological structure. More specifically, it is an attempt to describe how the child achieves an increasingly stable and sophisticated view of himself and the world around him. The acquisition of internal representations of the infant and those who care for him are the building blocks of identity formation and individuation. The former includes the capacity for relatedness and cohesiveness of self and the latter refers to the establishment of autonomy or separateness. Table 7.4 summarizes patterns of attachment. There is an extensive literature on attachment patterns and subsequent development of psychopathology (Kay, 2005).

By 18 months, play begins to be more directed toward peers, but this does not become the predominant form of play until the third year. Along with the striving toward autonomy that characterizes Erikson’s second stage, there emerge more negative

**Table 7.4** Newborn States of Arousal

States of Arousal	Characteristics
Quiet sleep	Regular respirations, limited movements
Active sleep	Rapid eye movements, irregular respirations, large muscle paralysis Most common state in newborn period
Drowsy	Transitional state between sleep states and waking states
Quiet alert	Sustained gaze, limited movements, maximal alertness Limited in first few weeks
Active alert	Active movements, mild distress occasionally
Crying	Unable to attend to other stimuli

ffective interactions within the context of the attachment relationship. This phenomenon is widely recognized within the popular culture as the arrival of the “terrible twos”. However, the quality of the attachment relationship earlier in life has been shown to predict better preschool social adaptation and a stronger sense of self-worth. Included in it is the observation that patterns of social dominance become established during the third year of life and that insecurely attached preschoolers exhibit more conflict and aggression in the establishment of their social status. These early social strivings are compatible with Erikson’s third stage, which has as its central developmental objective the achievement of initiative within the context of potential failure and guilt.

Gender differences emerge by 2 years of age. Boys are more aggressive and tend to play with toys that can be manipulated. Girls prefer doll play and artwork. However, boys and girls also engage in both types of play. By the end of the third year, gender preference in play has emerged, and the preference is to play with children of the same sex. This preference remains throughout childhood. Associative play, which refers to play that involves other children and the sharing of toys but does not include the adopting of roles or working toward a common goal, becomes more prominent during the preschool years. Cooperative play also emerges along with a strong tendency to include elements of pretend play into the cooperative sequences. The cultural context begins to shape the nature of social interaction even at these earliest stages of development.

During the school years, the role of peers in shaping social behavior becomes predominant. Small groups form, and the concept of clubs becomes important. Shared activities, including the collection of baseball cards or doll clothes, are a common

**Table 7.5** Ideal Task Accomplishment to Attain Adolescence

- Disengagement from parents along with ability to make decisions about onw’s life
- Value system respecting self and others
- Solid employment, possibly beginning a vocation
- Fixed sexual identity
- Long-term sexual relationship

and important characteristic of this period. Sharing secrets and making shared rules also serve as organizing social parameters. Social humor develops, and appearance and clothing become an important social signaling system. It is a time of practicing and developing athletic, artistic and social skills that are associated with Erikson’s fourth stage of achievement of industry within the context of a sense of potential interpersonal inferiority.

In adolescence and throughout the adult years, social and sexual relationships play a complex and powerful role in shaping experience. With the onset of strong sexual impulses and increasing academic and social demands in adolescence, the role of peer influences in shaping both prosocial and deviant behavior becomes powerful. Adolescence is the period during which Erikson described the central objective to be the establishment of an individual identity, and there has been wide acceptance of this sense of self-occurring within the context of the social and cultural experience. Table 7.5 describes the tasks of adolescence.

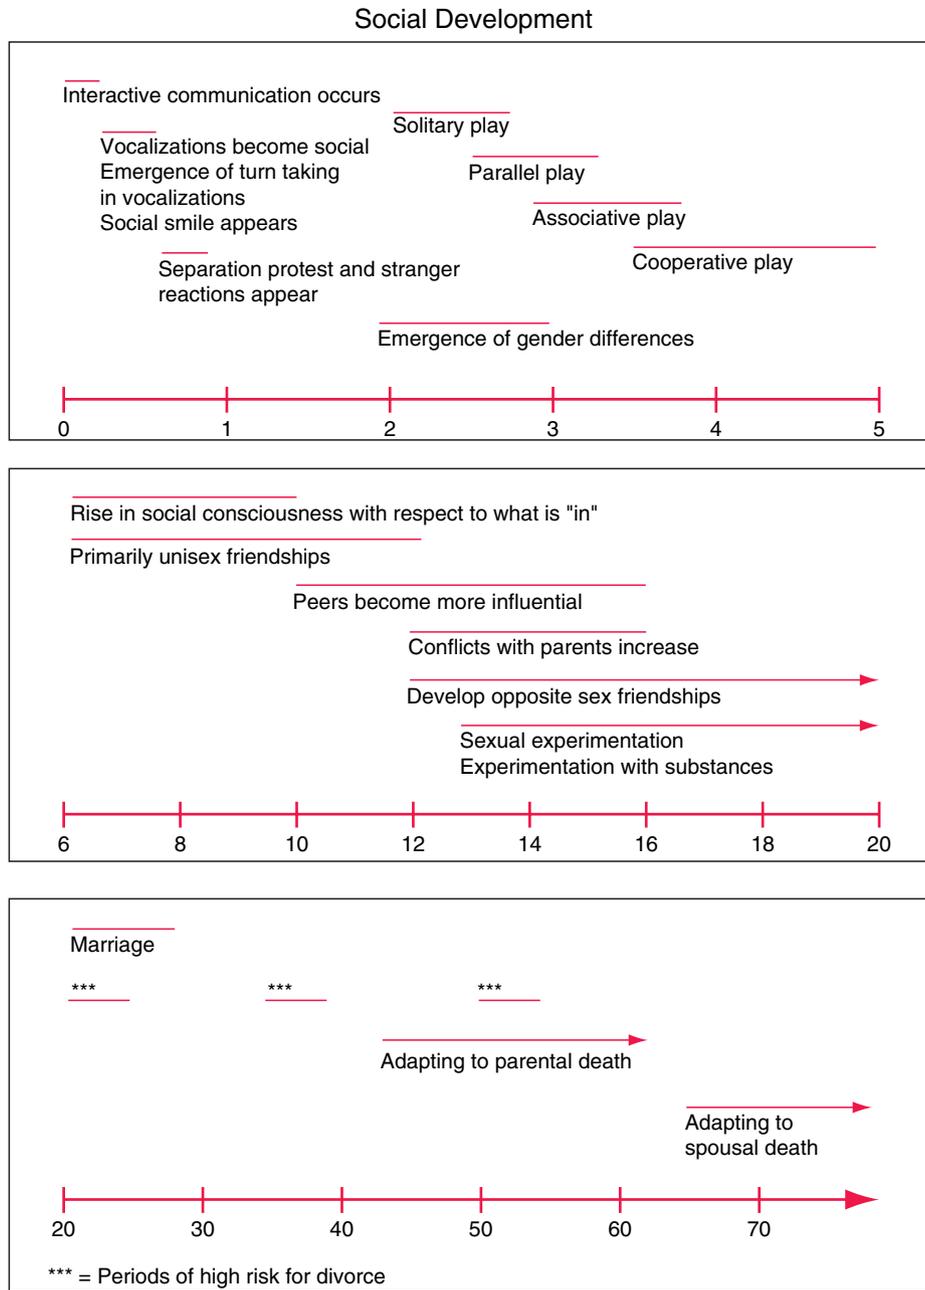

The roles of adulthood are complex and focused on the most basic issues of marriage, parenting, working and dealing with death. The key to understanding the sequential nature of adult development lies in the appreciation of both the relative complexity and the inner threat of the tasks and commitments that must be mastered. The twin anxieties of young adulthood involve the abilities to commit to one person and one job without sacrificing autonomy. Prospective studies suggest that by midlife a major developmental task for women is to achieve traits of independence, rationality and self-direction. Similarly it becomes equally enriching for men in midlife to achieve warmth, emotional expressiveness and relatedness (Vallant, 1977; Guttman, 1977). Individuals who achieve generativity almost always have evolved to stages of identity formation, achievement of intimacy and career consolidation. It is important to note that within the various Eriksonian stages, a selfless generativity reflects a clear capacity to care for and guide the next generation. The final stage of adult development, achieving integrity, may be compared to putting a garden to bed for the winter. Reflection on one’s life facilitates coming to terms with it and accepting the past.

A timeline of social development during the course of the lifespan is presented in Figure 7.6.

## Moral Development

The newborn infant lives in an interactive world but one that is free of moral directives or structure. However, by the second year of life, the emergence of “moral emotions” such as empathy, pride, embarrassment, shame and guilt demonstrates that the beginning of a code of moral behavior, in the most primitive sense, is being established. Moral emotions evoke a sense of shared experience with important others that is central to the process of moral internalization. By 36 months, most children demonstrate the internalization of parental standards even when their parents are not available to provide cues or reinforcement. The importance of emotions in the early evolution of moral behavior during the preschool years represents a distinct departure from the more traditional perspective that moral development does not occur until the establishment of concrete operation.

During the school years, the importance of rules and adhering to them becomes well defined. The moral code tends to be one of absolutes with strong consequences for transgressors. Extreme examples of children turning their parents into authorities because of political resistance provide a sobering perspective on the strength of the convictions of some children. However, for most boys and girls during this period, interpersonal relationships with

**Figure 7.6** Timeline (in years) of social development across the lifespan.

peers or siblings are a consideration in the determination of “chosen outcomes” when situational paradigms designed to clarify moral priorities are presented (Smetana *et al.*, 1991). There appears to be some gender difference in the quality of mercy demonstrated during the school years. Girls are more concerned with aspects of human interaction and boys preferentially seek blind justice.

The later evolution of moral principles is a complex process. With the development of abstract reasoning, adolescents progress through Kohlberg’s (1964) stages of conventional morality, which entail meeting the expectations of others (stage 3) and subsequently accepting the maintenance of societal norms and rules as an appropriate standard (stage 4). These stages do not progress in a strictly sequential manner. Stages 5 and 6, which ultimately lead to the conviction that moral principles of justice should supersede those of human-made laws, have not been eas-

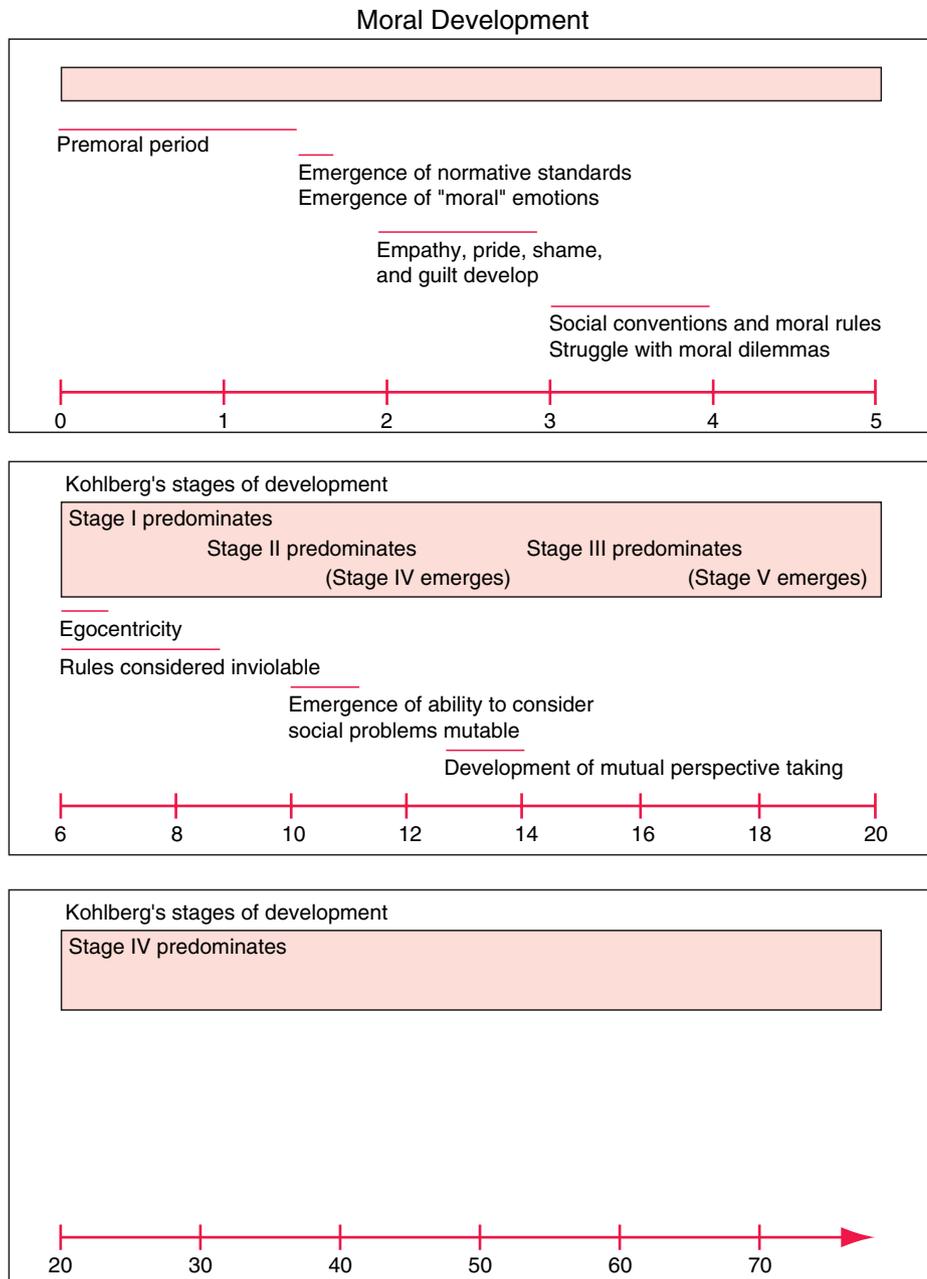

ily codified either, given the influence of complex emotions on behavior and the well-documented moral inconsistencies that occur over the course of adult development (Gibbs, 1979).

A timeline of moral development during the course of the lifespan is presented in Figure 7.7.

## Developmental Psychopathology

### Risk and Protective Factors

The risk and protective factor model is a paradigm that facilitates the understanding of developmental deviations. It can be applied at any stage of development. Risk factors have been divided into three large categories: those at the level of the individual, the family and the community.

**Figure 7.7** *Timeline (in years) of moral development across the lifespan.*

The first category of risk factors is defined at the level of the individual. Both physical and emotional considerations are relevant. Examples include atypical genetic polymorphisms, deficits in perception and high levels of generalized anxiety. Variable possibilities for adaptation exist, but for a trait or condition to be considered a risk factor there must be a demonstrated increase in the probability of subsequent emotional or behavioral disorder associated with the factor.

The second category of risk factors is conceptualized at the level of the family. One of the classic examples of a familial risk factor is a parent with a serious mental illness. It is difficult to define the mechanism by which this risk is transmitted. Each parent provides exactly one-half of the genome of the child. However, parents are also in a powerful position to shape the early environment of their children. The full range of family risk factors is quite broad, and extends beyond the influence of single individuals within the

family to include the impact of family dynamics which influence the development of the child. For example, a scapegoated child in a family environment that tolerates overt child maltreatment is at particularly high risk for the development of psychopathology.

The third category of risk factors is defined at the level of the community. Discrimination based on ethnic or racial status falls into this group of risk factors, as does social disadvantage. Although there is little controversy regarding the negative consequences of discrimination and poverty, the quantification of this risk has been problematic. Community risk factors rarely occur in the absence of individual and familial risk factors, making it difficult fully to understand their specific influence. Table 7.6 elucidates some important developmental risk factors.

One strategy that has been used to determine the overall risk for developmental psychopathology is to add up the specific factors

**Table 7.6** Development Risk Factors

Risk Factors	Biological Effect	Psychological Effect	Social Effect
Poverty	Malnutrition	Attachment problems	Family dysfunction, environmental threat
Child maltreatment	Trauma effects, failure to thrive	Disturbed affective responsiveness, poor social interaction, attachment problems	Antisocial behavior and conduct disorder
Maternal substance abuse	Impaired prenatal central nervous system development	Inconsistent and unpredictable parenting, attachment problems	Family dysfunction
Premature birth and serious illness in infancy	Delayed or disrupted central nervous system development, increased development disorders	Increased parental stress	Environmental destabilization

that a child must deal with, creating an adversity index. This has been accomplished for young children (Sameroff, 1986) as well as applied to risk factors occurring later in development (Rutter, 1985a, 1985b). Most individuals can cope with a small number of risk factors, particularly if protective factors are also present. However, under the weight of multiple risk factors, most individuals begin to show signs of disturbance. Sophisticated research designs have been developed to estimate relative contributions (Topolski *et al.*, 1997). Curiously, the quantitative effects of protective factors have been less extensively studied, although investigations into the life course of resilient individuals provide some understanding of these factors (Mrazek and Mrazek, 1987).

Resilient children represent one of the most fascinating opportunities to understand the mechanisms by which risk and protective factors interact. The study of the children of mothers with schizophrenia or bipolar disorder has been an area of investigation that is of particular interest to psychiatrists. Perhaps this is because these children have been perceived to have had both a high risk for the inheritance of genes that confer poor adaptive skills and the misfortune of having a parent with impaired capacities for sensitive responses to their early developmental needs. What is striking is that some of these children turn out to be productive and happy adults despite what appear to be overwhelming odds.

In adulthood, resilience depends on the ability to find, use and internalize social supports. Throughout the life span, maturity of ego defense is an important characteristic of resilience (Vaillant, 1993). The use of mature defenses has been associated with health – whether health was defined as the presence of successful objective life adjustment, the absence of psychopathology, or the achievement of subjective self-satisfaction. The number of risk and protective factors appears to be more significant than the specificity of stressors.

A timeline of the development of psychopathology during the course of the lifespan is presented in Figure 7.8.

### High-Risk Periods for Psychopathology

Psychiatrists who treat children and adolescents are particularly aware of the precursors and onset of psychiatric illnesses. Two examples of age-specific vulnerabilities will be discussed, but Figure 7.8 gives an overview of the periods of most probable onset for many of the major psychiatric disor-

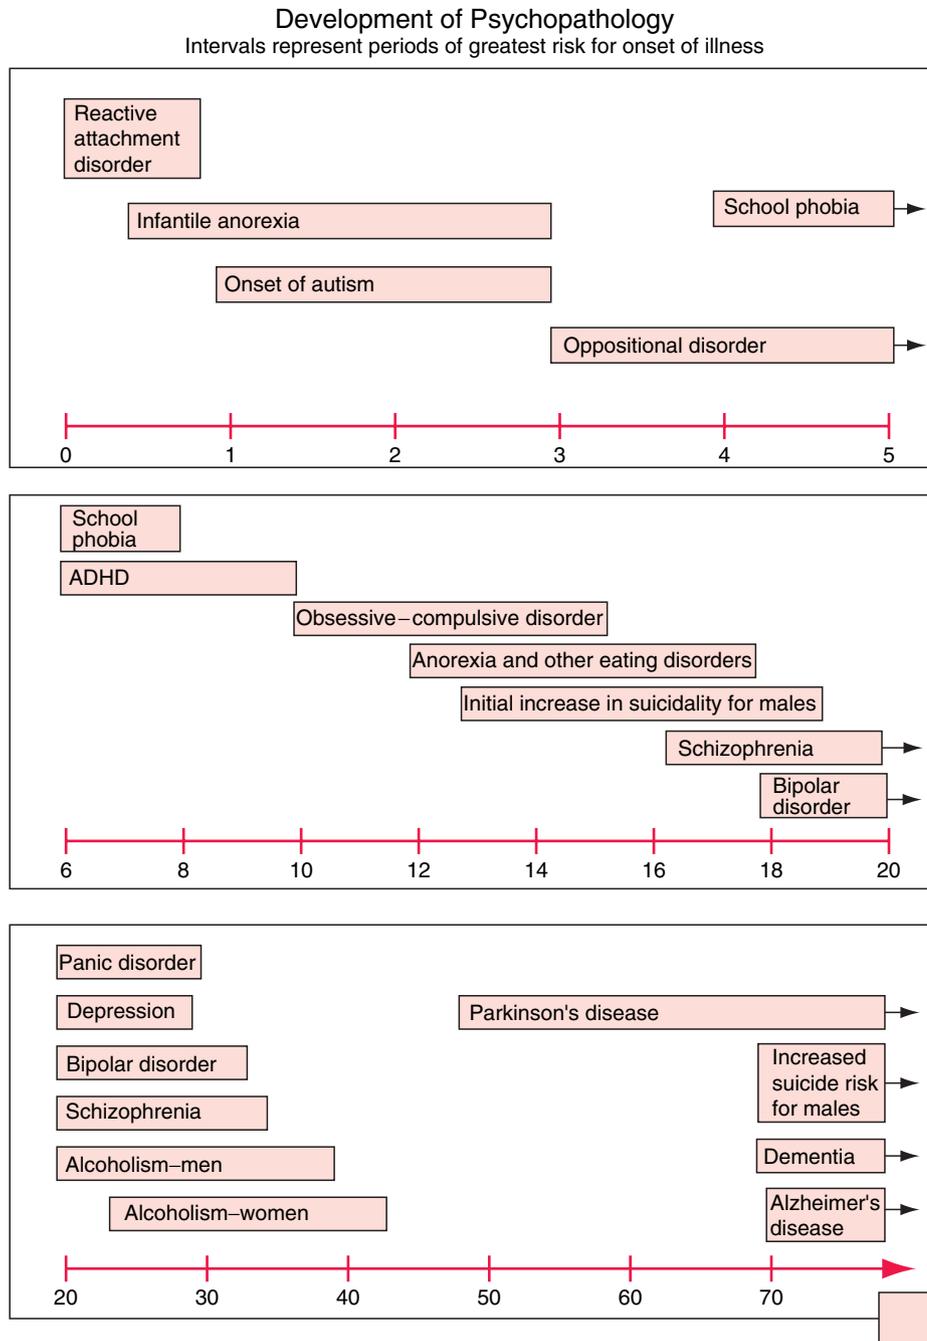

ders. The first example is autism, which is unusual in both its invariant early onset and its striking presentation. The second is suicide, which is particularly interesting because of episodic periods of particularly high risk during the developmental course.

Autism is a disease of early onset that has been shown to have a strong genetic basis. Nevertheless, the role of the environment in affecting the onset of autism is still striking, as demonstrated by the quite dramatic variability in the symptom presentations and ultimate adaptations of monozygotic twins. Autistic children appear normal at birth. During their first months of life, they begin to develop severe deficits in their capacity to form relationships and communicate with others. Once fully expressed, autism has a devastating impact on the subsequent development of afflicted children. What is perhaps most striking is the inevitability of early expression as there are no examples of onset later in childhood or adolescence.

Suicide provides a sharp contrast to autism. Suicide is highly associated with mental disorder in general and affective disorder in particular. It has also been shown to be moderately heritable. Whereas the onset of suicidal thoughts does occur in rare cases in the preschool period, the capacity to commit suicide increases with age. After puberty the rate of suicide increases nearly tenfold. The underlying explanation for this dramatic increase is complex and involves consideration of risk factors at the level of the individual, family and community. However, the ultimate life course pattern is striking, as there is a second dramatic increase in suicidality in the later years of life. The explanation for this second increase usually focuses on the increase in medical problems of the elderly, but the multiple emotional losses of these years also provide a vulnerable context for depression and despair.

### Interlineal Decalage

Piaget and Inhelder defined uneven developmental progress of specific cognitive abilities as a decalage (1969). Psychiatrists must often help patients deal with a decalage across lines of development. Although this chapter is largely devoted to the explanation of normal development, there has been a systematic effort to illustrate how deviations in development may lead to the onset of developmental psychopathology. Normality can be defined as a multilinear progression of development without a decalage, or unevenness of progress, across any of the primary domains of

**Figure 7.8** Timeline (in years) showing the development of psychopathology across the lifespan.

function. Normal children learn to think, to make friends, to deal with intense affects, and to honor the customs of their society. Problems occur when development is uneven. The patterns of these interlineal decalages are varied and their complexity is in large part one of the persistent areas of fascination for psychiatrists. To illustrate this process, two straightforward decalages are discussed. Finally, a more complex example of a severe arrest in development is presented.

Cognitive delays can result in a decalage in which a teenager has the mental capacity of a second-grader while having the sexual urges and emotional swings of a normal adolescent in high school. The cognitive ability of such a teenager may not be perceived as abnormal in the context of a protected classroom. However, within the general population, he will be clearly labeled as

deviant and will be at high risk for experiences that will place him in jeopardy for negative social and academic outcomes. Beyond dealing with the obvious limitations in achievement, there are also emotional risks to be considered if intellectual limitations cannot be placed within a context that protects such an adolescent from ridicule and humiliation.

Emotional delays provide a similar potential for a variety of decalages. A child who is cognitively normal or even precocious may remain emotionally immature. The decalage can be widened if intensive academic effort and subsequent successes become the predominant strategy that the child develops for dealing with social awkwardness or peer rejection. Temper tantrums that were expected in the early years become less easily tolerated in the child “genius” who repeatedly demands to have family

and social events orchestrated on her or his terms. In more severe cases, frustration and despair may interfere with adaptation in the same way that they do in the child who is cognitively delayed.

If a domain of function becomes arrested, the decalage becomes more severe. In these cases, overt psychopathology often results. A clear example is the development of conduct disorder and, subsequently, antisocial personality disorder. In these individuals, physical, cognitive and social developments appear to be progressing well, but a specific deficit in the development of moral judgment occurs. In some cases, the deficit is best described as the persistence of an immature sense of right and wrong, but in other adolescents there is a deviant development of amorality that is abnormal at any stage of development. Given the resistance of adults with antisocial personality disorder to current treatments, there is a strong case for focusing on the origins of this developmental decalage with the expectation that earlier intervention may be more effective than later efforts to treat.

### The Psychiatrist as a Developmentalist

All psychiatrists inevitably become students of development. The life histories of their patients demand developmental formulations to achieve a sense of understanding of the origins of the presenting symptoms and disturbing behaviors that bring the patients to psychiatric treatment. Perhaps one of the most poignant examples is Huntington's chorea. The gene that causes this disease has been identified, and it is possible to know accurately whether an infant is destined to struggle with the symptoms of this crippling disability many decades in the future. Yet it is the life experiences of this individual that shape many of the coping strategies that determine the ultimate outcomes of these future struggles. Anticipating the challenges of later life and understanding the origins of the strengths and weaknesses of each patient are at the core of the therapeutic process, whether it involves influencing the balance of the central neurotransmitters or identifying and supporting available community resources.

# Psychopathology Across the Life-Cycle

Psychopathology is the study of the nature and causes of mental disorders. Because definitive etiologies for most mental disorders have not been identified, psychopathology for the most part is focused on the myriad manifestations of psychiatric illness. An elusive concept itself, mental disorder has been defined in the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR) (American Psychiatric Association, 2000, p. xxxi) as “a clinically significant behavioral or psychological syndrome or pattern that occurs in an individual and that is associated with present distress (e.g., a painful symptom) or disability (i.e., impairment in one or more important areas of functioning) or with a significantly increased risk of suffering death, pain, disability, or an important loss of freedom”.

The manifestations of psychiatric illness can be grouped into five broad domains of human functioning: 1) consciousness, orientation, memory, and intellect; 2) speech, thinking, perception, and self-experience; 3) emotions; 4) physical functioning; and 5) behavior and adaptive functioning. These five areas encompass the processes by which humans know about themselves and the world around them; how they think, reason, learn, and express themselves; how they feel and express these feelings; how they perceive their bodies and experience their sensations and essential functions; and how they act and react to both internal and external stimuli.

In this chapter, we discuss the ways in which psychiatric illness presents across the life-cycle and in which the manifestations of disorder may vary according to the patient’s developmental life stage (e.g., infancy, childhood, adolescence, adulthood and late life). We also discuss variation by gender, because psychiatric disturbance often takes different forms in men and in women. Fundamental to our discussion is the notion that different life stages (and genders) are associated with differential incidence and prevalence rates of particular mental disorders as a result of the developmental tasks of the epoch and corresponding stressors (Rutter, 1989a). Thus, developmental considerations may help to explain both the origins of individual disorders and their course (Rutter *et al.*, 1994). In addition, age appears to have a pathoplastic effect on the manifestations of psychiatric illness such that the same disorder may have different manifestations at different ages.

## Continuity, Persistence and Progression Across the Life-Cycle

Epidemiological research suggests that considerable stability or continuity of mental disorders can be observed from childhood into adolescence, at least for broad diagnostic groupings.

In particular, behavior disorders in childhood are associated with increased risk of behavior disorders in adolescence, especially for boys, and childhood emotional disorders are associated with increased risk of adolescent emotional disorders, especially for girls (Costello and Angold, 1995). The more severe the disorder, the more likely it is to persist (Cohen *et al.*, 1993a). In addition, epidemiological surveys of adults indicate that the age at onset of disorders for many patients was during adolescence, further reinforcing the notion of persistence or progression of disorders from childhood across the life-cycle (Burke *et al.*, 1990).

## Stress-diathesis Model of Psychopathology

Theories of the causes of mental disorders are many and are the subjects of other chapters. For simplicity, we take the position that etiology in psychopathology is multifactorial. Most mental disorders are likely to be caused by both a predisposition or vulnerability at the level of brain biochemistry and experience with acute life events or chronic stressful life circumstances. Such a model helps to explain why a person with a strong family history of depression, for example, may be asymptomatic for long periods but may experience depression after a loss.

## Pathoplastic Effects of Age

Age appears to influence psychopathology in three ways (Table 8.1). A few mental disorders appear almost to be age-specific and not to occur outside a certain age range. Feeding disorder of infancy or early childhood (failure to thrive) is a disturbance restricted to the first several years of life because of a child’s total dependence on caregivers for food during this time. Dementia of the Alzheimer’s type is much more common after the age of 65 years; few cases develop before age 50 years.

More commonly, disorders that may occur at virtually any age have an usual onset at certain stages in life. Mental retardation, learning disorders, disruptive behavior disorders and elimination disorders, among others, usually have their onset and are first diagnosed during childhood. The median age at onset for

**Table 8.1** Pathoplastic Effects of Age

Age specificity of disorders
Usual age at onset
Age effects on symptom expression

the first psychotic episode of schizophrenia is in the early to mid-twenties for men and in the late twenties for women (American Psychiatric Association, 2000).

Most mental disorders can occur at various times in life's stages. Some of these are expressed differently depending on age. For example, although the core symptoms of major depression are the same regardless of a person's age, in children somatic symptoms, irritable mood and social withdrawal may be especially common. In depressed elderly persons, cognitive symptoms such as memory loss, disorientation and distractibility may predominate.

## Problems of Childhood

### Individual Differences

Children differ from each other in ways that affect their psychological functioning from birth. They differ in intelligence, in temperament and in genetic endowment for both risk for and resilience against mental disorder.

Intelligence is the ability to reason, plan, think abstractly, solve problems, understand and learn. Average intelligence is associated with a score of 100 (IQ) on a standardized intelligence test. About 67% of children have IQs between 85 and 115 and about 95% between 70 and 130. Estimates of the heritability of IQ range from 0.4 to 0.8 (Plomin, 1990) indicate that heredity plays a larger role than environment. Higher intelligence is correlated with successful adaptation in life, and substantially reduced intelligence is associated with developmental and behavioral problems and functional impairment (see the discussion of mental retardation).

### Types of Problems

Psychopathology in childhood falls into four major groups of problems (Table 8.2). Many of the disorders of childhood appear to be severe forms of problems that are more or less continuously distributed, common and "normal" occurrences. Thus, clinical depression may appear to be a severe form of sadness and disappointment, conduct disorder a severe form of aggressiveness, and anorexia nervosa a severe form of adolescent dieting and dissatisfaction with body shape (Rutter and Sandberg, 1985).

Estimates are that 5 to 15% of 9- to 10-year-old children suffer from an emotional or behavior disorder of sufficient severity to cause impairment in everyday functioning (Cox, 1994). The co-occurrence of several disorders (i.e., comorbidity) is common in childhood (Caron and Rutter, 1991). As can be seen in Table 8.3, comorbidity both within and between disorder types can be observed.

### Developmental Problems

Childhood is a time of growth, physical and social maturation, and the acquisition of skills necessary to deal independently and

successfully with the environment. Children who are greatly delayed in their development or who never acquire the requisite skills or maturity associated with their developmental stage have developmental problems. Developmental disorders fall into five main types: intellectual, learning, motor skills, communication and pervasive developmental disorders.

The most severe developmental problems are evident in infancy. For example, the infant with autism may manifest limited eye contact, facial responsiveness and smiling, and may be difficult to hug or may appear to dislike physical contact. Restricted social relationships emerge, however, after the third or fourth year of life. For children with other pervasive developmental disorders, infancy may be normal, with the onset of the abnormal behavior occurring months or even years after birth. In milder forms, such as Asperger's syndrome (Tantum, 1988), in which communication skills are spared, a pervasive developmental disorder may not be recognized until preschool or the actual beginning of school. The course after diagnosis is variable, depending on the subtype.

### Emotional Problems

The emotional problems of children involve anxiety and depression. Although these problems have counterparts in adults, children frequently experience and express their disturbances of feelings or emotions differently from adults. Because of their more limited vocabulary and understanding of emotional life, children may not express their emotional distress verbally as well as some adults do. Thus, even in the emotional disorders of childhood, disturbances in behavior and in physical functioning are apt to be prominent in the clinical presentation. Children are not unlike so-called alexithymic adults, whose expression of emotions is indirect and nonverbal.

Some children may be excessive worriers in general. They may worry about school performance, athletic prowess, appearance and popularity, parental expectations, potential catastrophic events, and so on. Children who worry excessively are said to have generalized anxiety disorder. Moody periods are common in children, but children may also exhibit prolonged and persistent disturbances of mood, usually depression.

The manifestations of mania in younger children may involve irritability, emotional lability, or admixtures of dysphoria and hypomania, as well as more typical symptoms of hyperactivity, grandiosity, pressure of speech and distractibility (Carlson, 1990; Strober *et al.*, 1989). As many as one-third of children with major depressive episodes may show bipolar disorder by adolescence (Geller *et al.*, 1994). Early-onset bipolar disorders may have a poorer prognosis than later onset disorders. Childhood major depressive disorder also appears to

increase the risk for the development of personality disorders in young adulthood (Kasen *et al.*, 2001).

### Behavior Problems

Behavior problems in children fall into the general groupings of oppositional behavior, hyperactivity, excessive aggressiveness and conduct disturbance. An appropriate degree of control over behavior is a necessary development for a child to function in a family, in school, and with peers.

### Disturbances in Physical Functioning

A number of developmental tasks of childhood involve primarily physical functions. These include developing proper eating and sleeping habits (Wolke, 1994), bowel (Hersov, 1994) and bladder (Shaffer, 1994) control and sexual identity (Paikoff and Brooks-Gunn, 1994). Disturbances may occur in these functions during childhood.

Table 8.4 summarizes the estimated prevalence and sex distribution of DSM-IV-TR mental disorders seen in children.

### Problems of Adolescence

Adolescence is the period of life between puberty and age 19 years. For the great majority of children, the physiological events of puberty signify the end of childhood. Achievement of financial independence from the family of origin through work and formation of love relationships outside the family usually signify the end of adolescence and the beginning of adulthood. In the modern world, these goals may not be attained until the early or middle twenties or later. There are many important developmental phases in adolescence. Although moody, confused and rebellious “adolescent turmoil” is no longer considered the norm for young people, some emotional troubles are fairly common. These may turn out to be symptomatic of nothing more than the stresses and strains of normal development, or they may be the early signs of significant psychological disturbance.

### Types of Problems

Common problems of adolescence are listed in Table 8.5. Rarely, schizophrenia may have a late adolescent onset. As might be expected, comorbidity is common among disorders of adolescence. Table 8.6 summarizes these patterns.

### Problems in Self-image and Physical Functioning

Disturbances in body image and eating behavior have peak ages at onset during adolescence and early adulthood. Persistence of disturbed eating behaviors into early adulthood is often accompanied by the development of personality disorders in many cases. Bulimia nervosa has been shown to be associated with borderline personality disorder in contrast with anorexia nervosa, which was found to be associated with avoidant personality disorder (Skodol *et al.*, 1993).

Although adolescents tend to sleep late, excessive daytime sleepiness may become a problem during adolescence. Excessive sleepiness may indicate the onset of narcolepsy, a rare disorder characterized by sleep attacks, accompanied by cataplexy (sudden, bilateral loss of muscle tone), and/or hypnopompic or hypnagogic hallucinations or sleep paralysis (Regestein, 1994).

\*Prevalence estimates are as follows: common, .5%; less common, 2–5%; rare, 1–2%; very rare, .1%; NK, not known.

A preoccupation with an imagined or exaggerated defect in appearance may develop in adolescence. Unlike the normal concerns of adolescents with their physical appearances, excessively time-consuming concerns that cause great distress or interfere with functioning suggest body dysmorphic disorder.

Table 8.7 summarizes the estimated prevalence and sex distribution of DSM-IV mental disorders commonly seen in adolescents.

### Problems of Early Adulthood

The period between the ages of 20 and 30 years is commonly referred to as early adulthood.

### Early Adult Development

Developmental tasks of early adulthood include achieving emotional and financial independence from parents and forming intimate relationships with people outside the family of origin. Stage-specific stressors include leaving home, education and

career choice, in some cases service in the armed forces, finding and maintaining employment, courtship and marriage, and sexual relations, among others.

### Types of Problems

Problems of young adulthood fall mostly into the categories listed in Table 8.8. By the end of early adulthood, people have passed through the ages of greatest risk for first onset of the majority of recognized mental disorders. Comorbidity between disorders becomes the rule rather than the exception. In a population survey in the USA, 14% of those evaluated had three or more lifetime disorders and accounted for more than 50% of the mental disorders found, both on a lifetime basis and in the year before the assessment (Kessler *et al.*, 1994).

\*Prevalence estimates are as follows: very common, .0%; common, 5–10%; less common, 2–5%; rare, 1–2%; very rare, .1%; NK, not known.

The relationships between comorbid “disorders” are complex. Whether they indeed represent independent entities with distinctive etiologies, pathogenetic mechanisms and outcomes, or merely reflect different ways in which fundamental psychopathological disturbances are manifest over time, between sexes, or across aspects of psychological functioning remains to be determined. In some cases, one disorder is clearly antecedent to another. Examples include disorders of childhood, such as separation anxiety disorder or conduct disorder, that evolve into adult versions – in these cases, panic disorder with agoraphobia or antisocial personality disorder, respectively. Sometimes, as in the case of attention-deficit/hyperactivity disorder, residual symptoms persist and form the basis for developing problems such as substance abuse or personality dysfunction. At other times, a second disorder may develop as a consequence of a primary disorder – in reaction to it or as a complication. Examples include

**Table 8.8** Psychopathology in Early Adulthood

Emotional problems
Problems of behavior and adaptive functioning
Problems in physical functioning
Problems in reality testing

major depressive disorder developing after a person has been incapacitated by panic disorder with agoraphobia, or sedative, anxiolytic, or alcohol abuse developing because the person attempted to self-medicate for the condition. Alternatively, disorders appear more or less contemporaneously and reflect an underlying diathesis or vulnerability. Thus, patients present with several disorders, all suggestive of a problem of generalized impulsivity, such as bulimia nervosa, a substance use disorder and an impulse control disorder (e.g., kleptomania). Personality disorders often develop in the context of underlying traits affecting specific capacities such as impulse control or interpersonal relatedness, as dysfunction becomes widespread.

Table 8.9 summarizes patterns of comorbid mental disorders in early adulthood.

### Emotional Problems

Although disturbances in mood can occur at any age, the peak ages of onset of mood disorders are probably in the twenties. Mood disturbances may be acute and episodic or insidious and chronic. They may be relatively mild or severe and may be accompanied by psychotic features or suicidal behavior. The most common mood disorders are major depressive disorder, dysthymic disorder, bipolar disorder and cyclothymic disorder.

Although several anxiety disorders have their onset most often in childhood or adolescence, as previously described, others have increased risk for onset in early adult life. In particular, many cases of acrophobia (fear of heights) and situational phobias, such as of elevators, flying, or closed places, develop in early adulthood (American Psychiatric Association, 2000). There is a rise in the rate of panic disorder in women in early and middle adult life (Regier *et al.*, 1988). Obsessive–compulsive disorder has a later age at onset in women than in men, during the twenties rather than the teens. Acute stress disorder and PTSD can occur at any age but are prevalent in young adults.

Disorders such as panic disorder, other specific phobias, social phobia and generalized anxiety disorder, which are more likely to begin in childhood or adolescence, may persist or recur during early adult life.

The severity, duration and proximity of a person's exposure to a traumatic event influence the risk of developing either an acute stress disorder or PTSD (March, 1993). Acute stress reactions which do not resolve (Classen *et al.*, 1998), peritraumatic dissociation (Shalev *et al.*, 1996) or emotional numbing in response to the stressor (Epstein *et al.*, 1998) predict later PTSD. Social support, family history, childhood experiences, personality variables and preexisting mental disorders also affect risk. Men and women appear equally vulnerable. Dissociative disturbances may occur in the absence of reexperiencing or avoidance symptoms, often in response to severe stress (Spiegel and Cardena, 1991).

Milder, time-limited reactions to stressors of any severity may also occur. These are common occurrences that might follow the breakup of a romantic relationship or the loss of a job. The symptoms may be of depression, anxiety, or disturbance of conduct. They cause temporarily decreased performance at school or work or impairment in social relationships. Provided that the consequences of the stressor are resolved (i.e., the person resumes dating or obtains a new job), the course of the symptoms and impairment should be less than 6 months.

### Behavior and Adaptive Functioning

Problems with various types of impulsive behaviors and problems with adaptive functioning in general seem particularly prone to

become manifest in early adulthood. These problems may develop, in part, secondary to the increased stresses of movement away from the protective environments of school and family that characterize the period.

Of major significance in the twenties is the stabilization of patterns of perceiving, relating to, and thinking about the environment and oneself that we call personality. Also, however, in the twenties, the potential for the development of inflexible and maladaptive traits that cause distress or interfere with effective social and occupational functioning may arise. Thus, personality disorders may become evident.

### Disturbances in Physical Functioning

Certain disturbances in physical functioning are likely to become manifest in early adult life. These include disturbances in sexual functioning, sleep disturbances and some physical complaints that cannot be fully explained on the basis of a known general medical condition.

Certain disturbances characterized by physical complaints without known medical etiology have a high incidence rate in early adulthood. Specifically, conversion reactions, hypochondriasis and somatization disorder can be first diagnosed in this age group.

### Problems in Reality Testing

Problems in reality testing are reflected in abnormalities of speech, thinking, perception and self-experience. They are suggestive of psychotic disorders such as schizophrenia. Although schizophrenia and its counterpart disorder of breifer duration, schizophreniform disorder, may have an onset in late adolescence (or in later adulthood), the most common age at onset is in early adult life.

Patients who have illness episodes that are characterized by major episodes of mood disturbance, either depressed or manic, accompanied by schizophrenia-like psychotic symptoms and whose delusions and hallucinations are also present

when mood symptoms are not, are said to have schizoaffective disorder.

The vast majority of disorders with typical onset in early adult life persist or recur in middle adult life. Some of these disorders may also have their initial onset after age 30 years. Table 8.10 summarizes the estimated prevalence and sex distribution of mental disorders of early adulthood.

## Problems of Middle Adult Life

### Middle Adult Development

Middle adult life may be applied to ages 30 to 65 years, which are characterized developmentally by consolidation and generativity in career and family life. Although potentially the most productive years of life, they are also fraught with obstacles and frustrations in the achievement of personal goals. Common stressors include marriage and divorce, parenting, career setbacks, recognition of unattainable goals and death of parents. Any of these may serve as the focus of a midlife crisis.

### Types of Problems

Psychosocial stressors may precipitate episodes of already existing disorders of virtually any type or initiate disorders *de novo*. Relatively few disorders have a typical onset between 30 and 65 years (Table 8.11). They include particular anxiety, psychotic, sleep and substance-related disorders, and disorders associated with general medical conditions.

### General Medical Conditions

Because medical conditions have increased incidence during adult life, psychopathological conditions resulting from the direct physiological effects of general medical conditions are on the rise. General medical conditions (and their treatments) can cause delirium, dementia, amnesic disorder, psychotic disorder, mood

disorder, anxiety disorder, catatonic disorder, sexual dysfunction, sleep disorder and personality disorder.

Medical conditions can also act as psychosocial stressors (Popkin *et al.*, 1987), in which case the prognosis also depends on the management of the stress and the treatment of the mental disorder.

The estimated prevalence and sex distribution of the few mental disorders with a peak in age at onset in middle adult life are included in Table 8.10.

**Table 8.12 Psychopathology in Late Life**

Memory impairment  
Emotional problems  
Substance abuse  
Problems in physical functioning  
Problems in reality testing

## Problems of Late Life

### Late Life Development

The developmental demands of late life are many. Coping with physical illness, disability, or a diminished capacity for physical activity; adapting to retirement or reduced productivity at work; and dealing with grief after the loss of friends or a spouse are all frequent and challenging tasks. Maintaining emotional equilibrium by finding a new balance between desirable and undesirable events and circumstances (Baltes, 1987) is a major undertaking.

### Types of Problems

Risk for mood disturbances in late life remains high. Other emotional problems, substance abuse and problems in physical functioning and in reality testing may occur. However peak age of risk is mainly for memory, or other impairment associated with the dementias (Gurland, 1996), or delirium (Table 8.12).

Table 8.13 summarizes the estimated prevalence and sex ratio of selected mental disorders of late life.

## Conclusion

Psychopathology occurs throughout the life-cycle, from infancy to death. Certain forms of psychopathology are limited to specific stages in life, but most can occur at any stage. Particular

disorders have a peak age at onset during specific intervals of the life-cycle. Some seem related to the developmental themes of the stage in which they tend to develop. The manifestations of psychopathology may change in expression in relationship to age. Men and women differ in their susceptibilities to certain disorders, the age at which they are at greatest risk, certain symptom patterns, and, in some cases, in their prognoses.

Given the wide range of psychopathology encountered in the life-cycle, clinicians must cast a wide net in collecting diagnostically relevant information. They must exert good clinical judgment in interpreting the information collected, including a judicious weighing of the evidence supporting diagnostic criteria. They must view patients through the filter of their cultural context. And they must apply accepted diagnostic algorithms to reach the most accurate diagnosis for each patient's problem. The remaining chapters in this section are meant to assist in these endeavors.

PART

Three

Scientific Foundations  
of Psychiatry

---

## Overview

At its most basic level, the discipline of psychiatric epidemiology is the study of the patterns of mental disorders, including how frequently disorders occur, how they are distributed in populations, and what are associated risk factors. Psychiatric epidemiology also defines the time course of mental disorders including their onset, duration and recurrence. Recently, the field has greatly expanded and now includes detailed examinations of the natural history of psychiatric disorders, genetic epidemiology, the relationships between physical and mental disorders, and studies of the use and outcomes of mental health treatments. This expansion has required significant advances and developments in psychiatric epidemiologic methods (Tsuang and Tohen, 2002).

Important characteristics that distinguish psychiatric epidemiological research from other clinical investigations are the inclusion of representative samples and the application of systematic methods for determining diagnosis or outcome. The specific type of sample and choice of mental health measure depend on the goal of the study. Three types of samples are generally used in epidemiology. For studies aimed at establishing prevalence and incidence rates, the population-based survey is the optimal method. Complex sampling procedures have been developed to ensure random selection for both single-stage and two-stage studies. For studies of rare disorders, identified patients are usually ascertained from registries or a representative set of psychiatric treatment facilities. However, because only a minority of individuals with diagnosable disorders are ever treated for psychiatric problems within the mental health care system (Regier *et al.*, 1993; Kessler *et al.*, 1994; Wang *et al.*, 2000), these sources may omit true case patients who do not present for treatment.

The development of structured diagnostic interview schedules tailored to clear operationalized diagnostic criteria was the crucial element underlying the recent progress in psychiatric epidemiology. As a result of the development of structured diagnostic interview schedules, the need to establish the prevalence of specific disorders was finally realized, at least within the limits of our current ability to operationalize mental disorders and within the constraints inherent in interview data (Fennig and Bromet, 1992). Estimates suggest that approximately 12% of children (Institute of Medicine, 1989) and 15% of adults (Regier *et al.*, 1988) currently meet criteria for one or more mental disorders. More precise estimates will be possible as more sensitive diagnostic tools become available.

## The Scope of Inquiry in Psychiatric Epidemiology

“Epidemiology” is derived from the Greek words *epidemos*, meaning “among the people”, and is defined as the study of “the

patterns of disease occurrence in human populations and of the factors that influence these patterns” (MacMahon and Pugh, 1970). Because the ultimate goal of epidemiological research is to understand the cause of disease and prevent its occurrence, epidemiology is the backbone of public health.

Important advances have been made in psychiatric epidemiology, largely since World War II. To make such advances, investigators have had to overcome formidable problems that are unique to the study of psychiatric disorders. Foremost among their achievements has been the development of the ability to define mental disorders reliably and efficiently. This accomplishment has in turn allowed investigators to conduct descriptive analyses that have yielded much-needed estimates of the incidence, prevalence, age at onset, and frequency of recurrence of mental disorders.

The ability to accurately categorize cases and noncases has also been essential for allowing psychiatric epidemiologists to progress from simple descriptive work establishing rates to analytical research aimed at identifying risk factors, as well as biological and psychosocial variables that modify the effects of these risk factors. Examples of promising areas in which there has been significant research activity recently include investigations of the genetic bases for psychiatric disorders (Risch and Merikangas, 1990) and the modification of risk by environmental exposures, especially in the prenatal period (Neugebauer *et al.*, 1999).

Whereas traditional epidemiology has largely been concerned with the occurrence and causes of disease, clinical epidemiology has emerged as a closely related discipline which seeks to identify the occurrence and determinants of clinical outcomes from illnesses (Weiss, 1985; Sackett *et al.*, 1985). Clinical epidemiologic studies employ the same principles and methods of population-based epidemiology, but are usually conducted among clinical samples. Recent clinical epidemiologic investigations such as the NIMH Collaborative Program on the Psychobiology of Depression (CPPD) and the Harvard–Brown Anxiety Research Program have provided important information on prognostic factors associated with the natural history of psychiatric disorders (Judd *et al.*, 1998; Rogers *et al.*, 1999). Other examples include two countywide longitudinal studies of first-admission psychosis (Beiser *et al.*, 1989; Bromet *et al.*, 1992), which included patients from all facilities in the respective geographical regions, or a follow-up study of first-episode psychotic patients admitted to the McLean Hospital in Belmont, Massachusetts (Tohen *et al.*, 1992). Psychopharmacoepidemiology has been an especially fast growing component of clinical epidemiologic inquiry (Wang *et al.*, 2002b), in part because psychotropic medications are now widely used in both general medical and psychiatric populations. Many psychopharmacoepidemiologic studies have consisted of

descriptions of the patterns and predictors of psychiatric medication use (Olfson *et al.*, 2002; Wang *et al.*, 2000) as well as investigations of unanticipated hazards from psychiatric medications (Wang *et al.*, 2001a, 2001b, 2001c, 2002a, 2002c).

Clinical epidemiologic research has also begun to evaluate the economic costs associated with mental disorders, both the direct costs for provision of mental health services as well as the indirect costs to society, secondary to the disability caused disorders. The WHO Global Burden of Disease (GBD) study (Murray and Lopez, 1996) identified mental disorders as among the most costly diseases in the world. For example, major depression was the single most burdensome disease in the world among individuals under 45 years of age. Another closely related area of inquiry is that of mental health services research. This discipline investigates the patterns of utilization of mental health services, unmet needs for treatment, barriers to help seeking, the appropriateness and quality of treatments, and premature dropout from treatment (Kessler *et al.*, 2001; Wang *et al.*, 2000, 2002; Edlund *et al.*, 2002).

The accumulation of information on risk factors for mental disorders, their outcomes, and treatment has in turn led to another important line of inquiry in psychiatric epidemiology, namely, interventional research. In addition to efficacy trials of psychiatric treatments conducted under rigorously controlled conditions (Tohen *et al.*, 2000, 2002), recent experimental studies have also begun to include effectiveness trials of “real-world” treatment strategies (Katon *et al.*, 1995, 1996; Simon *et al.*, 2000; Wells *et al.*, 2000). Finally, the proliferation of effective but costly interventions, coupled with growing constraints on health care budgets, have also made it imperative to study not only the effectiveness of interventions but also their cost-effectiveness and cost-benefits. For this reason, economic analyses now frequently accompany efficacy and effectiveness trials of interventions (Schoenbaum *et al.*, 2001).

## Epidemiological Methods

Conducting investigations across this broad scope of inquiry has required the development of rigorous psychiatric epidemiologic methods. The following section contains a brief description of some of the basic elements of this methodology.

### Measures of Disease Frequency

Epidemiological studies examine the incidence and prevalence rates of disorders in populations at risk and the factors associated with onset and recurrence. A rate is determined by the number of cases (the numerator) divided by the population at risk (the denominator).

#### Incidence

Incidence rates refer to new cases that arise in a healthy population during a fixed time. The most commonly applied incidence rate in psychiatric epidemiology is the cumulative incidence rate, also known as the “incidence proportion” (Selvin, 1991), that is, the proportion of a population at risk that has a disease during a specified time. The range is from 0 to 1. The numerator includes new cases of the illness, and the denominator is composed of individuals at risk of becoming diseased for the first time. In cumulative incidence, the duration of the observation needs to be defined (e.g., new cases in 1 month, 1 year, or 5 years).

Cumulative incidence is appropriate when a study has a fixed cohort design (i.e., when all of the members of the cohort are observed for the same time). However, when attrition occurs, the cumulative incidence rate is a less desirable measure. Individuals lost to follow-up who would have become case patients are excluded from the numerator, whereas the denominator, which is the total population, remains unchanged. Moreover, those who become lost to follow-up are often a biased subgroup of the original study population (Eaton *et al.*, 1992). Therefore, cumulative incidence should be considered most reliable when there is a small loss to follow-up during the specified time. When loss to follow-up occurs or when the occurrence of a health outcome is measured in a dynamic cohort (i.e., when members of the cohort come in and out) different statistical adjustments must be employed (Selvin, 1991).

$$\text{Cumulative incidence} = \frac{\text{number of new cases}}{\text{total population at risk}}$$

In epidemiology, incidence rate refers to the number of new cases occurring in a specified time period divided by the sum of time periods of the observation for all individuals in the population at risk, or person-time (Rothman and Greenland, 1998). In effect, this statistic measures the instantaneous force of morbidity or disease occurrence (Rothman and Greenland, 1998). Miettinen (1985) also referred to it as incidence density. The denominator person-time is the observational experience during which a particular outcome may occur. The range of an incidence rate is 0 to infinity. The incidence rate is measured in units of the reciprocal of time (time<sup>-1</sup>). The units of incidence rates are time<sup>-1</sup>. Because the units and the numerical value of an incidence rate are difficult to interpret, incidence rates are usually compared with each other to obtain incidence rate ratios.

$$\text{Incidence rate} = \frac{\text{number of new cases}}{\text{person-years}}$$

#### Prevalence

Prevalence rates measure the proportion of individuals who have the disease at a specified point or period in time. Incidence refers only to new-onset cases, whereas prevalence includes all new, recurrent, or chronic cases in the numerator and the entire population, including those with a history of the disorder, in the denominator. The point prevalence rate is the proportion of a population affected by a disease at a given point in time. Period prevalence refers to the proportion of a population affected by a disease during a specified time period, such as 6 months, 1 year, or lifetime. Prevalence rates are influenced by the duration of a disease. For nonchronic disorders, such as major depression, the point prevalence is usually lower than the period prevalence. For chronic conditions, such as schizophrenia, the point prevalence and period prevalence are expected to be similar.

$$\text{Prevalence rate} = \frac{\text{number of cases}}{\text{total population at risk}}$$

In general, prevalence data are less useful than incidence data for etiological research. Prevalence is determined not just by factors that cause a disease but also by factors secondary to the disease itself. On the other hand, prevalence measures are useful in public health or service utilization situations. For instance, the geographical location and planning of specific services of a

community mental health center are usually based on findings from prevalence studies.

### Measures of Association

Incidence rates can be used to calculate two types of effects. One is the attributable risk, or the absolute effect. The attributable risk is the difference between two incidence rates. This is most commonly used in comparing rates of exposed with nonexposed populations. The second type of effect is the relative risk, which is the ratio of the incidence rates of the exposed and unexposed groups. In case-control studies, it is not possible to estimate incidence rates. Relative risks, however, can be calculated with an odds ratio, which is the ratio of the odds of exposure of the case patients to that of the control subjects.

### Instruments to Identify Cases

The calculations defined in the preceding assume a fundamental requirement of epidemiological research, the ability to define a case. Historically, defining “caseness” in psychiatric epidemiologic studies has been difficult. The development of structured diagnostic interview schedules tailored to clear operationalized diagnostic criteria has been the crucial element underlying the recent progress in psychiatric epidemiology.

The feasibility and benefits of structured, or semistructured, interview schedules that could systematically elicit criteria for objectively defined disorders further became evident after the appearance and widespread use of instruments such as the Schedule for Affective Disorders and Schizophrenia (SADS) (Endicott and Spitzer, 1978), the companion interview for the Research Diagnostic Criteria (Spitzer *et al.*, 1978). The SADS and the Research Diagnostic Criteria were originally developed for use by psychiatrists in the multisite collaborative study of the psychobiology of depression sponsored by the NIMH (Katz *et al.*, 1979). Other standardized psychiatric interviews that have been commonly used are the present state examination (Wing *et al.*, 1974) and its successor, the schedule for clinical assessment in neuropsychiatry (Wing *et al.*, 1990); the structured clinical interview for DSM-III-R (Spitzer *et al.*, 1992); and the diagnostic interview for genetic studies developed by the NIMH-sponsored centers for genetic linkage research (Nurnberger *et al.*, 1994). Puig-Antich and colleagues have also developed an instrument for use with children, the Kiddie-SADS, that has been modified for epidemiological studies (Orvaschel, 1985).

The first widely used of a new family of instruments is the Diagnostic Interview Schedule (Robins *et al.*, 1981). The Diagnostic Interview Schedule was originally designed for the five-site epidemiological catchment area (ECA) study of DSM-III disorders (Regier *et al.*, 1984). The ECA methodology and findings are described in more detail later. Subsequent versions of the Diagnostic Interview Schedule incorporated revised DSM-III (DSM-III-R) as well as *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (DSM-IV) criteria. In the field of children’s mental health, fully structured diagnostic interview schedules have also been designed, such as the Diagnostic Interview Schedule for children (Costello *et al.* 1988; Jensen *et al.*, 1995).

Another fully structured instrument is the composite international diagnostic interview (CIDI), developed in collaboration with the World Health Organization (WHO 1990) and NIMH (Wittchen *et al.*, 1991). The CIDI was designed to be used with both DSM and ICD diagnostic criteria and to be available in multiple languages.

### Psychometric Properties of Instruments

Because classification in psychiatric epidemiology is based on self-report or interviewer-based rating scales and questionnaires, several features of an instrument must be tested and quantified. An instrument’s sensitivity (proportion of those with true-positive results identified as such by the study instrument) and specificity (proportion of those with true-negative results identified as such by the study instrument) are one set of measures. For an instrument to be useful in epidemiology, it should have high sensitivity and at least moderately high specificity.

To identify cases accurately, an instrument used for case identification must be reliable and valid. Reliability refers to the reproducibility of a measure (i.e., the consistency of measurement regardless of the rater, the situation, or the time of administration). Interrater agreement is usually calculated with statistical methods, such as the kappa statistic, that control for chance agreement. Test-retest reliability, or temporal stability, is calculated with product-moment or intraclass correlation coefficients. Validity refers to whether a construct is measured accurately. This concept is more difficult to establish in psychiatry because there is no “gold standard” or biological marker for the disorders under study.

### Risk Factor Identification

Risk factors are characteristics whose presence increases the chances for development of a disease. A true risk factor must exist before a disease develops. For example, being male and having a family history of alcoholism are risk factors for the development of alcoholism (Merikangas, 1990). When a variable cannot be definitively proved to predate the onset of a disorder, it is best conceptualized as a correlate. For example, socioenvironmental factors, such as adverse life events and chronic strain, that are statistically associated with the development of depressive disorders should usually be regarded as correlates because it is usually not possible to disentangle the causal sequence of these relationships.

### Types of Epidemiological Studies

In general, epidemiological studies are designed to find associations between exposures and health outcomes. A main concern in epidemiological studies is the selection of study groups on the basis of either disease status or exposure status. Epidemiological studies (Table 9.1) can be classified as 1) experimental, 2) quasi-experimental, and 3) nonexperimental or observational.

### Experimental Studies

The main distinction of experimental studies is that the investigator assigns the status of exposure or nonexposure to each subject.

**Table 9.1** Types of Study Designs

Experimental
Quasi-experimental
Nonexperimental (observational)
Longitudinal
Case-control studies
Cohort studies
Prospective
Retrospective
Cross-sectional

The assignment to the exposure group becomes part of the study protocol. Once subjects are assigned to exposed or nonexposed groups, they are observed for a time, and observations about changes in morbidity are recorded. The most common experimental design is the clinical trial, in which clinical populations are exposed to a specific treatment protocol to measure an outcome, usually resolution of symptoms. To ensure the integrity of a clinical trial, three main elements are necessary (Miettinen, 1985): 1) “randomization”, to ensure comparability of the populations; 2) “placebo”, to ensure comparability of the effects; and 3) “blinding”, to ensure comparability of information.

In randomization, subjects are randomly assigned to different exposure groups to attempt to ensure that subjects in each group have similar clinical and demographic characteristics. Randomization should theoretically achieve a balance of unknown factors in the different groups.

To control comparability of extraneous effects of a specified treatment, experimental studies use placebo-controlled groups. A placebo controls for factors that may affect the outcome of the study independently of the exposure status. For example, if subjects in an open trial are aware of what medication they receive, this knowledge could bias their response to the treatment. Similarly, subjects who are aware of being in an untreated control group could respond over time in a biased fashion. Thus, one goal in assigning patients at random to treatment or placebo-control groups is to minimize observation bias. In a single-blind study, only the patient is unaware of the actual treatment. In a double-blind study, the investigator and the subject of investigation are unaware of treatment assignment. In a triple-blind study, the data analyst is also not informed of the meaning of the group assignment code.

### Quasi-experimental Studies

Natural experiments that permit comparisons of two populations, one that receives an exposure and the other that does not, are referred to as quasi-experimental studies. To be considered quasi-experimental, baseline data must have been collected before the exposure event. Without that requirement, the study is simply a retrospective observational study.

### Nonexperimental Studies

Nonexperimental studies are divided into cross-sectional and longitudinal designs.

#### Cross-sectional Designs

Cross-sectional designs are typically employed in surveys aimed at providing data on the distribution of disorders in the population. Differences in rates by basic demographic data are also usually derived. In epidemiology, cross-sectional designs are usually best employed when causal hypotheses are not being tested. For example, when a community wants to investigate the distribution of an illness to decide on the need for psychiatric services, a cross-sectional survey is highly appropriate.

#### Longitudinal Designs

Longitudinal designs are divided into case-control and cohort studies and are characterized by a time interval between cause and effect. In cross-sectional studies, there is no interval between exposure and illness, which are measured at the same point in time.

**Case-Control Studies.** In case-control studies, subjects are defined in terms of having (case patients) or not having (control

patients) the disease of interest. The groups are compared in terms of history of exposure. In general, two types of control groups are used: hospital control groups and population control groups. The selection of the control group is a key point in terms of validity. Control subjects should be selected independently of exposure status. Case and control patients may be matched on different characteristics, the key issue being that control patients should represent those individuals who, if they had the disease, would be selected as case patients (Miettinen, 1985).

Case-control studies can assess whether a risk factor is more prevalent in case than in control patients but may not be able to establish the rate of disease after exposure to that risk factor. For the purpose of estimating the true rate of disease associated with an exposure, the prospective cohort study design is the preferable methodology.

**Cohort Studies.** In cohort studies, subjects are identified in terms of exposure or nonexposure status and are observed for a specified time to determine the presence or absence of a health outcome. Cohort studies are divided into prospective and retrospective. In prospective cohort studies, the exposure or nonexposure status is defined when the study is initiated. The subjects of investigation are followed up into the future to determine disease or nondisease status. In retrospective studies, the status of exposed or nonexposed is defined in the present. In prospective cohort studies, exposures of the present are evaluated; in retrospective cohort studies, exposures of the past are being evaluated. Cohort groups share the common exposure status and are observed to ascertain the presence or absence of a disease or outcome.

For comparison groups, a cohort study can use an internal subset of the population under study, by comparing exposed with unexposed members of the cohort, or an external comparison. A comparison cohort can be selected from a similarly defined population.

The major strength of the cohort design is the possibility of estimating a temporal relationship between exposure and disease. With a cohort study, it is possible to study rare exposures and to evaluate multiple outcomes from a single exposure. The limitation of cohort studies is primarily one of feasibility because most such studies are expensive and involve study populations who are difficult to recruit and maintain for follow-up.

### Threats to Validity in Epidemiological Studies

An essential feature of epidemiological studies is a comparison of two groups in terms of presence or absence of exposure or presence or absence of disease. For the measurements to be comparable, the investigator should ensure absence of bias. Biases can be divided into three general types: 1) selection bias; 2) information or observation bias; and 3) confounding bias.

#### Selection Bias

Selection bias can arise when the sampling procedure is influenced *a priori* by the disease or the exposure.

Another example, referred to as self-selection bias, occurs when subjects who have been exposed to an event are more likely to participate in a study if they have the disease or prodromal stages of the disease under study. A similar type of selection bias can occur when subjects are solicited from newspaper or other similar advertisements.

## Information (Observation) Bias

In case-control studies, information bias occurs when the details about prior exposure are obtained in a noncomparable manner or are subject to poor recall. To minimize such bias, exposure data should be collected without knowledge of disease status. This procedure is known as blindness. However, because of selective recall, when the sole source of information is the affected individual, this type of bias sometimes presents insurmountable problems.

## Confounding Bias

Confounding bias results when a third factor that is a cause of the disease under study is also associated with the exposure. A confounding factor is a cause of the disease under study independent of its association with the exposure.

## Examples of Psychiatric Epidemiologic Studies

Dohrenwend and Dohrenwend (1982) have divided the growth of psychiatric epidemiological research into three periods, or generations. This section describes the key studies and prevalence rates from the most recent of these periods.

### Third-generation Studies

The methodology for the third-generation epidemiological studies reflected the view in American psychiatry in the early 1970s that mental illness could be delineated into discrete, operational categories. These changes in nosology were exemplified in the 1970s with the development of the Feighner criteria at Washington University in St Louis (Robins and Guze, 1970; Feighner *et al.*, 1972) and culminated in the creation of DSM-III a decade later. By operationalizing diagnoses with specific criteria, it was possible to create structured diagnostic assessments to elicit the symptoms needed for these categories. Preliminary evidence about the utility of using diagnostic procedures in community samples was obtained in a third-wave follow-up of the New Haven Study noted before. In this study, Weissman and colleagues (1978) successfully administered the SADS-L in a community population. This and other studies (Bromet *et al.*, 1982) demonstrated that structured diagnostic instruments designed for clinical investigations could produce meaningful findings when administered in population-based studies.

The third-generation studies, thus, are characterized primarily by the use of structured diagnostic assessment procedures. In the next sections, we describe two of the largest third-generation studies, the NIMH-sponsored ECA project (Regier *et al.*, 1984, 1985, Robins *et al.*, 1991) and the NCS (Kessler *et al.*, 1994).

### The Epidemiological Catchment Area Study

In response to the 1978 President's Commission on Mental Health Report, NIMH sponsored the Epidemiological Catchment Area (ECA) project to determine the prevalence of mental disorders in specific sites and the proportion receiving mental health services (Regier *et al.*, 1984). Parallel to the planning of the ECA study, the APA published the DSM-III (American Psychiatric Association, 1980), which had clearly defined operational criteria that facilitated case definition. Thus, the concept of a case as a discrete entity that had been achieved in the late 1970s permitted the categorical determination of psychiatric caseness as opposed to the dimensional assessment of symptom

impairment. As a prelude to the ECA, the NIMH cosponsored the development of the Diagnostic Interview Schedule (reviewed above).

The basic design involved face-to-face baseline interviews with random samples of adults selected from the catchment areas, 6-month telephone follow-up interviews to obtain interim information on medical and psychiatric service use, and 1-year face-to-face interviews with the original sample. The initial response rate ranged from 68% (Los Angeles) to 79% (St Louis and Durham) (Leaf *et al.*, 1991). Overall, 12% of the original respondents were lost to or refused to participate in the follow-up interview. Eaton and collaborators (1992) reported that failure to be tracked was associated with being male, young, unmarried and Hispanic; refusal to participate was associated with being older, married and uneducated.

## Prevalence

Overall, 32.2% of the adults included in the five sites met criteria for one or more of the assessed mental disorders during their lifetime (Table 9.2. Phobias and alcohol abuse and dependence were the most common mental disorders (Regier *et al.*, 1985). The lifetime prevalence for phobia was 12.5%, and the 1-month prevalence was 6.2%. The rates for drug abuse and dependence were 5.9% for lifetime and 1.3% for 1-month prevalence.

The ECA study investigators did extensive analyses of the variation in prevalence rates by demographic characteristics.

**Table 9.2** Lifetime Prevalence Rate of Specific Diagnostic Interview Schedule (DIS)/DSM-III Disorders\*

Disorder	Estimated Prevalence Rate (% Population)
Any DIS disorder covered	32.2
Any DIS disorder except cognitive impairment, personality disorder, and substance abuse	19.6
Substance use disorders	16.4
Alcohol abuse and dependence	13.3
Drug abuse and dependence	5.9
Schizophrenia and schizophreniform disorders	1.5
Affective disorders	8.3
Manic episode	0.8
Major depressive episode	5.8
Dysthymia	3.3
Anxiety disorders	14.6
Generalized anxiety disorder	8.5
Phobia	12.5
Panic	1.6
Obsessive-compulsive disorder	2.5
Somatization disorder	0.1
Personality disorder	
Antisocial personality	2.5
Cognitive impairment (severe)	1.3

\*Based on five ECA sites standardized to the 1980 US census.

**Table 9.3** Epidemiological Catchment Area Study: Lifetime Prevalence Rate of Any Psychiatric Disorder

	Lifetime Prevalence (%)	
	N	
Total	19640	
Sex		
Men	8419	36
Women	11221	30
Age (yr)		
<30	4872	37
30–44	4650	39
45–64	4194	27
65+	5912	21
Ethnicity		
White	13091	32
Black	4697	38
Hispanic	1606	33
Education		
Not completed high school	8818	36
High school or more	10565	30
Occupational status of men (30–64 yr)		
Total	3452	35
Unemployed	774	48
Unskilled	599	40
Skilled or higher	2061	30
Rural/urban		
Urban	4694	34
Rural	2107	32
Marital history		
Married and never divorced or separated	9216	24
Single and never cohabited for 1 yr	3424	33
Ever divorced or separated	5906	44
Unmarried and cohabited	986	52

For lifetime diagnosis, 36% of men at some point suffered from an addictive or mental disorder, compared with 30% of women (Table 9.3).

The pooled 1-month prevalence rates for the five sites (see Table 9.4) was 15.4% for all ages for any DSM-III disorder. The age group 25 to 44 years had the highest overall rate of 17.3%. Although this age pattern was also true for women, men aged 18 to 24 years had the highest overall rate. This occurred because of the peak in rates of drug abuse and dependence in men in this age group. Anxiety disorders were most prevalent at 11.7% in women 25 to 44 years old, compared with only 4.7% for men in the same group. The overall prevalence for all affective disorders was 5.1%; the age group with the highest prevalence was women 25 to 44 years old.

### Incidence

Incidence rates were calculated based on the 12-month follow-up assessments of healthy individuals found during the initial assessments (Regier *et al.*, 1993).

During the 1-year follow-up period, 6% of the total population had one or more new disorders (Regier *et al.*, 1993). Also, 5.7% of those with a history of a mental disorder suffered a relapse or a new condition in the 1-year period for a total of 12.3% of new cases in 1 year.

### Use of Mental Health Services

Although 28.1% of the sample had diagnosable mental or addictive disorders, only 14.7% (23 million) received care, indicating that a disproportionate number of individuals suffering from mental and addictive disorders did not receive treatment. Conversely, although 22% of respondents who had recently used a medical care facility met criteria for a DSM-III disorder, 17% of nonusers had a diagnosable illness (Regier *et al.*, 1993; Eaton *et al.*, 1992; Narrow *et al.*, 1993, Kessler *et al.*, 1987). The disorders making the greatest contribution were alcohol abuse and dependence in men and major depression in women. The ECA study found that 0.9% received inpatient treatment in a specialty mental and addictive disorders facility during a 1-year period. Among individuals with any DSM-III disorder who received mental health services, 28.5% sought treatment from either a mental health clinician or medical physician (see Table 9.5).

### Comorbidity of Mental and Substance Use Disorders

The ECA study provided valuable data about the prevalence of comorbidity of alcohol and substance use disorders with mental disorders (Regier *et al.*, 1985, 1990). Before the ECA study, most of the information about comorbidity came from populations in treatment settings. Since the early 1950s, it has repeatedly been found that patients in clinical settings typically present themselves for treatment because they have more than one disorder, a phenomenon first described by Berkson (1946). Thus, clinical populations provide a biased (and inflated) view of comorbidity.

The ECA study defined comorbidity as the occurrence of more than one disorder and did not require that the disorders overlap temporally. Up to 29% of individuals with a mental disorder suffer from a comorbid substance use disorder. Similarly, individuals with alcohol use disorder have twice the risk of having a comorbid mental disorder and more than five times the risk of having a comorbid drug use disorder. Among individuals with alcohol use disorders, the most common comorbid mental disorder was anxiety disorder, with a prevalence of 19.4%. For individuals with drug use disorder, 22% suffered from a mental disorder.

In summary, findings from the ECA confirmed the widespread and impairing nature of mental disorders reported in the second-generation community studies described above. The methodologic rigor with which the ECA was conducted was instrumental at dispelling the disbelief and criticism of methodology that frequently accompanied second-generation studies. The rates in the five ECA sites confirmed the high prevalence of untreated mental disorder. ECA results, such as the finding that individuals with mental disorders were relatively more likely to use general medical services compared with those without disorders, raised provocative questions for a new generation of psychiatric epidemiologists.

### The National Comorbidity Survey

Because the ECA study was conducted in five specific sites, each selected because it contained unique population characteristics,

**Table 9.4** One-Month Prevalence Rate (%) of Specific Diagnostic Interview Schedule (DIS)–DSM-III Disorders\*

the findings could not be readily extrapolated to the USA as a whole. Therefore, the NCS was designed to estimate the prevalence and comorbidity of psychiatric and substance use disorders in the mainland USA. The NCS was designed by Kessler and colleagues (1994) as the first population-based study administered to a nationally representative sample in the USA using a

structured diagnostic interview. It built upon a history of conducting (second-generation) national studies of the prevalence of psychiatric symptoms in the USA at the University of Michigan. The NCS also built on the knowledge and experience of the ECA study. Among its many advantages, it uniformly included a set of demographic and psychosocial risk factors.

**Table 9.5** Epidemiological Catchment Area Study: Mental Health Visits in Service Sector in 1 Year

Diagnosis	Proportion with Mental Health Visits (%)
Any Diagnostic Interview Schedule/DSM-III disorder	28.5
Any Diagnostic Interview Schedule/DSM-III disorder except substance abuse	31.9
Any mental disorder with comorbid substance use	37.4
Substance use disorder	23.6
Alcohol abuse and dependence	22.0
Drug abuse and dependence	29.8
Schizophrenia and schizophreniform disorders	64.3
Affective disorders	45.7
Manic episode	60.9
Major depressive episode	53.9
Dysthymia	42.1
Anxiety disorders	32.7
Phobia	31.1
Panic	58.8
Obsessive–compulsive disorder	45.1
Somatization disorder	69.7
Antisocial personality	31.1
Severe cognitive impairment	17.0

### Prevalence

Table 9.6 presents the NCS 1-year and lifetime prevalence rates of the various psychiatric disorders. Lifetime prevalence rates are the proportion of individuals who ever experienced a disorder, and 1-year prevalence represents the proportion of individuals who experienced a disorder in the year before the interview. The lifetime prevalence for any DSM-III-R disorder was 48.7%, and the 12-month prevalence was 27.7%. When grouped by diagnostic category, the lifetime prevalence rates were 24.9% for anxiety disorders, 26.6% for substance abuse and dependence, and 19.3% for affective disorders. As expected, anxiety and affective disorders were more common in women, and substance abuse was more common in men.

### Comorbidity

An important focus of the NCS was the assessment of comorbidity. Interestingly, whereas 21% of the sample experienced only one disorder, 14% met criteria for three or more lifetime disorders. Furthermore, among individuals with a lifetime disorder, 53.9% had three or more lifetime disorders. Among individuals with a disorder occurring in the past 12 months, 58.9% experienced three or more disorders. The level of comorbidity was most dramatic for individuals with a severe disorder in the past 12 months, defined as active mania, nonaffective psychosis, or active disorder of other types that either resulted in hospitalization or created severe role impairment. In that subset of respondents, 89.5% had three or more disorders.

### Risk Factors and Correlates

The NCS also yielded important data on demographic correlates and potential risk factors for mental disorders. Several earlier

patterns of association observed for gender and other characteristics were confirmed.

### Use of Mental Health Services

The NCS also examined the patterns of use of health services by the respondents. Only 40% of individuals with a mental disorder ever received professional care, and only 25% received their care in the mental health specialty sector. On the other hand, 60% of individuals with three or more comorbid disorders received professional help, 40% in the mental health specialty sector. Furthermore, one third of persons with three or more comorbid disorders received professional help in the past year compared with only 20% of those with one disorder. These findings indicate that the use of health services is concentrated in the segment of the population with a high degree of comorbidity.

Subsequent analyses of service utilization in the NCS have shed light on the magnitude and potential determinants of important subcomponents of the problem of unmet needs for mental health treatment. For example, while only a minority with active major depression received any care in the prior year, an even smaller percentage (7%) received treatment that could be considered minimally adequate (Katz *et al.*, 1998). Even among the extremely vulnerable and impaired population that met criteria for active serious mental illness (SMI), only 40% received any treatment in the prior year (Kessler *et al.*, 2001) and only 15% received care that could be considered minimally adequate (Wang *et al.*, 2002). Among NCS respondents with mental disorders who received treatment in the prior year, 19% dropped out prematurely (Edlund *et al.*, 2002).

### The Ongoing NCS Research Program

The NCS will continue to yield important new findings in the future, though a new series of landmark studies are currently in the field (Kessler and Walters, 2002). In one ongoing component of this research, the National Comorbidity Survey-2 (NCS-2), the baseline NCS respondents were reinterviewed a decade later. When linked with the prospectively-collected data that respondents had provided in the baseline NCS, the NCS-2 will be an important source of information on the patterns and predictors of the course of mental disorders. The NCS-2 will also provide investigators with the ability to study the effects of primary disorders on the development and course of secondary disorders. An additional survey with a new national sample of 10 000 respondents, the national comorbidity survey-replication (NCS-R), is also being conducted together with the NCS-2. The NCS-R data will provide much needed data on temporal changes that may have occurred in the past decade. The tremendous utility of such analyses is perhaps best illustrated in mental health services research, where the last decade has seen dramatic changes in treatments and service delivery systems, yet the impact of these changes on unmet needs for treatment remains largely unknown. A survey is also being conducted among 10 000 adolescents, the NCS-A, and will yield much needed information on the occurrence and correlates of mental disorders in this population. Finally, as part of the WHO WMH (Womens Health and Gender) 2000 initiative, the NCS-R is being administered as parallel community epidemiological survey in over 20 developing as well developed countries throughout the world. The cross-national comparisons made possible by these surveys will provide a unique look at the occurrence, burdens and patterns of treatment for mental disorders around the globe.

**Table 9.6 National Comorbidity Survey: Lifetime and 12-Month Prevalence Rates (%)**

Disorders	Male		Female		Total	
	Lifetime Rate	12-Month Rate	Lifetime Rate	12-Month Rate	Lifetime Rate	12-Month Rate
Affective disorders						
Major depressive episode	12.7	7.7	21.3	12.9	17.1	10.3

# Psychiatric Pathophysiology: Schizophrenia

## Pursuing the Pathophysiology of Schizophrenia

For decades there existed only indirect techniques to study the living human brain. Now, with the advent of *in vivo* brain imaging, the structure, chemistry and function of the living human brain in health and disease and in multiple behavioral and pharmacologic states can be directly assessed. With the characterization of the human genome, we can begin to link disease characteristics with abnormal regional protein alterations to begin to draw together disease characteristics with tissue targets of illness. This will provide critical direct information about brain behavior in schizophrenia to enable productive and integrative data collection.

The observation that persons with schizophrenia perform poorly on tasks that require frontal neocortical function has long suggested that the frontal cortex is involved in the mechanisms of schizophrenia (Bleuler, 1978). Several laboratories have developed this idea further, showing that frontal function is abnormal in schizophrenia (Ingvar and Franzen, 1974; Weinberger *et al.*, 1986), proposing that the disturbed frontal function can influence dopamine dynamics in the striatum (Meyer-Lindenberg *et al.*, 2002), and that symptomatic (Andreasen, 1991), cellular (Lewis, 2000), neurochemical (Akbarian *et al.*, 1993), dendritic (Selemon *et al.*, 1995), and expression differences (Middleton *et al.*, 2002) exist in this area in persons with the illness. Other brain regions have also been the focus of considerable productive study in schizophrenia, including the hippocampus (Benes *et al.*, 1991; Gao *et al.*, 2000; Heckers *et al.*, 1998), thalamus (Andreasen *et al.*, 1994; Pakkenberg, 1990), and the cerebellum (Andreasen *et al.*, 1994). Within these brain areas, evidence exists for neurochemical abnormalities in dopaminergic transmission (Laruelle *et al.*, 1996), in excitatory synaptic function (Gao *et al.*, 2000; Olney and Farber, 1995; Tsai *et al.*, 1995), and in GABA-mediated inhibition (Benes *et al.*, 1996). Multiple formulations of pathophysiology in schizophrenia have been articulated, each based on a body of knowledge and an orientation to the illness.

## Clinical Pharmacology in Schizophrenia

Pharmacologic data collected from living persons with schizophrenia has implicated two neurotransmitter systems in the pathophysiology of the illness. These include both the midbrain dopamine system and the cortical NMDA-sensitive glutamate system. For dopamine-mediated neurotransmission, comprehensive evidence exists that blockade of dopamine-mediated

neurotransmission in the central nervous system reduces the psychosis of schizophrenia (Davis, 1969; Seeman, 1995), thus suggesting the involvement of dopamine dynamics in psychosis pathways. Because other strategies to diminish dopaminergic transmission, e.g., partial dopamine agonist action (Tammaing 2002), and dopamine synthesis blockade (Walinder *et al.*, 1976), are also antipsychotic, the hypothesis has broad pharmacological support. Indeed, a treatment based on the action of a low intrinsic-activity partial dopamine agonist is now on the market, namely aripiprazole. Moreover, the recent data that schizophrenia is associated with increased dopamine release (Laruelle *et al.*, 1996) are consistent with the hypothesis that a hyperactive dopamine system may be a pivotal part of the pathophysiology in schizophrenia.

A putative role for glutamatergic transmission at the NMDA receptor in schizophrenia is based on more recent pharmacologic observations. The action of NMDA-sensitive glutamate antagonists (specifically, the noncompetitive antagonist ketamine) in causing psychotomimetic symptoms in normal persons (Krystal *et al.*, 1994; Lahti *et al.*, 2001; Malhotra *et al.*, 1996) and in worsening psychosis in schizophrenia (Lahti *et al.*, 1995) implicates this system in mediating psychosis. These data suggest that reduced glutamatergic transmission at the NMDA receptor in the brain could be associated with psychosis in schizophrenia, especially given the supportive tissue histology (Harrison, 1999) and neurochemistry (Gao *et al.*, 2000). Most studies suggest that it is in the limbic cortex, including the anterior cingulate, hippocampus and ventral striatum, where this change is most critical.

## Preclinical Studies Relevant to the Pathophysiology of Schizophrenia

Several classes of drugs capable of inducing psychosis in humans act as behavioral stimulants in animals, for example, rodents. In general, such behavior differs from the activity pattern caused by exposing normal animals to a new environment in that it is more primitive in its stereotyping and has lost the rich exploratory repertoire. Tentatively, such abnormal behavior can be looked upon as a model of psychosis with both positive and negative symptom elements and a cognitive deficit component. Examples of psychotomimetic drugs inducing such abnormal behavior are the dopamine-receptor agonists acting directly or indirectly and the glutamatergic antagonists acting on the NMDA-sensitive glutamate receptor.

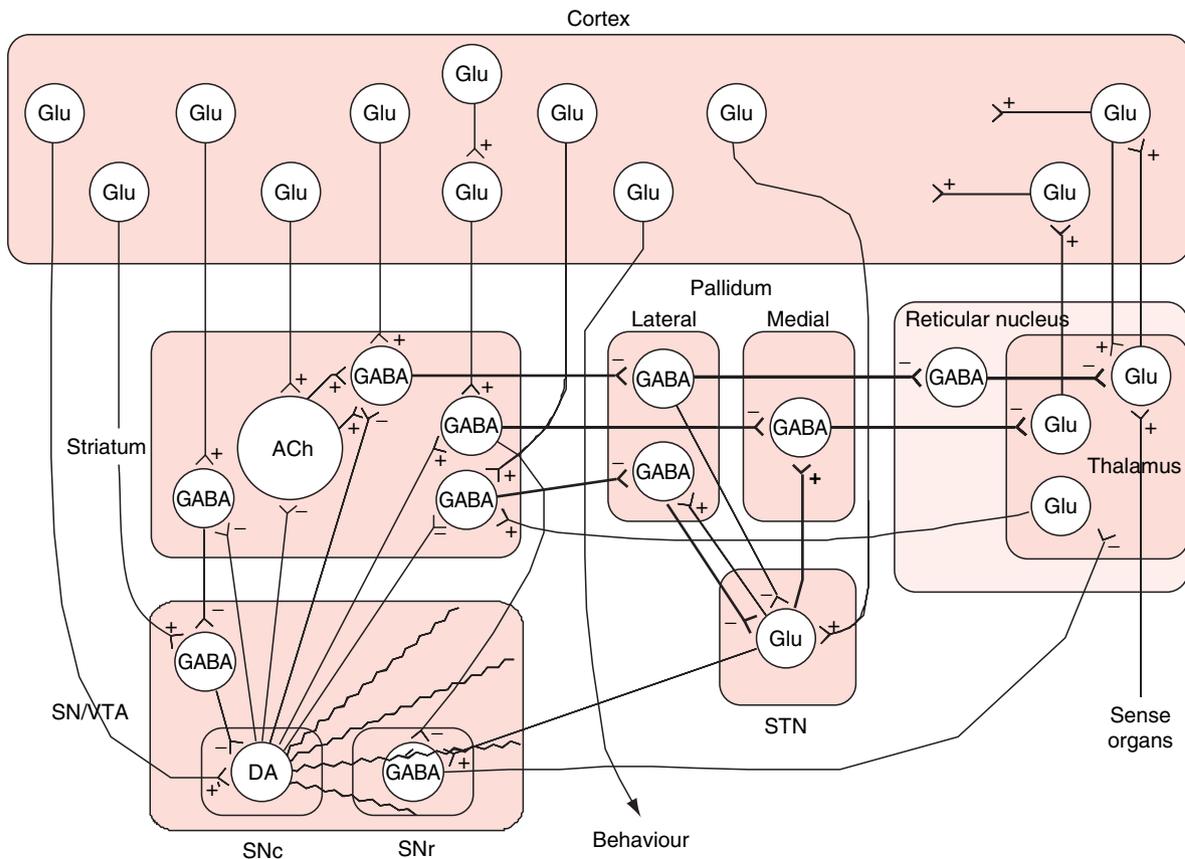

Multiple observations regarding these systems suggest that glutamatergic pathways, presumably emanating from the cerebral cortex, exert a strong inhibitory and stabilizing effect on an array of subcortical, potentially psychosis-inducing mechanisms, involving both monoaminergic and cholinergic pathways. The mechanism underlying this stabilizing glutamatergic function appears to be complex. In part it seems to be located postsynaptically to the (limbic) striatum, where corticostriatal pathways control both direct and indirect striatopallidothalamic pathways, as detailed in Figure 10.1. These pathways appear to regulate the sensory input to the cerebral cortex as well as the arousal. The direct and indirect pathways are mutually antagonistic, the former being activating and the latter inhibitory on the thalamocortical glutamatergic projections. Both the direct and the indirect pathways are also controlled by dopaminergic projections, whereby the former are activating (via  $D_1$  receptors) and the latter inhibitory (via  $D_2$  receptors). In addition, glutamatergic and glutamatergic/GABAergic pathways seem to control the monoaminergic neurons themselves by means of an accelerator and a brake mechanism, respectively (Carlsson *et al.*, 2001). These observations support glutamatergic involvement in schizophrenia and emphasize the interaction of glutamate with other, largely subcortical transmitter systems and open up possibilities for a multifactorial dysregulation in complex neurocircuits where,

besides glutamate, GABAergic, monoaminergic and cholinergic systems participate in the psychotogenic process (Carlsson and Carlsson, 1990).

Several drugs in different states of development will probably shed additional light on the multifactorial aspects of psychotogenesis, for example, agonists acting at the glycine site of the NMDA receptor, glycine-reuptake inhibitors, ampakines, drugs acting on the metabotropic glutamate receptors, partial dopamine receptor agonists and dopaminergic stabilizers lacking intrinsic activity on dopamine receptors (Carlsson *et al.*, 2001).

### Systems Pathology in Schizophrenia: The Limbic Cortex

In looking for sites of pathophysiology in the cerebral cortex, several lines of evidence point to abnormal limbic function. Decades of postmortem research in schizophrenia have reported structural, histologic, and neurochemical changes in limbic cortex (Jakob and Beckmann, 1989). Abnormalities in hippocampal size (Bogerts *et al.*, 1985), axial orientation (Scheibel and Kovelman, 1981), neuronal and nonneuronal number (Benes *et al.*, 1991, 1998; Heckers *et al.*, 1991; Jeste and Lohr, 1989), and changes in neurochemical markers of transmission and development (Akbarian *et al.*, 1993; Gao *et al.*, 2000; Tsai *et al.*,

**Figure 10.1** Neurocircuitries of the basal ganglia. Detail of the striatopallidothalamic pathways. Among these, the top and bottom pathways drawn with thick lines contain three GABAergic neurons and are referred to as “indirect”, i.e., inhibitory pathways. The pathway in between contains two GABAergic neurons and is referred to as “direct”, i.e., excitatory. Explanation: SNc, = substantia nigra, pars compacta; SNr, = substantia nigra, pars reticulata; VTA, = ventral tegmental area; STN, = subthalamic nucleus; Glu, = glutamate; ACh, = acetylcholine; and DA, = dopamine. Reproduced with permission from Carlsson and Carlsson A (1990) Interactions between glutamatergic and monoaminergic systems within the Basal Ganglia: Implications for schizophrenia and Parkinsons disease. *Trends Neurosci* 13, 272–276.

1995) have all been reported in postmortem schizophrenia tissue, although not always reliably replicated (Altshuler *et al.*, 1987; Jakob and Beckmann, 1989). Curiously, often more pronounced or significant changes are reported in the left compared with the right hemisphere (Zaidel *et al.*, 1997).

### Postmortem Limbic Cortex Abnormalities in Schizophrenia: Structural Changes

Much focused work in the human limbic cortex in schizophrenia began after Scheibel and Kovelman (1981) described an alteration in pyramidal cell apical dendrite orientation in the hippocampus, in its anterior and middle section, particularly at the subicular-CA<sub>1</sub> border. In a later extension of this work, they correlated symptom severity with the extent of the dendritic disorientation (Kovelman and Scheibel, 1984). However, other studies have not uniformly replicated these findings (Altshuler *et al.*, 1987; Christison *et al.*, 1989; Vogel *et al.*, 1997), but the original findings are still often referenced as evidence for neuroanatomical abnormalities in the hippocampus. Weinberger (1996) highlights several studies describing cytoarchitectural abnormalities in the entorhinal cortex (including the specific loss of NADPH-diaphorase neurons Nicotinamide Adenosine Dinucleotide Phosphate) as providing the best evidence for neuropathological findings (Akbarian *et al.*, 1993; Arnold *et al.*, 1991; Jakob and Beckmann, 1986). Other studies have reported significant reductions in the volumes or cross-sectional areas of the entorhinal cortex or hippocampus in schizophrenia (Bogerts *et al.*, 1985; Brown *et al.*, 1986; Colter *et al.*, 1987; Falkai and Bogerts, 1986; Falkai *et al.*, 1988), but these results have not been uniformly replicated (Benes *et al.*, 1991; Heckers *et al.*, 1991).

Hippocampal size is reduced bilaterally, albeit mildly, in the illness especially in anterior areas (Becker *et al.*, 1996; Bilder *et al.*, 1995; Bogerts *et al.*, 1990; Suddath *et al.*, 1989). Shape analyses of the hippocampus have suggested regional abnormalities of volume in schizophrenia. Importantly, regional shape abnormalities are predominantly localized to the head, implicating only a delimited area within hippocampus as abnormal (Csernansky *et al.*, 1998).

### Neurochemical Changes

Changes in GABA<sub>A</sub> receptor density, in GABA release and in glutamate-related transmitters and their enzymes in hippocampus have been reported in the illness (Simpson *et al.*, 1992; Tsai *et al.*, 1995). While there appears to be no change in the density of hippocampal NMDA glutamate receptors (Ishimaru *et al.*, 1992; Kerwin *et al.*, 1990; Kornhuber *et al.*, 1989), kainate binding, particularly in CA<sub>2</sub>, has been found reduced in several studies (Kerwin *et al.*, 1988, 1990; Simpson *et al.*, 1992) but not consistently (Deakin *et al.*, 1989). Reduced levels of non-NMDA receptor binding (Kerwin *et al.*, 1990) and lower concentrations of non-NMDA receptor mRNA (Harrison *et al.*, 1991), have both been reported in CA<sub>3</sub>. The previous finding of an alteration in the NR<sub>1</sub> subunit and an increase in NR<sub>2B</sub> in postmortem tissue from schizophrenia (Gao *et al.*, 2000) suggests a reduction in excitatory glutamate transmission at hippocampal NMDA receptors in this illness.

In addition, considerable evidence of compromised cognitive function, especially short-term memory and attention, exists in schizophrenia (Green, 1996; Gruzeliel *et al.*, 1988; Venables, 1992). These dysfunctions may represent the behavioral correlates of hippocampal pathology.

## In Vivo

### Functional Limbic Cortex Change in Schizophrenia

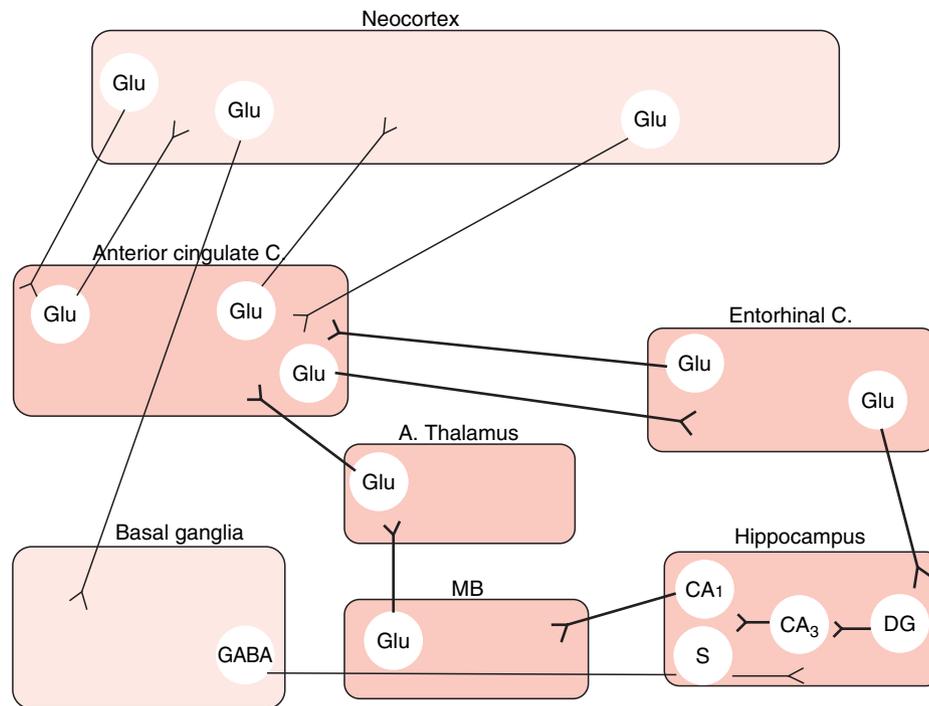

Functional studies of human brain in schizophrenia have directly demonstrated an alteration in neuronal activity in the limbic cortex in the illness (Fletcher, 1998; Haznedar *et al.*, 1997; Heckers *et al.*, 1998; Medoff *et al.*, 2001; Nordahl *et al.*, 1996; Tamminga *et al.*, 1992). Anterior cingulate cortex consistently shows alterations in schizophrenia when persons are imaged medication-free and matched for performance. Moreover, connectivity analyses suggest that the anterior cingulate rCBF is not tightly coupled to hippocampal activity during tasks of learning and memory, as it is in normal persons. Although the entire body of these data have not yet suggested the pivotal limbic pathology, they do implicate abnormal function of these structures in the illness. Moreover, as suggested in the preclinical studies, such pathology could destabilize the function of subcortical brain areas in psychosis.

An analysis of connectivity in auditory discrimination experiments directly suggests that a systems failure occurs within limbic cortex in schizophrenia. A malfunction within the limbic cortex and the subsequent disruption of related neocortical areas and secondary dysregulation of subcortical structures may underlie the manifestations of schizophrenia. This working hypothesis suggests that it may be the resultant “misbehavior” of the limbic system itself that generates positive and cognitive symptoms in schizophrenia, possibly through its connections with neocortical and subcortical structures. These speculations raise the possibility that the primary origin of the circuit dysfunction could be varied, but inevitably result in a characteristic “psychosis” circuit abnormality (Figure 10.2).

### Functional Effects of D<sub>2</sub> Dopamine Receptor Blockade

The clinical evidence of a systems basis of psychosis, along with the preclinical data suggesting multiple and complex neurotransmitter interactions within these symptoms, builds a plausible “psychosis circuit” for schizophrenia and potentially for its treatment. The effective functioning of the human brain to facilitate cognitive, motor and affective performance, is dependent not only on the proper functioning of individual regional neuronal groups dedicated to specific tasks, but also to interacting brain systems which function to connect neural systems to perform a particular mental task and systematically to direct information flow in the brain. Because schizophrenia is not characterized primarily by a neural or behavioral deficit, but rather by productive symptoms and by a “confusion” of neural activity with resulting mental malfunction, a system hypothesis of schizophrenia pathology is plausible. The idea that psychosis is the consequence of dysfunction somewhere within the limbic cortex, seen during cognitive work and even during routine mental function is supported by a great deal of research. This putative dysfunction is prominently manifest in the anterior components of the limbic system. Hence this change primarily influences the frontal regions of the neocortex, leaving the posterior hippocampus and the posterior neocortex relatively unaffected. Exactly where the primary limbic pathology is located within these anterior areas is a matter of speculation, but it could be multiple sites with a single resultant systems dysfunction.

Importantly, this idea allows for the real possibility that other drug actions can be exerted at other sites within the relevant

**Figure 10.2** Neurocircuitries of the limbic system. This illustration of limbic connectivity provides a depiction, albeit simplistic, of the flow of information within limbic regions. Information transfer is bidirectional in all instances except in the hippocampal trisynaptic pathway where transmission is unidirectional (forward only). At many junctures, the limbic cortex influences subcortical structures, particularly those in the ventral basal ganglia, and in the neocortex, particularly the frontal cortex.

circuits. The 5HT<sub>2A</sub> antagonist activity of the second generation drugs may well be exerted, either partially or wholly, in frontal cortex. Moreover, the glutamate-enhancing activity of the second generation drugs at the NMDA receptor, whether tied to this serotonin action or independent from it, may well be a cortical action. This formulation increases the complexity but also the therapeutic potential of psychosis treatment (Carlsson and Carlsson, 1990).

# Psychiatric Pathophysiology: Mood Disorders

## Genetic Factors

The familial nature of mood disorders has long been observed. It has been established that bipolar I disorder is more heritable than the other mood disorders, that an early age of onset is associated with greater heritability, and that heritable risk decreases in proportion to the amount of genetic material shared by members of a pedigree (Kelsoe, 2000). Genetic factors can interact with environmental factors to influence the vulnerability to mood disorders in different ways. For example, Kendler (1998) explored two such mechanisms: “genetic control of sensitivity to environment”, and “genetic control of exposure to the environment”. “Genetic control of sensitivity to the environment” suggests that genes, in part, render individuals relatively vulnerable or relatively invulnerable to the pathogenic effects of environmental stress. The depressogenic effect of stressful life events is substantially greater in those at high versus low genetic risk to the mood disorders. “Genetic control of exposure to the environment” suggests that genetic factors influence the probability that individuals will select themselves into high versus low risk environments. The genetic risk factors for major depression in part express themselves by influencing the probability that individuals will experience stressful life events, particularly of an interpersonal nature.

## Molecular Genetic Research

Molecular biology studies have reported, replicated, or failed to replicate various associations between several specific genes or gene markers and mood disorders (Sevy *et al.*, 1995; Reus and Freimer, 1997; Sherman *et al.*, 1997; Kendler, 1998; Dubovsky and Buzan, 1999; Kelsoe, 2000; Berrettini, 2000; Craddock and Jones, 2001; Johansson *et al.*, 2001).

Why have no genetic associations been consistently replicated? Reasons include: 1) complexity of the phenotype; 2) the likelihood that multiple genes and gene combinations contribute to the phenotypes; 3) gene–environment effects; 4) the complexity of the environment; and 5) the low power of sample sizes studied to date (Dubovsky and Buzan, 1999; Kelsoe, 2000; Mann *et al.*, 2001). A major problem of studies in psychiatric genetics is that psychiatric diagnoses are not known to be biologically homogeneous entities. Syndromal psychiatric diagnostic categories such as depression or anxiety disorders potentially include etiologically, pathologically and prognostically heterogeneous disorders (Charlton, 1997; Sher, 2000a). However, behavioral geneticists remain cautiously optimistic and hope that genetic studies promise a new era of understanding and treatment of mood disorders. There is confidence in

the existence of genetic factors in mood disorders without having as yet succeeded in identifying the responsible genes.

## Monoamine Alterations

### Serotonergic System

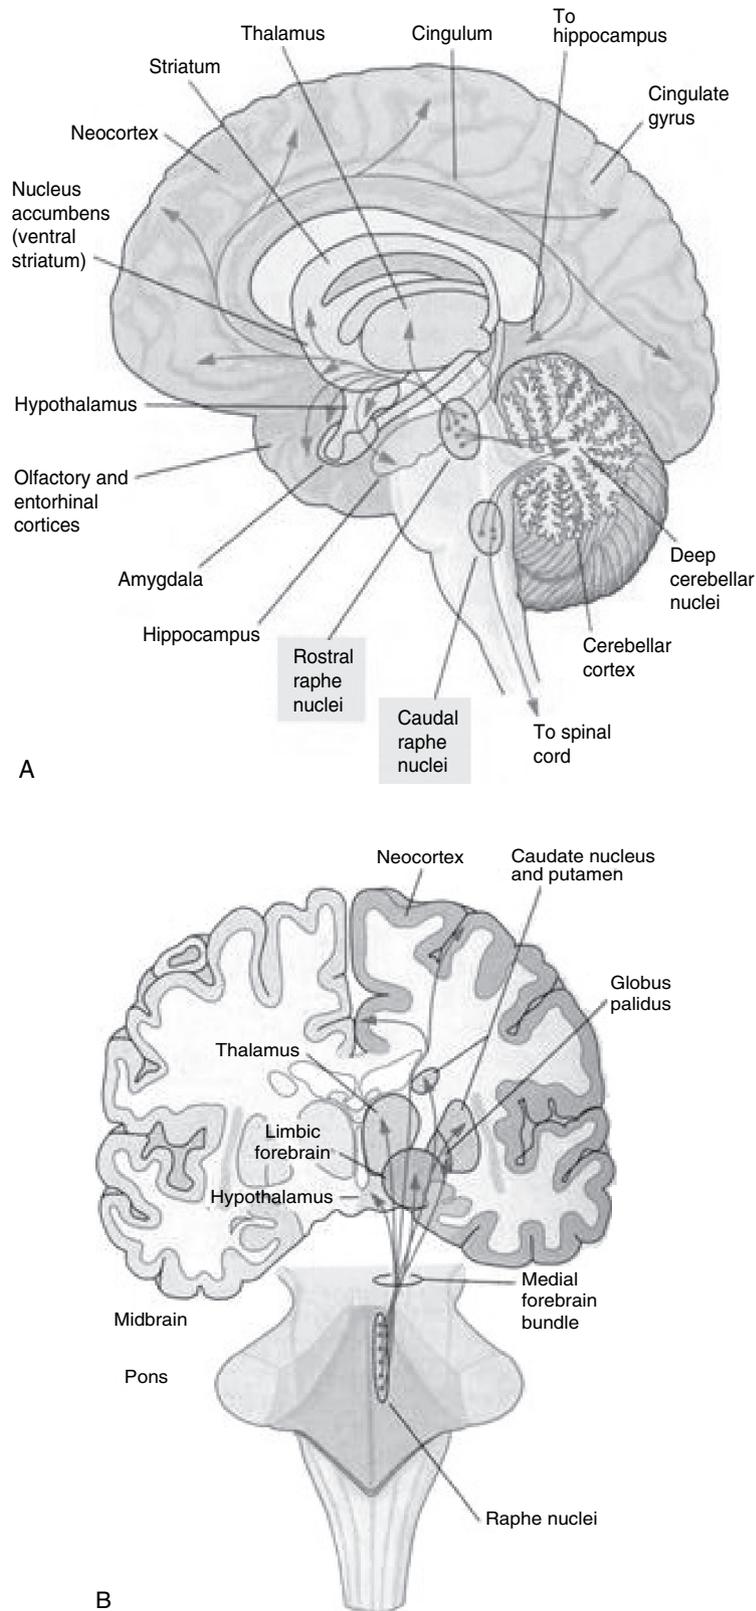

Serotonin has been implicated in the pathophysiology of depression and bipolar disorder (for reviews, see Mann, 1999; Oquendo and Mann, 2000; Shiah and Yatham, 2000; Mann *et al.*, 2001; Nemeroff *et al.*, 1997; Meltzer and Lowy, 1987; Coppen, 1969; Mace and Taylor, 2000; Kandel, 2000; Charney *et al.*, 1981) (Table 11.1 and Figure 11.1). This hypothesis proposed that the vulnerability to either depression or mania was related to low serotonergic activity, attributable to either less serotonin release or fewer serotonin receptors or impaired serotonin receptor-mediated signal transduction. Prange *et al.*, (1974) formulated a permissive hypothesis of serotonin function in bipolar disorder. They suggested that a deficit in central serotonergic neurotransmission permits the expression of bipolar disorder, and that both the manic and depressive phases of bipolar disorder are characterized by low central serotonergic neurotransmission. Over the last 30 years, a variety of studies of the serotonergic system have reinforced its role in major depression and identified additional associations with suicidal behavior, impulsivity, aggression, eating disorders, obsessive–compulsive disorder, anxiety disorders, personality disorders, seasonal changes in mood and behavior, and alcohol abuse and dependence. The serotonergic system also plays a role in the regulation of a variety of basic biological functions including sleep, appetite, circadian rhythm and cognitive function.

Medications that target the serotonin transporter site and selectively inhibit reuptake of serotonin (e.g., fluoxetine, sertraline, paroxetine, fluvoxamine, citalopram) have all been shown to be effective antidepressants (Nemeroff *et al.*, 1997; Sampson, 2001;

**Table 11.1** Studies of the Serotonergic System in Major Depression

CSF 5-HIAA levels	↓?
Postsynaptic 5-HT <sub>2A</sub> receptors in brain and platelets	↑
Serotonin transporter binding in brain and platelets	↓
Platelet serotonin uptake	↓
Prolactin response to fenfluramine, clomipramine, and l-tryptophan	↓

↑ higher; ↓ lower

**Figure 11.1** The major serotonergic pathways. (A) A lateral view of the brain shows the course of the major serotonergic pathways. Although the raphe nuclei form a continuous collection of cell groups throughout the brain stem, they are graphically shown here as two groups, one rostral and one caudal. (B) A coronal view of the brain demonstrates some of the major targets of the serotonergic neurons. Reproduced with permission from *Principles of Neural Science 4th Ed.* Kandel ER (2000) *Disorders of Mood: depression, Mania and Anxiety Disorders.* Copyright McGraw Hill Education.

Mace and Taylor, 2000). Some antidepressant drugs specifically act at one of the many serotonin receptor subtypes. For example, suggested antidepressive/anti-anxiolytic medications buspirone and gepirone are 5-HT<sub>1A</sub> receptor agonists, and fewer 5-HT<sub>1A</sub> receptors are implicated in the pathophysiological mechanism of depression and anxiety (Yocca, 1990; Apter and Allen, 1999).

Considered together, studies of serotonin function in major depression suggest both hypofunction and likely compensatory changes that would increase serotonergic activity (Brown *et al.*, 1994; Leonard, 1994; Dubovsky and Buzan, 1999). Findings such as 1) lower serotonin and 5-HIAA levels in postmortem brain stem and lower CSF 5-HIAA; 2) relapse of depression with diet acute depletion of tryptophan; 3) fewer serotonin transporter sites in prefrontal cortex; 4) fewer postsynaptic 5-HT<sub>1A</sub> receptors; and 5) the antidepressant properties of medications that enhance serotonergic transmission suggest that underactivity of the serotonin system is part of the pathogenesis of depression. Conversely, more 5-HT<sub>2A</sub> receptor binding in the frontal cortex of depressed individuals who committed suicide, fewer brainstem 5-HT<sub>1A</sub> autoreceptors and fewer serotonin transporters in the raphe nuclei would tend to increase serotonergic transmission in major depression. There is evidence for the contribution of serotonin in mania and in the mechanism of action of mood stabilizers (Shiah and Yatham, 2000); however, the data on the role of the serotonergic system in mania are fewer and not consistent. Alterations in functioning of other neurotransmitters in mania such as norepinephrine, dopamine, acetylcholine and GABA, and their interaction with serotonin may also contribute. Future studies of serotonergic activity in mood disorders will need further to differentiate primary pathogenesis from compensatory changes.

### Noradrenergic System

There are multiple lines of evidence that the noradrenergic system is disordered in depression (Berman *et al.*, 1996; Charney, 1998; Heninger *et al.*, 1996; Leonard, 1997; Owens, 1997; Kandel, 2000; Potter *et al.*, 1993; Schatzberg and Schildkraut, 1995; Nemeroff *et al.*, 1997; Ressler and Nemeroff, 1999) (Table 11.2 and Figure 11.2).

A large body of metabolite data are consistent with the hypothesis that there are abnormalities in the noradrenergic system in depression. The conflicting findings, however, are not consistent with simple increased or decreased noradrenergic activity.

### Dopaminergic System

Some studies have found that CSF levels of the dopamine metabolite homovanillic acid (HVA) are lower in patients with major depression than in controls and that lower CSF HVA levels are found in more severely depressed patients (see Kapur and Mann, 1992; Brown *et al.*, 1994, for a summary) (Table 11.3). However, other studies failed to replicate these findings or found higher CSF HVA in patients with depression (Jimerson, 1987; Vestergaard *et al.*, 1978).

**Table 11.2** Studies of the Noradrenergic System in Major Depression

CSF and urinary MHPG	↑↓
Plasma norepinephrine and epinephrine levels	↑ in mania than in depression
α <sub>2</sub> -adrenergic binding in platelets	↑
Growth hormone response to clonidine and platelet α <sub>2</sub> -adrenergic responses	↓

↑ higher; ↓ lower

### Gamma-aminobutyric Acid

Gamma-aminobutyric acid (GABA) is the major inhibitory neurotransmitter in almost all areas of the CNS and regulates many CNS functions (Nemeroff *et al.*, 1997). A decrease in GABAergic activity may play a role in depression by regulating receptor responses to catecholamines (Enna *et al.*, 1986; Nemeroff *et al.*, 1997). Pathophysiological contributions of GABA and therapeutic effects of GABAergic medications in mood disorders may be mediated via effects on other neurotransmitter systems (Dubovsky and Buzan, 1999; Nemeroff *et al.*, 1997).

### Other Neurotransmitters

Cholinergic neurons containing acetylcholine project diffusely throughout the cortex (Thase, 2000). The involvement of cholinergic system in the pathogenesis of depression is supported by the following findings: cholinergic input reduces REM latency (decreased REM latency is seen in depression); some antidepressants have anticholinergic properties; lecithin, an acetylcholine precursor, reduces mania in some cases and can induce depression; and cholinergic rebound following abrupt withdrawal of anticholinergic medications can cause a relapse of depression (Dubovsky and Buzan, 1999; Dilsaver and Coffman, 1989; Janowsky and Risch, 1984; Keshavan, 1985).

There are emerging data that drugs that antagonize NMDA receptors have antidepressant effects (Przegalinski *et al.*, 1997; Papp and Moryl, 1994; Trullas and Skolnick, 1990).

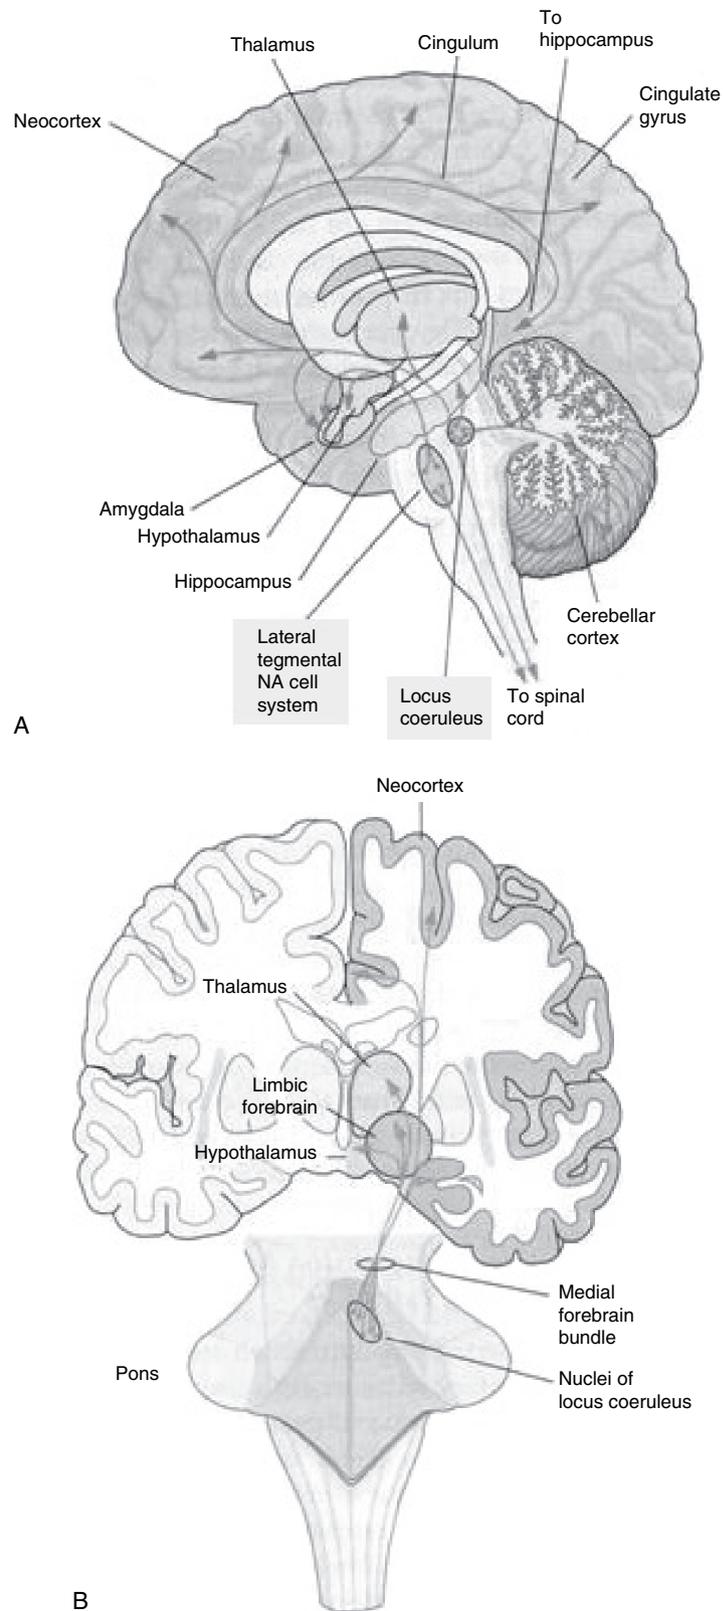

It is important to note that all neurotransmitters and receptors interact with and influence each other (Brown *et al.*, 1994; Leonard, 1994; Dubovsky and Buzan, 1999). Most cerebral functions are the result of the converging action of many different neurotransmitters. It is not likely that the pathophysiology of mood disorders is due to a single neurotransmitter (Brown *et al.*, 1994). More probably, mood disorders are disorders of the overall interaction of multiple transmitter systems. Alternatively, different components of depression may be related to different neurotransmitter dysfunction.

The binding of a neurotransmitter to a postsynaptic receptor triggers a cascade of chemical processes that include the second messenger systems (Thase, 2000; Dubovsky and Buzan, 1999; Thase and Howland, 1995). The bidirectional actions of second messengers allow unitary changes in second messenger function to produce diverse changes in transmitter synthesis and release, and in receptor activity, leading to complex neurotransmitter and receptor effects. There is evidence that mood-stabilizing drugs (e.g., lithium) act upon G proteins or other second messengers (Jesberger and Richardson, 1985; Kofman and Belmaker, 1993; Wang *et al.*, 2001; Chen *et al.*, 2001).

### Neuropeptides and Hormones

#### Cortical–Hypothalamic–Pituitary–Adrenal Axis

The cortical–hypothalamic–pituitary–adrenal axis has been intensely studied in patients with major depression (Carroll *et al.*, 1968; Sachar *et al.*, 1970; Stokes and Sikes, 1987; Brown *et al.*, 1994; Nemeroff *et al.*, 1997; Thase, 2000). The cortical–hypothalamic–pituitary–adrenal axis hyperactivity in depressed patients can be explained by hypersecretion of CRF and secondary pituitary and adrenal gland hypertrophy, although impaired negative feedback at various CNS sites including hippocampus and the pituitary are also likely to contribute. Downregulation of hippocampal mineralocorticoid receptors and expression is reported in depressed suicides (Lopez *et al.*, 1998). Hyperactivity of the cortical–hypothalamic–pituitary–adrenal axis also occurs in patients with bipolar disorder (Kirriike *et al.*, 1988; Stokes and Sikes, 1987). This increased cortical–hypothalamic–pituitary–adrenal axis activity has

**Figure 11.2** The major noradrenergic pathways. (A) A lateral view of the brain shows the course of the major noradrenergic pathways. The major noradrenergic pathways emanate from the locus coeruleus and from the lateral brain stem tegmentum. (B) A coronal view of the brain demonstrates some of the major targets of the noradrenergic neurons. (Source: Kandel ER [2000] *Disorders of mood: depression, mania, and anxiety disorders*, in *Principles of Neural Science*, 4th ed., [eds Kandel ER, Schwartz JH, and Jessell TM]. McGraw-Hill, New York.)

**Table 11.3 Studies of the Dopaminergic System in Major Depression**

CSF HVA levels	↓ (psychomotor retardation)
Plasma dopamine and HVA levels	↑ in psychotic depression
Plasma HVA and dopamine levels in response to the administration of glucocorticoids	↑ in controls, may contribute to the development of psychotic depression
Platelet MAO activity	↑ in unipolar ↓ in bipolar
Serum dopamine	↓
β-hydroxylase activity	

↑ higher; ↓ lower

been observed in mixed mood states (Evans and Nemeroff, 1983; Krishnan *et al.*, 1983; Swann *et al.*, 1992), mania (Godwin, 1984), and in depression in rapid-cycling patients (Kennedy *et al.*, 1989). Effect of treatment and recovery from depression are associated with partial reversal of HPA overactivity and may be required for recovery (Garlow *et al.*, 1999; Christensen and Kessing, 2001).

### Hypothalamic–Pituitary–Thyroid Axis

About 5 to 10% of people evaluated for depression have previously undetected or subclinical thyroid dysfunction (Thase, 2000). Jackson (1998) suggests that some patients with depression, although generally viewed as chemically euthyroid, have alterations in their thyroid function including slight elevation of the serum thyroxine (T4), blunted thyrotropin (TSH) response to thyrotropin-releasing hormone (TRH) stimulation, and loss of the nocturnal TSH rise. One possible explanation for the blunting of the TSH response to TRH challenge is a downregulation of TRH receptors in the pituitary, in response to the increased levels of TRH secreted into the hypophyseal–portal circulation (Garlow *et al.*, 1999). Elevated CSF concentrations of TRH in depressed patients were reported by Kirkegaard *et al.* (1979) and Banki *et al.* (1988), but not by Roy *et al.* (1994). It has been proposed that brain thyroid hormones may play a role in the mechanisms of seasonal affective disorder and light therapy (Sher, 2000b, 2001).

### Hypothalamic–Growth Hormone Axis

Mood disorders are associated with alterations in the activity of the growth hormone axis (Toivola *et al.*, 1972; Schilkut *et al.*, 1975; Mendlewicz *et al.*, 1985; Nemeroff *et al.*, 1997; Garlow *et al.*, 1999; Thase, 2000). The most consistent finding in depression is a blunted growth hormone response to clonidine, an alpha-2 receptor agonist (Toivola *et al.*, 1972; Thase, 2000).

### Brain Growth Factor

Multiple neurochemical factors, including thyroid hormones, somatostatin, growth hormone and brain-derived neurotrophic factor (BDNF) may affect brain growth and development (Krawiec *et al.*, 1969; Leroux *et al.*, 1995; Oppenheimer and Schwartz, 1997; Duman *et al.*, 2000). BDNF, a major neurotrophic factor in the brain, is critical for the survival and guidance of neurons during development, but is also required for the survival and function of neurons in the adult brain (McAllister *et al.*, 1999; Duman *et al.*, 2000).

Recent studies demonstrate that antidepressant treatment upregulates the cyclic adenosine monophosphate (cAMP)-

response element-binding protein (CREB) cascade and expression of BDNF (Duman *et al.*, 1999). Upregulation of CREB and BDNF raises the possibility that antidepressant treatment could oppose the cell death pathway. These findings suggest that regulation of the cell death pathways could also contribute to the actions of agents used for the treatment of bipolar disorder.

### Substance P

Substance P, an undecapeptide, is abundant both in the periphery and in the CNS, where it is usually colocalized with one of the classical neurotransmitters, most commonly serotonin (Baby *et al.*, 1999; Argyropoulos and Nutt, 2000; Stout *et al.*, 2001). A role for substance P is proposed in the regulation of pain, asthma, psoriasis, inflammatory bowel disease and, in the CNS, emesis, migraine, schizophrenia, depression and anxiety. Drug development has focused most intensively on the substance P-preferring receptor, neurokinin-1. Although originally studied as potential analgesic compounds, recent evidence suggests that neurokinin-1 receptor antagonists may possess antidepressant and anxiolytic properties. If confirmed by further controlled clinical studies, this will represent a mechanism of action distinct from all existing antidepressant agents. The existing preclinical and clinical literature is suggestive of, but not conclusive, concerning a role of substance P and neurokinin-1 receptors in the pathophysiology of depression and/or anxiety disorders.

### Neuroimaging Studies

Neuroimaging technology provides opportunities for elucidating the anatomic correlates of mood disorders (Thase and Howland, 1995; Kegeles and Mann, 1997; Soares and Mann, 1997a, 1997b; Dougherty and Rauch, 1997; Drevets *et al.*, 1999, 2000, 2001). Neuroimaging studies of major depression have identified structural and functional abnormalities in multiple areas of the orbital and medial prefrontal cortex, the amygdala, and related parts of the striatum and thalamus (Thase and Howland, 1995; Soares and Mann, 1997a, b; Dougherty and Rauch, 1997; Drevets *et al.*, 1999; Dubovsky and Buzan, 1999; Drevets, 2000, 2001).

The most consistently identified functional neuroimaging finding has been prefrontal lobe dysfunction, as indicated by reduced blood flow and glucose metabolism (Soares and Mann, 1997b; Drevets, 2000, 2001). There is evidence of abnormalities in basal ganglia, temporal lobe and related limbic structures. Unipolar depression is associated with dysfunction primarily in the prefrontal cortex and basal ganglia, while bipolar depression may be associated with dysfunction in the temporal lobe, in addition to these other areas. Some of these functional abnormalities appear mood-state-dependent and are located in regions where cerebral blood flow increases during normal and some pathologic emotional states. These neurophysiologic differences between depressives and control subjects may thus implicate areas where physiologic activity changes to mediate or respond to the emotional, behavioral and cognitive manifestations of major depressive episodes. Other abnormalities persist following symptom remission, and are found in orbital and medial prefrontal cortex areas where postmortem studies demonstrate reductions in cortex volume and histopathologic changes in primary mood disorders (Mann and Arango, 1999). These areas appear to modulate emotional behavior and stress responses, based upon evidence from brain mapping, lesion analysis and electrophysiologic studies of humans and experimental animals. Dysfunction involving these regions is thus hypothesized to play a role in the pathogenesis of depressive symptoms. Taken together, these findings

implicate interconnected neural circuits in which pathologic patterns of neurotransmission may result in the emotional, motivational, cognitive and behavioral manifestations of primary and secondary affective disorders.

The development of selective ligands for neuroreceptor imaging is providing rapidly expanding capabilities for noninvasive quantitation of *in vivo* receptor binding and neurotransmitter function. PET and SPECT studies provided important information regarding the role of serotonergic receptors in the pathogenesis of mood disorders. Such studies will permit more complete characterization of the neurotransmitter abnormalities suggested by studies of body fluids, postmortem tissue and neuroendocrine function. This area is becoming one of the most important applications for PET and SPECT technologies.

# Psychiatric Pathophysiology: Anxiety Disorders

One thing is certain, that the problem of anxiety is a nodal point, linking up all kinds of important questions: a riddle, of which the solution must cast a flood of light upon our whole mental life.

Freud 1917

## Introduction

In the 50 years since DSM-I, the rubric of “anxiety disorder” has evolved and expanded to encompass generalized anxiety disorder (GAD), panic disorder (PD), phobias, obsessive–compulsive disorder (OCD) and post traumatic stress disorder (PTSD) (Rickels and Rynn, 2001). Given the complex circuitry required to integrate behaviors characteristic of the anxiety disorders (Lang *et al.*, 1998; Coplan and Lydiard, 1998; Davis 1998), it seems implausible that a single gene product or transmitter system will ultimately be identified as the sole mediator of any anxiety disorder.

Most contemporary neurobiological theories of anxiety disorders are grounded on the molecular mechanisms of drugs used to treat these disorders. Despite the ever-increasing use of genetically engineered mice (which has certainly added to our knowledge base), this “reverse engineering” approach remains the standard in biological psychiatry, in part because of the difficulties inherent in validating animal models of psychiatric disorders. Further, when a drug is shown to be effective, variants of the drug (differing in potency and/or efficacy) often facilitate hypothesis testing in both animals and humans. This chapter describes preclinical studies linking four major transmitter systems (GABA, glutamate, serotonin and norepinephrine) to anxiety disorders. This selection was based on the mechanism of action of drugs currently approved to treat one or more of the anxiety disorders.

## Gamma-aminobutyric Acid (GABA)

GABA is the principal inhibitory transmitter in the vertebrate central nervous system, with about one-third of all synapses using GABA as a transmitter. Fifteen years after their introduction into clinical practice, benzodiazepines were shown to augment the actions of GABA (Haefely and Polc, 1986). A compelling body of evidence indicates that augmentation of GABAergic transmission mediates the principal pharmacological actions of the benzodiazepines. The efficacy of benzodiazepines in the treatment of anxiety disorders (including GAD, PD and social

phobia) has been well documented by double-blind, placebo-controlled studies (Ballenger, 1999; Blanco *et al.*, 2002).

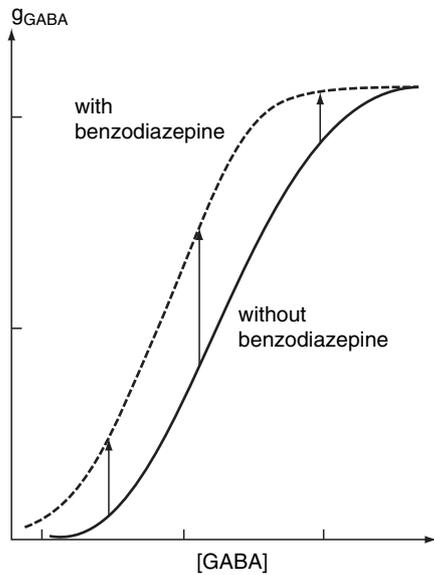

From a cellular perspective, benzodiazepines act as allosteric modulators, increasing the apparent affinity of GABA at GABA<sub>A</sub> receptors (Figure 12.1). By binding to a specific subset of amino acids on the *N*-terminal of the GABA<sub>A</sub> receptor alpha and gamma subunits (Wong *et al.*, 1992; Tretter *et al.*, 1997), benzodiazepines (and structurally unrelated compounds that bind to overlapping sequences on these subunits) effect this increase in the apparent affinity of GABA to its recognition site (Haefely and Polc, 1986).

Despite the evidence that benzodiazepines and other strategies directed at augmenting GABAergic transmission are effective in the treatment of anxiety disorders, this evidence does not directly implicate GABA<sub>A</sub> receptors in their pathophysiology. Nonetheless, convergent pharmacological and physiological evidence are consistent with the hypothesis that GABAergic pathways are intimately involved in the behavioral, somatic and endocrine manifestations of anxiety.

There are two principal lines of pharmacological evidence implicating GABAergic pathways in anxiety. The first involves the demonstration that so-called benzodiazepine receptor *inverse agonists* produce a constellation of actions (behavioral, somatic and endocrine) reminiscent of anxiety in rodents and primates, including man. Recall that the principal cellular action of benzodiazepines is to increase the apparent affinity of GABA at GABA<sub>A</sub> receptors, manifested as a left shift of the GABA concentration effect curve (Figure 12.2).

The second line of pharmacological evidence linking GABA<sub>A</sub> receptor dysfunction to anxiety disorders stems from reports that flumazenil is panicogenic in PD patients but not in control subjects (Nutt *et al.*, 1990; Woods *et al.*, 1991). It can be hypothesized that flumazenil acts as a GABA negative (inverse agonist) compound in some subsets of PD patients with an **atypical** GABA<sub>A</sub> receptor composition in circumscribed areas of the central nervous system (CNS). While there is no direct evidence to support this hypothesis, positron emission tomography (PET) studies have demonstrated a global reduction in the binding of <sup>11</sup>C flumazenil throughout the brain in patients with PD compared with controls.

Findings from multiple lines of research indicate that GABA<sub>A</sub> receptors may have evolutionary significance as a **bio-warning** system and perhaps as a means of compensating for perturbations in the environment. If stress-induced activation of GABA<sub>A</sub> receptors (manifested in these studies as increases

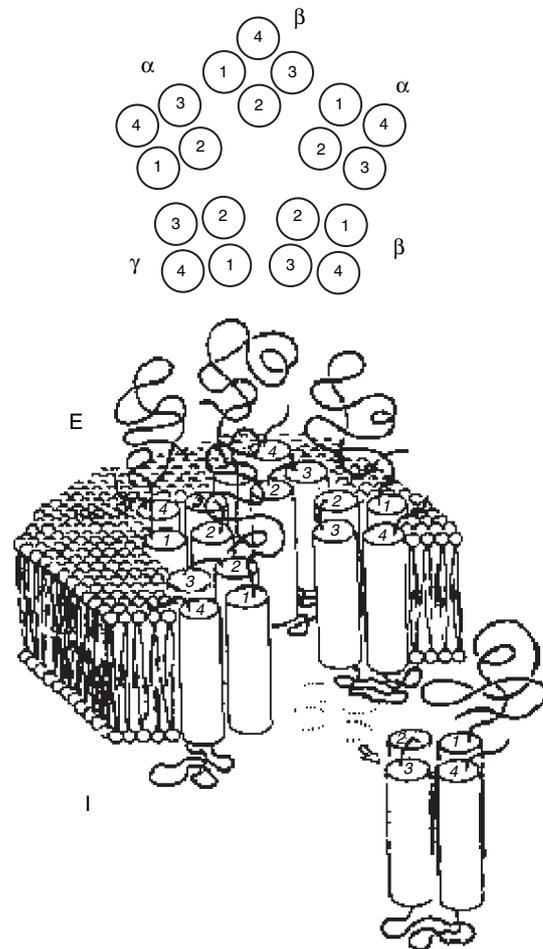

**Figure 12.1** Benzodiazepines augment GABAergic transmission. Ordinate: Magnitude of GABA-induced (chloride) currents ( $g_{GABA}$ ); abscissa: concentration of GABA applied. In systems expressing GABA<sub>A</sub> receptors (ranging from spinal neurons to cells transfected with mRNAs encoding GABA<sub>A</sub> receptor subunits), application of GABA increases chloride conductance, generally producing membrane hyperpolarization. While unable either to gate (like GABA and GABA mimetics) or directly open (like anesthetic concentrations of barbiturates) these GABA-gated chloride channels, benzodiazepines increase the apparent affinity of GABA, producing the illustrated left shift in its concentration-effect curve. An increase in the apparent affinity of endogenous GABA produced by benzodiazepines (and related compounds) is thought to mediate the principal pharmacological actions of these compounds, including their antianxiety actions. Reproduced with permission from *Physiology of GABA enhancement by benzodiazepines and barbiturates*. In *Benzodiazepine/GABA Receptors and Chloride Channels*, Haefley W and Polc P [1986] Olsen R and Venter C [eds]. Alan R. Liss, New York. With permission from John Wiley, New York.

in TBPS binding) is an attempt to compensate for environmental perturbations, then benzodiazepines (and low doses of barbiturates which increase the frequency of channel opening) (Study and Barker, 1981) may be viewed as pharmacological mimicry of the organism's initial attempts to cope with the disruption of its environment.

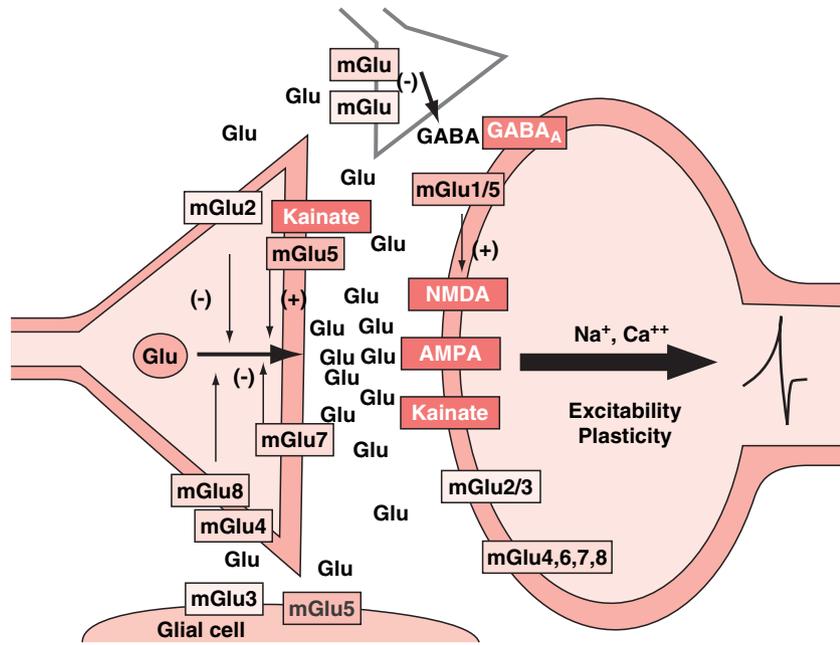

## Glutamate

Glutamate is the principal excitatory transmitter in the mammalian CNS. A discussion of the role of glutamatergic transmission is included in this overview based on an extensive preclinical literature linking modulation of both ionotropic (*N*-methyl-D-aspartate) and metabotropic (mGluR2) glutamate receptor subtypes (Figure 12.3) to anxiety (Skolnick, 2000). Further, a recent, albeit preliminary, clinical study

**Figure 12.2** Model of the GABA<sub>A</sub> receptor. GABA<sub>A</sub> receptors are hetero-oligomers, with the great majority of native receptors containing  $\alpha$ ,  $\beta$ , and  $\gamma$  subunits. The stoichiometry of a recombinant receptor containing an  $\alpha$ ,  $\beta$ , and  $\gamma$  subunit (this subunit combination represents the majority of GABA<sub>A</sub> receptors in mammalian brain) (De Blas AL [1996] *Brain GABA<sub>A</sub> receptors studied with subunit-specific antibodies*. *J Mol Neurobiol* 12, 55–71) is  $2\alpha$ ,  $2\beta$ , and  $1\gamma$ , arranged as illustrated in the top panel (Klausberger T, Sarto I, Ehya N et al. [2001] *Alternate use of distinct intersubunit contacts controls GABA<sub>A</sub> receptor assembly and stoichiometry*. *J Neurosci* 21, 9124–9133). Binding sites for benzodiazepines (and related compounds) are formed by the amino-terminal domains (located in the extracellular space, E) of the  $\alpha$  and  $\gamma$  subunits. Each subunit possesses four transmembrane spanning domains (illustrated as cylinders 1–4), with the second transmembrane spanning domain forming the lumen of the GABA-gated chloride channel. Symbols: E, extracellular space; I, intracellular space. (Source: Modified from Olsen R and Towin A [1990] *Molecular biology of GABA<sub>A</sub> receptors* *Faseb J* 4, 1469–1480; Klausberger T, Sarto I, Ehya N et al. [2001] *Alternate use of distinct intersubunit contacts controls GABA<sub>A</sub> receptor assembly and stoichiometry*. *J Neurosci* 21, 9124–9133.)

(Levine et al., 2001) appears to validate preclinical findings indicating that glutamate receptors are a valid target for the

**Figure 12.3** *Glutamate receptors: cellular localization and function. The majority of ionotropic glutamate (AMPA, kainate and NMDA) receptors are postsynaptic. These glutamate receptors mediate fast excitatory transmission through associated ligand-gated cation (sodium and calcium permeant). Among ionotropic glutamate receptors, the NMDA subfamily has been most closely linked to anxiety disorders (see text for details). Metabotropic glutamate receptors are distributed across the synapse region (including neighboring glia) and appear to serve modulatory roles via coupling to phospholipase C or adenylate cyclase. Among metabotropic glutamate receptors, group II (mGluR2 and mGluR3) have been most closely linked to anxiety disorders (see text for details). (Schoepp DD [2001] Unveiling the functions of presynaptic metabotropic glutamate receptors in the central nervous system. *J Pharmacol Exp Ther* 299, 12–20. Reproduced by permission of American Society for Pharmacology and Experimental Therapeutics).*

development of novel anxiolytics. Like serotonin receptors, the glutamate receptor superfamily includes both ionotropic and G-protein coupled receptors (GPCR). The structural and molecular details of both receptor classes have been reviewed in detail (Schoepp, 2001; Conn and Pin, 1997; Palfreyman *et al.*, 1994; Cotman *et al.*, 1995). A brief overview of two glutamate receptor subtypes is provided as a background to place preclinical and clinical findings in context.

### NMDA Receptors

NMDA receptors are broadly and unevenly distributed across the mammalian CNS.

In addition to reports that NMDA antagonists are anxiolytic, there is a body of preclinical literature indicating that NMDA receptor activation is **anxiogenic**. These studies are reminiscent of, and in some sense parallel, studies with benzodiazepine receptor inverse agonists.

### Linking NMDA Receptors to Biogenic Amine-based Anxiolytics

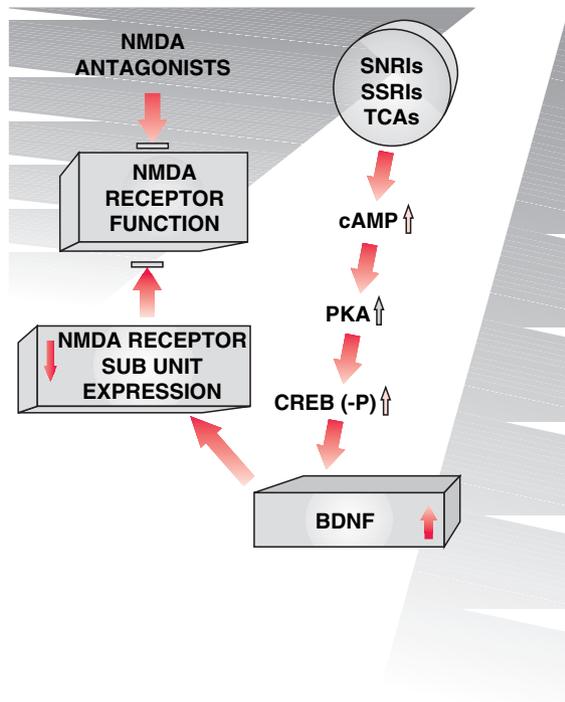

In preclinical studies, chronic treatment with biogenicamine-based antidepressants used in the treatment of anxiety disorders blunts NMDA receptor function (Skolnick, 1999). In view of the anxiolytic-like actions of NMDA antagonists in

preclinical tests, the body of evidence indicates that NMDA receptors may represent a downstream target for biogenic amine-based antidepressants. While this hypothesis has been used to explain the **therapeutic lag** associated with biogenic amine-based antidepressants (Skolnick, 1999), it may also contribute to the delay in onset of these serotonin and norepinephrine modulators used to treat anxiety disorders (Figure 12.4).

### Group II Metabotropic Glutamate Receptors

Metabotropic glutamate receptors are classified as “family 3” G-protein coupled receptors (GPCRs). Group II metabotropic receptors (that include mGluR2 and mGluR3 receptors) are negatively coupled to adenylate cyclase, and the mGluR2 receptor subclass is found both pre- and extrasynaptically. Several lines of evidence indicate that glutamate activates these mGluR2 receptors, resulting in a rapid inhibition of glutamate release, creating a negative feedback loop (Schoepp, 2001; Scanzfani *et al.*, 1997). Since activation of Group II metabotropic receptors appears to require an elevated glutamate concentration, an agonist at these receptors would effectively dampen glutamatergic transmission (including activation of NMDA receptors) without remarkably affecting synaptic glutamate under resting conditions.

Based on these data and reports that telencephalic glutamate concentrations are rapidly elevated during stress

**Figure 12.4** *Linking NMDA receptors to biogenic amine-based anxiolytics: By increasing the synaptic availability of biogenic amines, MAOIs, TCAs, and SSRIs can activate adenylate cyclase through  $G_s$ -coupled receptors. Increases in intracellular cyclic AMP increase protein kinase A activity, which may then phosphorylate a cyclic AMP response element binding protein (CREB), increasing the transcription of BDNF. Exposure to BDNF can diminish NMDA receptor function (see text and Skolnick [1999] for details). In view of preclinical studies linking NMDA receptors to anxiety disorders, downregulation of NMDA may represent a downstream target for biogenic amine-based agents. While this hypothesis has been used to explain the therapeutic lag associated with biogenic amine-based antidepressants, it may also contribute to the delay in onset of these serotonin and norepinephrine modulators used to treat anxiety disorders. Reprinted from *European Journal of Pharmacology* 375, Skolnick, *Antidepressants for the new millennium*. Copyright 1999, with permission from Elsevier.*

(Moghaddam, 1993), it may be hypothesized that activation of Group II metabotropic receptors and the subsequent reduction in glutamate release will result in an anxiolytic action. An emerging body of preclinical data (Skolnick, 2000) as well as a recent clinical report (Levine *et al.*, 2001) support this hypothesis.

## Serotonin

An association between serotonergic transmission and anxiety disorders was established more than 30 years ago with reports (Graeff and Schoenfeld, 1970; Geller and Blum, 1970) that inhibitors of serotonin synthesis (such as *p*-chlorophenylalanine) reduced the ability of punishment (e.g., footshock) to suppress operant responding. Many studies have confirmed and embellished the basic findings that destruction of serotonergic pathways and/

or a reduction in the synthesis of this biogenic amine results in an animal behaving as if it had been administered an anxiolytic. There is a complementary body of evidence that serotonin receptor activation exacerbates anxiety. For example, challenge doses of meta-chlorophenylpiperazine (a serotonin agonist) were anxiogenic in PD patients (Charney *et al.*, 1987b), individuals with OCD (Zohar *et al.*, 1987) and in patients with GAD (Nutt, 2001). The observation that anxiety can initially be exacerbated in GAD patients receiving SSRIs (Nutt, 2001) provides perhaps the most compelling evidence that acute elevation of synaptic serotonin is anxiogenic.

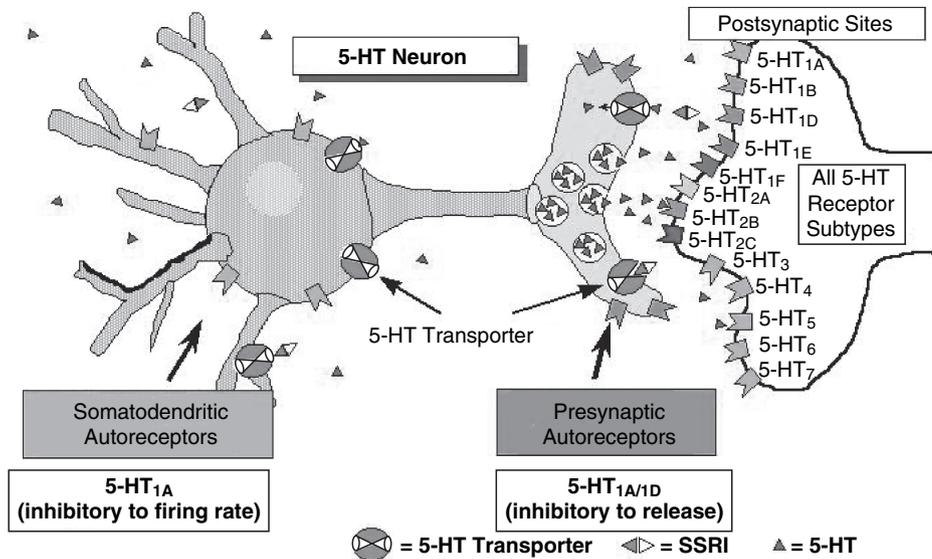

## Norepinephrine

Like serotonergic neurons, noradrenergic neurons are anatomically restricted, with the majority (>70%) found in the nucleus locus coeruleus. Noradrenergic neurons also possess an extensively ramified system of efferent projections, diffusely innervating brain regions (e.g., cortex, amygdala, hippocampus, hypothalamus) associated with anxiety disorders. From a historical perspective, the evidence linking norepinephrine (and by implication, the recognition sites subserving this transmitter) to anxiety disorders clearly predates (Blaschko, 1972) the other transmitters described in this chapter. The ability of stress to impact brain norepinephrine levels has been known for almost 40 years (e.g., Barchas and Freedman, 1963; Maynert and Levi, 1964). A wide range of stressors have been reported to increase norepinephrine turnover in the CNS (Stone, 1975; Tilson *et al.*, 1975). This activation of noradrenergic neurons by stress can be attenuated by benzodiazepines (Taylor and Laverty, 1973; Ida *et al.*, 1985).

The locus coeruleus sends projections to many fore-brain areas associated with fear and anxiety via the dorsal noradrenergic bundle. Redmond and his colleagues (Redmond and Huang, 1979) provided perhaps the most compelling preclinical data linking noradrenergic pathways to anxiety disorders. Thus, it was demonstrated that electrical stimulation of the locus coeruleus in monkeys produced fear-like behaviors, and that “symptom” severity appeared dependent on the strength of the applied stimulus. Bilateral ablation of the locus coeruleus blunted the behavioral responses of animals to threatening environmental stimuli (Redmond and Huang, 1979). Pharmacological studies in humans have also implicated noradrenergic pathways in some of the anxiety disorders.

A variety of clinical and preclinical findings indicate that physiological or pharmacological activation of noradrenergic pathways mimics or exacerbates anxiety. At face value, these findings are at odds with the reported efficacy of TCAs and MAOIs in anxiety disorders (Hoehn-Saric, 2000; Buller and Jorga, 2000). In a broad sense, this body of evidence parallels the apparent contradictory findings that increasing serotonergic transmission is associated with anxiety, yet drugs whose primary neurochemical action (e.g., SSRIs) results in increased synaptic concentrations of serotonin are useful in the treatment of anxiety disorders.

Future studies on potential targets downstream of the monoaminergic synapse (e.g., Rossby and Sulser, 1997) (Figure 12.5) may result in a better understanding of the anti-anxiety actions of these compounds and the neurochemical substrates of anxiety.

**Figure 12.5** Serotonin receptor heterogeneity. The cell bodies of serotonin-containing neurons are primarily located in or near the brain stem raphe nuclei. These neurons possess long, extraordinarily arborized axons. Serotonin signaling is largely effected through G-protein-coupled receptors, although one ionotropic ( $5\text{-HT}_3$ ) receptor has been identified. The G-protein-coupled serotonin receptors include representatives of the  $G_s$  family (e.g.,  $5\text{-HT}_6$  receptors) positively coupled to adenylate cyclase, the  $G_i$  family (e.g.,  $5\text{-HT}_{1A}$  receptors) inhibiting adenylate cyclase, and receptors coupled to phospholipase C activation (e.g.,  $5\text{-HT}_{2C}$  receptors). Drugs that increase synaptic serotonin concentrations (e.g., SSRIs, TCAs) are effective in treating anxiety disorders. However, the functional and anatomical diversity of serotonergic pathways may contribute to both a delay in onset and a body of evidence that acute activation of serotonergic transmission is anxiogenic. # Psychiatric Pathophysiology: Addiction

Addiction is a complex maladaptive behavior produced by repeated exposure to rewarding stimuli (O'Brien, 2001). There are two primary features common to both natural and pharmacological stimuli that elicit addiction. First, the rewarding stimulus associated with the addiction is a compelling motivator of behavior at the expense of behaviors leading to the acquisition of other rewarding stimuli. Thus, individuals come to orient increasing amounts of their daily activity around the acquisition of the rewarding stimulus to which they are addicted. Secondly, there is a persistence of craving for the addictive stimulus, combined with an inability to regulate the behaviors associated with obtaining that stimulus. Thus, years after the last exposure to an addictive stimulus, re-exposure or environmental cues associated with that stimulus will elicit behavior aimed at obtaining the reward.

During the course of repeated exposure to strong motivationally relevant stimuli, specific brain nuclei and circuits become engaged that mediate the addicted behavioral response. It is generally thought that different rewarding stimuli involve different brain circuits, but also that there are regions of overlap forming a common substrate for all addictive stimuli. Studies using animal models of reward and addiction have focused on subcortical brain circuits known to be involved in drug reward, such as the dopamine projection from the ventral mesencephalon to the nucleus accumbens (Koob and LeMoal, 2001; Everitt and Wolf, 2002). Accordingly, molecular and electrophysiological studies of the cellular plasticity mediating the emergence of addictive behaviors have focused on the nucleus accumbens and ventral mesencephalon. However, over the last decade studies have emerged from both the animal literature and neuroimaging of drug addicts indicating that the expression of addicted behaviors such as sensitization and craving involves regions of the cortex and allocortex (Pierce and Kalivas, 1997; Volkow and Fowler, 2000; Grant *et al.*, 1996; Childress *et al.*, 1999). In this regard, two regions have come to be most closely associated with craving, the amygdala and frontal cortex (including the anterior cingulate and ventral orbitofrontal cortex). Prior to describing circuitry underlying the state of addiction, we will briefly examine the neurobiology associated with the development of the addicted state.

## The Development of Addiction

The acute administration of all addictive drugs, with the possible exception of the benzodiazepines, stimulates dopamine transmission in the projection from the ventral mesencephalon to the nucleus accumbens. This projection is generally referred to as the mesolimbic dopamine system; Figure 13.1

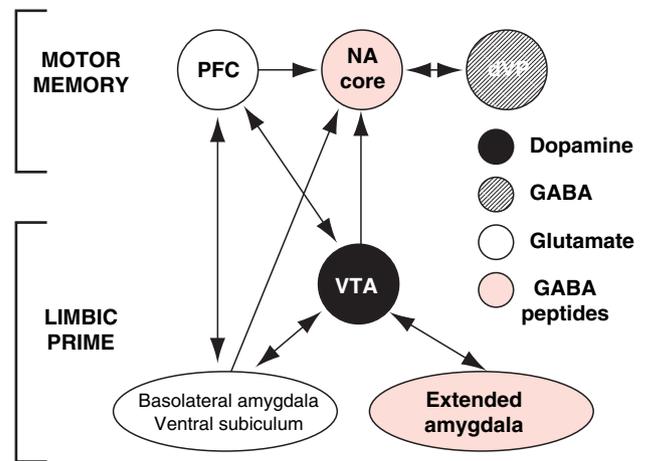

**Figure 13.1** Changes in dopamine release in the nucleus accumbens of rats treated acutely with various classes of addictive drugs, or exposed to positive (sucrose) or negative (footshock) environmental stimuli. The changes in dopamine levels were determined with microdialysis and the data are an idealized portrayal derived from the majority of extant literature. For specific examples of experimental measurements the reader is referred to the following references (Nisell M, Nomikos GG and Svensson TH [1994] Systemic nicotine-induced dopamine release in the rat nucleus accumbens is regulated by nicotinic receptors in the ventral tegmental area. *Synapse* 16, 36–44; Kalivas PW and Duffy P [1993] Time course of extracellular dopamine and behavioral sensitization to cocaine. I. Dopamine axon terminals. *J Neurosci* 13, 266–275; Yim HJ, Schallert T, Randall PK *et al.* [1998] Comparison of local and systemic ethanol effects on extracellular dopamine concentration in rat nucleus accumbens by microdialysis. *Alcohol Clin Exp Res* 22[2], 367–374; Salamone J, Cousins M, McCullough L *et al.* [1994] Nucleus accumbens dopamine release increases during instrumental lever pressing for food but not free food consumption. *Pharmacol Biochem Behav* 49, 25–31; Deutch AY and Roth RH [1990] The determinants of stress-induced activation of the prefrontal cortical dopamine system. *Prog Brain Res* 85, 357–393). Note that the effect of addictive substances on extracellular dopamine levels is of greater intensity and duration than the effect of motivationally relevant environmental stimuli.

illustrates the capacity of two drugs of abuse – cocaine and ethanol – to increase dopamine transmission in the nucleus accumbens. The pharmacological site of action by which different classes of drugs of abuse activate dopamine transmission varies and includes three general cellular mechanisms that encompass all drugs of abuse: 1) Receptors for the drug are on dopamine cell bodies and dendrites, and through these receptors drug administration directly stimulates dopamine neurons. Nicotine and marijuana are examples of drugs working in part through this mechanism (Cheer *et al.*, 2000; Nisell *et al.*, 1994). 2) Receptors are located primarily on GABAergic inhibitory afferents to the dopamine cells, and drug binding to these receptors reduces GABA release, thereby disinhibiting dopamine neuronal activity. Opioids and ethanol produce reward in part by this mechanism (Bunney *et al.*, 2001; Cameron *et al.*, 1997). 3) Finally, drugs can bind to presynaptic receptors to increase the presynaptic release of dopamine without directly altering the activity of dopamine neurons. The primary mechanism in this category is exemplified by amphetamine-like psychostimulants which bind to the dopamine transporter and increase dopamine release by blocking reuptake and/or promoting the release of dopamine by reverse transport (Seiden *et al.*, 1993).

Figure 13.1 also illustrates that mesolimbic dopamine is released by environmental stimuli that are motivationally relevant to the organism, regardless of the valence of the stimulus. For example, either positive motivational stimuli such as sex and food, or negative stressful stimuli will increase dopamine release. However, as indicated in Figure 13.1, regardless of the intensity of the natural stimulus, the extent of dopamine release is far less than that produced by drugs. This is especially true for the duration of dopamine release induced by a typical dose of addictive drugs that will endure for many minutes to hours, while a natural stimulus is thought to elevate dopamine for a period of only a few minutes, even if the stimulus itself is present for a greater length of time.

Unlike physiological stimuli, the increase in dopamine transmission does not diminish following repeated drug administration (although this varies with drug class, and some tolerance can be demonstrated to all drugs during a binge of drug taking). Thus, repeated drug use is associated with repeated increase in dopamine, thereby providing a repeated stimulus for cellular adaptation. Due to both the relative lack of tolerance to drug-induced dopamine release as well as to the fact that the quantity of release is well in excess of what is seen physiologically with naturally rewarding stimuli (see Figure 13.1), it is thought that dopamine-dependent neuroplastic changes induced by repeated drug use are beyond the physiological range of normal cellular adaptation. This pathological event precipitates a sequence of cellular changes that ultimately produce neuroadaptations that are widespread in cortical and limbic circuitry, and these adaptations constitute the underlying pathophysiology of addiction. Although the addiction-associated neuroadaptations are impacted by drug class, dose and withdrawal period, it is thought that excessive, nonphysiological release of dopamine is a critical initiator of the pathology.

Identifying the specific changes in gene expression and cellular function that are associated with the development of addiction is an area of active research, and the interested reader is referred to recent reviews of this literature (Nestler, 2001; Kalivas, 2002).

**Figure 13.2** Motive circuit thought to be involved in addiction. A role for these nuclei and interconnections between nuclei in addiction has been revealed using neuroimaging techniques in addicts and/or reinstatement animal models of drug-seeking behavior. (dVP-dorsal ventral pallidum, NAcore-core of the nucleus accumbens, PFC-prefrontal cortex, and VTA-ventral tegmental area.)

## Brain Circuitry and Addiction

Figure 13.2 will be used as a guide for this portion of the chapter and outlines the nuclei and the interconnections between these nuclei, which will be discussed. This circuit has been previously characterized as the motive circuit and contains brain nuclei that are considered critical substrates for drug reward and the development of addiction (as outlined above), such as the dopamine neurons in the ventral tegmental area and projections to the nucleus accumbens. In addition, the circuit contains prefrontal cortical and allocortical brain regions now known to be critical for the expression of behaviors commonly associated with addiction, such as drug craving.

## Human Neuroimaging and Animal Models Reveal Addiction Circuitry

The majority of our recent understanding of how the motive circuit (in Figure 13.2) is involved in addiction is derived from neuroimaging studies in human addicts and animal studies employing the reinstatement model of drug craving. The neuroimaging studies typically involve functional imaging of brain activity in addicts that are exposed to evocative stimuli, such as an injection of a low dose of drug or stimuli (e.g., the drug paraphernalia) that the addict associates with drug taking (Volkow and Fowler, 2000).

## The Motive Circuit as a Substrate of Addiction

The circuit illustrated in Figure 13.2 consists of interconnected nuclei that have been shown to be involved in the processing of drug reinforcement and in initiating behaviors to obtain such reinforcement. Neuroimaging studies have clearly identified cortical circuits that are activated by drug-associated stimuli in addicts. This includes areas of the prefrontal cortex, such as the anterior cingulate and the ventral orbital cortex, as well as some allocortical regions including the amygdala (Pierce and

Kalivas, 1997; Volkow and Fowler, 2000; Grant *et al.*, 1996; Childress *et al.*, 1999; Porrino and Lyons, 2000). In addition, some neuroimaging studies have revealed involvement of the ventral striatum (including the nucleus accumbens), especially in response to a small challenge dose of drug (Porrino and Lyons, 2000; Breiter *et al.*, 1997). In addition, the animal literature has identified two other brain regions to be critical in models of primed relapse. One area is the ventral tegmental area that, as outlined above, contains dopamine cells projecting to the cortex and nucleus accumbens. The other region that has been associated with stress-induced relapse is the bed nucleus of the stria terminalis, and probably the accompanying nuclei of the extended amygdala. Finally, recent evidence has emerged indicating a possible role for the ventral subiculum, where electrical stimulation was found to induce reinstatement of drug seeking for cocaine (Vorel *et al.*, 2001).

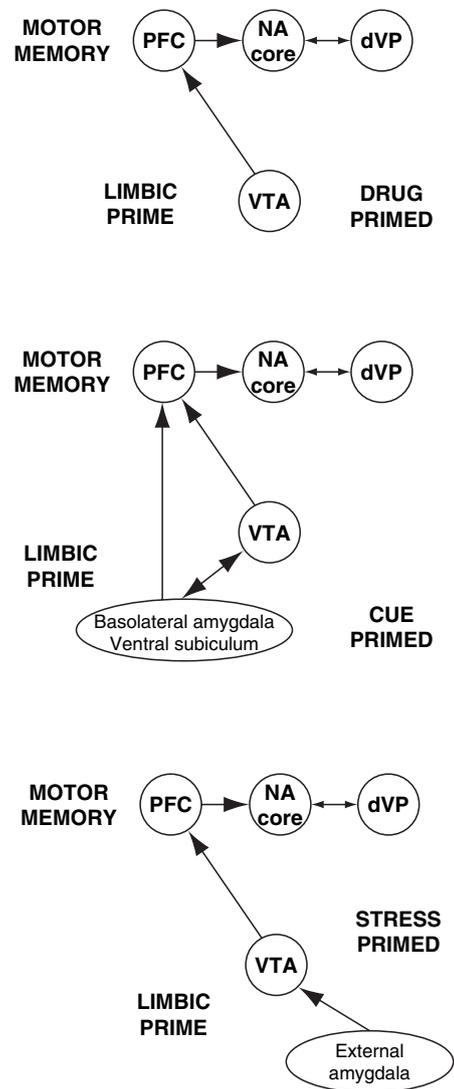

There is a growing realization that stimulus-evoked drug-seeking behavior is comprised of two circuits, a motor memory circuit and a limbic priming circuit (see Figure 13.2). The motor memory circuit consists of the motor nuclei in the motive circuit including the dorsal prefrontal and ventral orbital cortex, core of the nucleus accumbens and dorsolateral ventral pallidum. The limbic priming circuit activates the motor memory circuit in response to various stimuli. The stimuli activate the motor memory circuit via limbic circuitry, and the limbic nuclei involved are somewhat distinct depending upon stimulus modality. The ventral tegmental area is integral to all stimulus modalities, and the extended amygdala and basolateral amygdala contribute differentially depending on whether the stimulus is a stressor or a drug-associated cue, respectively (Figure 13.3).

### Motor Memory Circuit

This portion of the circuit may be integral to all forms of drug-taking behavior. Priming stimuli access this circuit primarily via the prefrontal cortex and evoke behaviors organized to obtain drug reward. Thus, the motor memory circuit functions akin to a procedural memory circuit and, when accessed by a priming stimulus, provides a programmed sequence of learned behaviors to obtain drug.

The regions of the prefrontal cortex most clearly shown in neuroimaging studies to be activated by drug-associated environmental or pharmacological cues are the anterior cingulate and ventral orbital cortices (Volkow and Fowler, 2000; Childress *et al.*, 1999). Both of these cortical areas make substantial glutamatergic projections to the nucleus accumbens (Groenewegen *et al.*, 1996).

Although the role of the accumbens to pallidum projection in primed reinstatement is only just emerging, this projection has long been known to mediate motor activity initiated by motivationally relevant stimuli (Mogenson *et al.*, 1980, 1993; Burns *et al.*, 1994). From this literature it is clear that both dopamine and glutamate transmission in the nucleus accumbens are necessary conditions for normal motor stimulation to occur (Burns *et al.*, 1994; Robbins and Everitt, 1996; Vanderschuren and Kalivas, 2000). The data show an association between glutamate, but not dopamine transmission in the nucleus accumbens and drug-seeking behavior. However, in contrast to the nucleus accumbens, dopamine transmission in the dorsal prefrontal cortex or basolateral amygdala has been shown to be critical to the execution of cocaine- or cue-primed reinstatement, respectively (See *et al.*, 2001; McFarland and Kalivas, 2001).

**Figure 13.3** Hypothesized circuits involved in the priming of craving and drug-seeking behavior by stress, learned associations, or an acute drug administration. While the motor memory circuit is postulated to be involved, regardless of the modality of the priming stimulus, the priming circuitry differs between the three classes of stimuli.

### Limbic Priming Circuit

#### Drug-primed Reinstatement

Acute administration of a drug that was previously self-administered is known to elicit craving and drug-seeking behaviors in experimental animals and human addicts (O'Brien 2001; Markou *et al.*, 1993). The role of dopamine at inducing priming is well established since both systemic and intra-cortical administration of dopamine blockers have been shown to inhibit drug-primed reinstatement. However, activation of dopamine neurons is apparently not a prerequisite, although having an intact dopamine system is permissive. Figure 13.3 illustrates the circuit critical for cocaine-primed reinstatement. It is proposed that this is a minimal circuit and that other drugs of abuse may involve additional brain nuclei that activate dopamine cells. For example, disinhibition of GABAergic input to dopamine cells

in the ventral tegmental area by a microinjection of morphine is known to elicit reinstatement in animals trained to self-administer heroin (Stewart, 1984).

### Cue-primed Reinstatement

When animals or humans experience drug effects in the presence of an environmental stimulus (cue), a learned association develops such that presentation of that cue will elicit craving and behavior organized to obtain drug reward. Cue-primed reinstatement of drug-seeking behavior is clearly dependent upon the functional integrity of the basolateral amygdala (Meil and See, 1997; Grimm and See, 2000). This region of the amygdala has also been shown to be critical for many forms of stimulus-reinforcer associations (Everitt *et al.*, 1999). Moreover, it was recently shown that in a manner analogous to the role of the prefrontal cortex in drug-primed reinstatement, blockade of D<sub>1</sub> dopamine receptors in the basolateral amygdala prevents cue-primed reinstatement (See *et al.*, 2001). This effect implies that presentation of the cue activates the projection from the ventral tegmental area to the basolateral amygdala, and is consistent with a well-developed electrophysiological literature showing that dopamine neurons in the ventral tegmental area increase burst firing following presentation of a cue that predicts a reward (Schultz, 1998).

### Stress-primed Reinstatement

Addicts often report that environmental stress can precipitate craving and drug-taking behavior (O'Brien, 2001; Lyvers, 2000). The regions of the brain most clearly associated with stress-primed reinstatement are associated with extended amygdala (Shaham *et al.*, 2000; Heimer *et al.*, 1993).

### Integration of Findings

Present knowledge suggests the possibility of a final common pathway for addiction, and possibly similar brain circuits between drugs and stimuli that provoke craving and relapse. The extant data support a common role of the motor memory circuit shown in Figure 13.3 that consists of the series projection from the prefrontal cortex to nucleus accumbens to ventral pallidum. Moreover, there is abundant evidence for enduring neuroadaptations in gene expression and neuronal function in the nucleus accumbens and prefrontal cortex following a bout of drug taking (Nestler, 2001; Kalivas, 2002). While the finding from multiple lines of research are promising in pointing towards a common site of intervention in addiction, it is important to note that such a generalization based primarily on work with psychostimulants is premature and requires substantially more research using other classes of drugs to validate. Similarly, the proposal for a final common motor memory pathway mediating craving and relapse induced by different modalities of stimuli is based on only a modest number of neuroimaging studies in addicts and experimental models of relapse. Nonetheless, sufficient supportive data has accrued to at least speculate on the prepotent involvement of the motor memory pathway in addiction, especially the glutamatergic projection from regions of the prefrontal cortex including the anterior cingulate and ventral orbital cortex to the core of the nucleus accumbens. Likewise, dopamine projections to prefrontal cortex and allocortical areas such as the basolateral amygdala are also critical.

These emerging hints and hypotheses pose directions for novel pharmacological therapeutic strategies for ameliorating craving and relapse associated with addiction. Notably,

pharmacological regulation of glutamate transmission in the cortical projection to the nucleus accumbens would seem to be a potential target. Given that enhanced release of glutamate appears to be associated with cue-, drug-, and perhaps, stress-primed relapse, diminishing that release would be one possible mechanism for pharmacotherapeutic intervention.

## Neuropathological Causes of Dementia in the Elderly

The most common neuropathological findings in demented elderly individuals are lesions associated with Alzheimer's disease (AD) and with cerebrovascular disease. Diseases such as Parkinson's disease, diffuse Lewy body disease, Pick's disease, and a constellation of heterogeneous diseases collectively identified as frontotemporal dementia and characterized by pronounced frontotemporal atrophy are also identified, albeit, less frequently (Green *et al.*, 2000; Xuereb *et al.*, 2000; Hachinski and Munoz, 2000; Perl, 2000; Dickson, 2001; Mckhan *et al.*, 2001). Often, AD and cerebrovascular disease, or AD and Parkinson's disease-like lesions (Perl *et al.*, 1998), are comorbid, making it difficult to ascribe dementia to either disease entity alone and blurring the distinctions between them (Xuereb *et al.*, 2000; Hachinski and Munoz, 2000; Perl *et al.*, 1998; Aguero-Torres and Winbald, 2000; Snowdon *et al.*, 1997; Hardy and Gwinn-Hardy, 1999).

## Neuropathology of Alzheimer's Disease

In his original work, Alzheimer described the plaques and tangles that have not only withstood modern scrutiny of the original index case (Graeber and Mehraein, 1999) but have become the diagnostic hallmarks of the disease known as Alzheimer's disease. Neurofibrillary tangles (NFT) and senile/neuritic plaques (NP) are the principal lesions of Alzheimer's disease (Rogers and Morrison, 1985; Tomlinson *et al.*, 1970) and form the basis for the neuropathological diagnosis of AD (Mirra *et al.*, 1991; Khachaturian, 1985; NIA-Reagan, 1997). In addition to NPs and NFTs, there is generally macroscopic evidence of cerebral cortical atrophy, reduced brain weight, and enlargement of the ventricles; however, because of the considerable overlap between AD and normal control subjects and the frequency of similar changes in other degenerative diseases (e.g., Pick's disease), these macroscopic findings are not diagnostically informative (Perl, 2000; Dickson, 2001; Adams and Duchon, 1992).

Neuritic plaques are extracellular spheroid elements (10–120  $\mu\text{m}$  in diameter) with complex structures that include amyloid fibrils and dystrophic neurites (Figure 14.1) that are frequently surrounded by microglia and reactive astrocytes. The core of the plaque is composed of amyloid beta-peptide ( $\text{A}\beta$ ) surrounded by abnormal neuronal processes and fragments (Glennner and Wong, 1984; Selkoe, 1991, 1994, 2000).  $\text{A}\beta$  is derived from the sequential proteolytic cleavage of a larger protein known as amyloid precursor protein (APP). APP is highly conserved in evolution being expressed in all mammals studied

and in most organs. An above-normal accumulation of NPs with  $\text{A}\beta$  cores in the cerebral cortex, hippocampal formation and subcortical structures has constituted the principal diagnostic measure of AD (Mirra, 1991; Khachaturian, 1985).

The precise mechanism(s) by which  $\text{A}\beta$  causes cell damage and neuronal degeneration are not presently understood. It should be kept in mind, however, that although it is broadly accepted that  $\text{A}\beta$  plays an important role in AD, its role as the primary etiological agent in the disease process is not universally accepted with certainty (Davies, 2000). Furthermore, how, if at all, NPs and NFTs interact and influence each other is far from being understood.

Neurofibrillary tangles constitute the second hallmark of AD. Although the most commonly used formal neuropathological diagnostic criteria for AD rely almost exclusively on the density of neocortical NPs (Mirra *et al.*, 1991; Khachaturian, 1985), a number of studies have argued that the development of NFTs, especially in the entorhinal cortex, represents the earliest neuropathological change in AD (Jellinger *et al.*, 1991; Braak and Braak, 1996b; Braak *et al.*, 1996; Hyman, 1997; Bouras *et al.*, 1993).

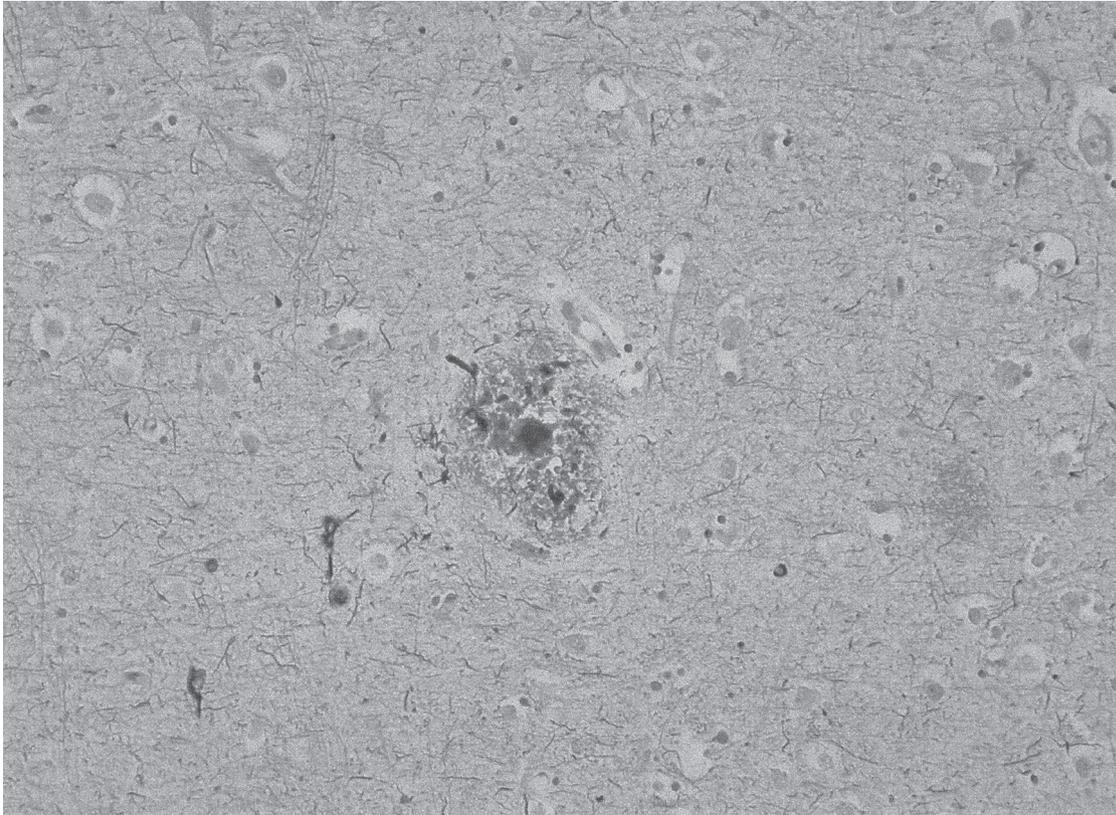

NFTs are intracellular coarse fibrillary structures that can surround the neuronal nucleus and extend into the neuronal processes. Although NFTs are observed in neurons that are otherwise apparently "healthy", it is generally, but not universally assumed that NFT formation leads to eventual neuronal death (Davies, 2000). NFTs are composed of pairs of approximately 10 nm filaments entwined into helices with a signature periodicity of approximately 160 nm.

Although neurons bearing NFTs in the hippocampus and the entorhinal cortex are observed in many if not most elderly individuals, the "spread" of NFTs to the neocortex (Braak stage III and above) is almost always associated with some level of dementia.

Despite considerable advances in understanding the neurobiology and genetics of  $\text{A}\beta$  and NFTs (see later), linkage between these two apparently diverse lesions has not been clearly established. It may be tempting to argue that AD is the result of the coincidence of two relatively independent neurobiological abnormalities. It is well established that a single mutation in the APP or an APP-related gene can cause AD. Thus, there are considerable gaps in our knowledge of the mechanisms by which the full spectrum of AD neuropathology is expressed and a more complete understanding of the etiology of AD must await further research.

## Neurochemical Deficits in Alzheimer's Disease

The neuropathology of AD is accompanied with significant neurochemical pathology and dysfunction. A central tenet of

**Figure 14.1** Typical appearance of a neuritic plaque in the neocortex of an Alzheimer's disease patient. Section stained using a modified Bielschowsky silver impregnation method. (Image courtesy: Dr Dushyant Purohit, The Mount Sinai School of Medicine, New York.)

Alzheimer's disease, established 20 years ago and repeatedly replicated, is the loss of cortical cholinergic markers, specifically the reduction of the activities of the enzymes choline acetyltransferase (ChAT) and acetylcholinesterase (AChE), in postmortem tissue from Alzheimer's patients (Perry *et al.*, 1977; Davies and Maloney, 1976; Bowen *et al.*, 1982). This abnormality has been shown to correlate with neuropathological markers and with the severity of dementia (Perry *et al.*, 1978; Bierer *et al.*, 1995a). Other neurochemical abnormalities that exist in the AD brain include loss of corticotropin releasing factor (CRF) (De Souza *et al.*, 1986; Nermeroff *et al.*, 1991) and somatostatin immunoreactivity (Davies and Terry, 1981; Davies *et al.*, 1980), and decreases in noradrenergic (Adolfsson *et al.*, 1979; Gottfries *et al.*, 1989; Chan-Palay and Asan, 1989; Teicher *et al.*, 1988), serotonergic (Cross *et al.*, 1986a, 1986b; Gottfries, 1990), GABAergic (Ellison *et al.*, 1986; Sasaki *et al.*, 1986; Simpson *et al.*, 1988; Chu *et al.*, 1987a, 1987b; Hardy *et al.*, 1987) and glutamatergic (Ellison *et al.*, 1986; Kowall and Beal, 1991; Chalmers *et al.*, 1990) markers in some patients. Table 14.1 summarizes some of the principal neuropathologic and neurochemical findings in AD.

### Synapses and Synaptic Proteins in Alzheimer's Disease

Given the neuronal degeneration and the reductions in neuronal size and arborization in AD, it is only reasonable that the numbers of synapses and their integrity should be compromised in AD. Synaptic neurotransmission, like all forms of exocytosis, requires an array of proteins. These proteins have varying ion

**Table 14.1** Most Frequently Observed Neuropathological and Neurochemical Features of Alzheimer's Disease Pathology

Neuropathology	Neurochemistry
<ul style="list-style-type: none"> <li>• Neuritic plaques in hippocampus, entorhinal cortex, cerebral cortex, and some subcortical nuclei.</li> </ul>	<ul style="list-style-type: none"> <li>• Profound cholinergic deficits including reduced activity of acetylcholine synthesizing (choline acetyltransferase) and degrading (acetylcholinesterase) enzymes.</li> </ul>
<ul style="list-style-type: none"> <li>• Neurofibrillary tangles in hippocampus, entorhinal cortex, cerebral cortex and some subcortical nuclei</li> </ul>	<ul style="list-style-type: none"> <li>• Reduced levels and immunoreactivity of neuropeptides, somatostatin and corticotropin releasing factor/hormone.</li> </ul>
<ul style="list-style-type: none"> <li>• Neuronal loss in hippocampus, entorhinal cortex, cerebral cortex and some subcortical nuclei including the forebrain cholinergic nuclei, nucleus basalis of Meynert, medial septum and diagonal band of Broca.</li> </ul>	<ul style="list-style-type: none"> <li>• Reduced levels of norepinephrine and serotonin and reduced numbers of neurons in their respective nuclei (locus coeruleus and Raphe, respectively) observed in some, but not all cases.</li> </ul>

and guanine nucleotide sensitivities, and possess intricate functional and biochemical kinships. Synaptic proteins on vesicles within the synapse and on synaptic membranes interact to enable neurotransmitter-bearing vesicles to dock with synaptic membranes and become ready for neurotransmitter release. Although losses of synaptic proteins are not unexpected in a degenerative disease, the fact that the loss of synaptic marker proteins significantly and profoundly correlate with the severity of dementia (Terry *et al.*, 1991; Masliah *et al.*, 1989; Lassmann *et al.*, 1993; Heinonen *et al.*, 1995; Tiraboschi *et al.*, 2000) suggest that the loss of synapses may play a pivotal role in the expression of the symptoms of AD.

### Inflammatory Processes in Alzheimer's Disease

The identification or recognition of neurobiological indices of inflammation in the AD brain was initially controversial because of the belief that the brain was immunologically privileged (Rogers and Shen, 2000). More than a decade of research and hundreds of studies have now confirmed the presence of inflammatory responses in the AD brain (Akiyama *et al.*, 2000) and have raised the possibility of the potential benefit of anti-inflammatory therapeutic avenues (Akiyama *et al.*, 2000; Aisen, 2000; Anthony *et al.*, 2000). It is generally acknowledged that inflammation of the brain or its neurons is unlikely to be the primary etiological factor in AD, but that it is initiated by AD-specific pathogenic processes such as deposition of NPs and/or NFTs. However, as in many other diseases, once initiated, inflammatory responses may contribute to the progression of the disease and its malignancy (Rogers and Shen, 2000).

### Genetic Factors in Alzheimer's Disease

Much has been learned regarding the contribution of genetic factors to AD over the past two decades (George-Hyslop, 2000a, 2000b). However, the impact of these genetic contributors to dementia severity is not yet well understood. Significant evidence has accumulated for genetic traits that confer susceptibility to AD. Four genes, beta-amyloid precursor protein ( $\beta$ -APP) (Selkoe, 1997, 2000b; George-Hyslop *et al.*, 1987; Robakis *et al.*, 1987; Goate *et al.*, 1991), presenilin-1 (PS1) (Selkoe, 1997, 2000b; Robakis *et al.*, 1987; Sherrington *et al.*, 1995), presenilin-2 (PS2) (Selkoe, 1997, 2000b; Robakis *et al.*, 1987; Rogaev *et al.*, 1995), and apolipoprotein E (APOE) (Selkoe, 1997, 2000b; Robakis *et al.*, 1987; Saunders *et al.*, 1993; Poirier, 2000) are of particular note. The fact that the three most prominent AD-associated mutations all affect APP processing, albeit by different mechanisms, increase  $A\beta$  production, strongly suggests that  $A\beta$  is a prominent pathogenetic agent in AD and strongly supports the amyloid hypothesis of AD (George-Hyslop, 2000a, 2000b), especially since emerging data suggest that even the epsilon-4 allele of APOE may influence  $A\beta$  processing.

Although a thorough understanding of the development of different neuropathological features of AD and their relationship to the progression of dementia must await the development of sensitive *in vivo* markers of neuropathology, the existing evidence supports the hypothesis that NPs and NFTs are “dose-dependently” associated with the earliest manifestations of AD-type dementia and that inflammatory responses and neurochemical deficits such as the cholinergic deficit become evident as dementia severity becomes more pronounced.

### Dementia in Schizophrenia and its Neuropathological and Neurochemical Sequelae

Chronic schizophrenia, with its onset in early adulthood can in geriatric years become a disorder that is commonly associated with dementia (Davidson and Haroutunian, 1995; Harvey *et al.*, 1992, 1996; Davidson *et al.*, 1995). The findings of continuing deterioration of the symptoms of schizophrenia, the cognitive performance of schizophrenics, especially the apparent dementia that has been documented in elderly schizophrenics (Davidson and Haroutunian, 1995; Harvey *et al.*, 1997, 1999a, 1999b;), and progressive enlargement of the ventricles, especially in poor-outcome schizophrenics (Davis *et al.*, 1998) has raised the possibility of a neurodegenerative component to the disease process or to its dementia.

The age-related emergence of cognitive impairment in schizophrenia fueled hypotheses linking dementia in elderly schizophrenics to AD and positing that the dementia of late-life schizophrenia was a consequence of comorbid AD (Davidson and Haroutunian, 1995; Arnold *et al.*, 1994). However, several large postmortem studies failed to support this hypothesis. Thus, although there is clear evidence for dementia in at least a subpopulation of elderly schizophrenics, the neuropathological and neurobiological substrates of this dementia have remained elusive and, as of yet, undetermined.

# Cognitive Neuroscience and Neuropsychology

## What Is Cognitive Neuroscience?

In the past two decades, much has been learned about cognitive phenomena from the constituent disciplines of cognitive neuroscience: neuropsychology, neurology, psychiatry, neuroimaging, neurobiology, computer science and cognitive psychology. The emergence of cognitive behavior from the underlying neuroanatomical substrate represents a fascinating, if elusive, process of scientific discovery. Although cognitive neuroscience is represented by a collection of disciplines, its goal is to provide a framework or process for integration in the study of cognitive phenomena. That is, the experimental information gained from these disciplines allows coordinated knowledge of brain systems to proceed both reductionistically (from macrocognitive to cellular levels) and laterally (from cognitive theories to neuropsychological theories).

The proper domain of cognitive neuroscience is vast. Motor functioning, attention, language, memory, executive control, vision, emotion, sensory functions and consciousness are only subsets of this domain. In this chapter, we selectively focus on a few critical areas of cognitive neuroscience – namely, memory, executive functions and language – and discuss these areas in depth. We highlight the structural and functional organization of these systems and discuss the relevant research from the cognitive neurosciences that address these areas. The reader is referred to a number of more comprehensive sources, where appropriate, for greater detail and discussion.

Beginning in 1901, Korbinian Brodmann undertook a series of landmark studies on the cytoarchitectonics of the mammalian cortex. It had been known before Brodmann that there were six layers of the human isocortex based on cell type and size. Brodmann extended this work on cytoarchitectonics to the subdivision of areas of cortex with similar cellular and laminar structure; he subdivided the human cerebral cortex into 47 areas. The result is a cytoarchitectonic map of the human cerebral cortex. Its development is critical to the interpretation and replication of findings in cortical localization. This system is the predominant one utilized today, especially with the use of single-cell recordings in animals and functional neuroimaging studies in humans. In a number of places we refer to Brodmann's areas with respect to localization of particular cognitive functions. Brodmann's map is depicted in Figure 15.1.

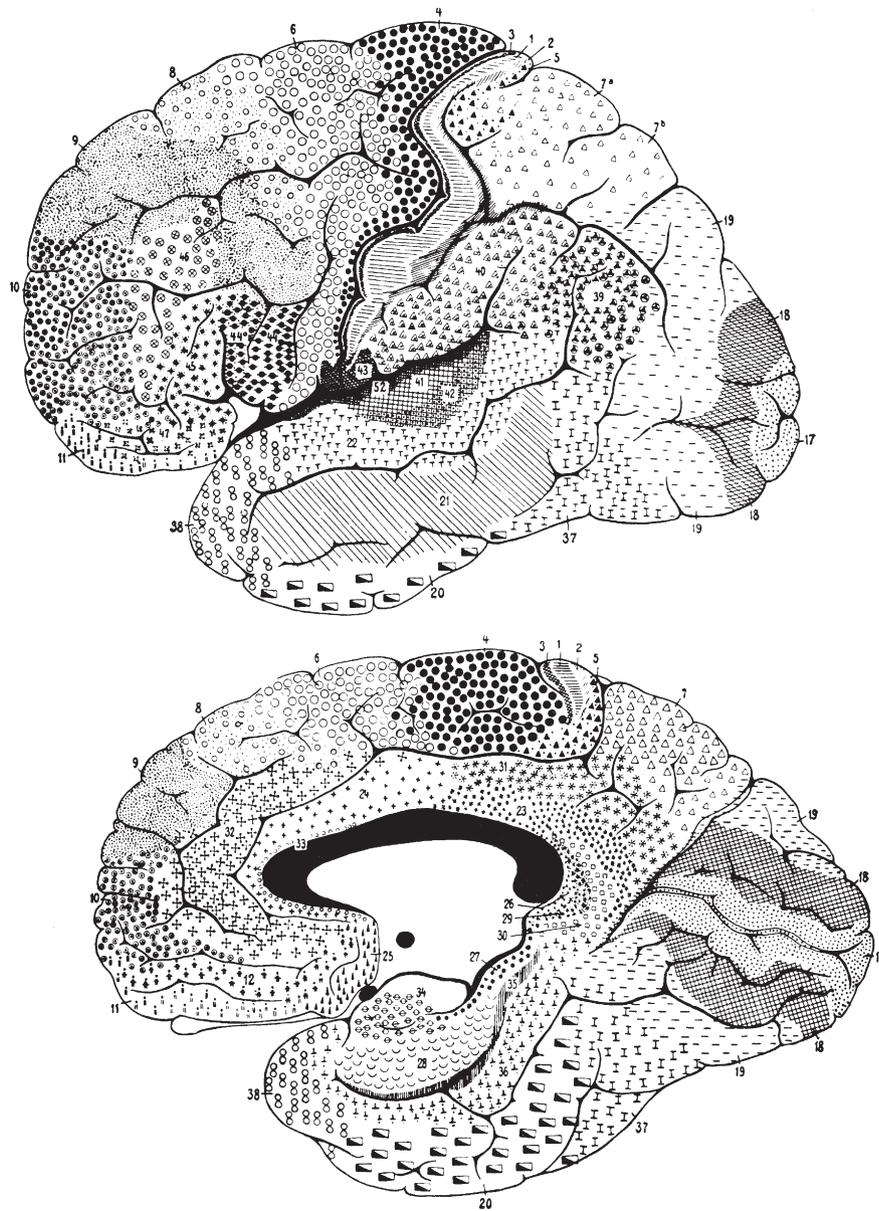

## Current Theoretical Conceptualization of Brain Organization

Current thinking in the cognitive neurosciences strikes a balance between local and holistic organization of functions. The current

emphasis is on “connectivity”, as both a theoretical heuristic and a set of models of neural behavior. The localizationist perspective of Wernicke introduced the rudimentary idea that interconnected brain regions could work in a serial fashion to perform a set of operations such as language. The Russian neuropsychologist Alexander Luria, who influenced much contemporary thinking in cognitive neuroscience, was himself influenced by the idea of connectivity.

By borrowing from the then emerging field of machine intelligence, the model of the brain as a digital computer operating in a serial processing framework was introduced. In this model, brain functions were seen as the constellation of interconnected neural networks, each operating in serial fashion, to produce macrocognitive processes from series of local microcognitive operations. Although the early artificial intelligence and information-processing traditions of cognitive psychology offered elegant models, they were limited by their underlying assumptions. First, the cognitive models that postulated the premise of connectivity between local networks did not explicitly link the cognitive realm with the underlying anatomical substrate, lending these theories a lack of neural reality. For example, this yielded models of attention that “worked” from a cognitive perspective but did not suggest an underlying neural mechanism.

Connectionist theories of the brain within the cognitive sciences have begun to offer models with greater neural and computational realism. In the computer realm, the development of massively parallel computing has suggested that extremely complex functions can be performed simultaneously, not in a serial fashion. The obvious extrapolation to neural science is to think of brain functions as having a parallel architecture, which would perform several operations simultaneously. In contrast to serial processing, parallel processing allows the relatively slow individual neurons to accomplish tasks in rapid real time. The other current concept applied to neural processing is that of distributed processing. Distributed processing refers to the coordination of functions that are distributed within and across brain regions. A particular function is therefore emergent from neural processing that is both parallel and distributed. This concept of neural function represents a compromise between local and holistic perspectives. The model of the brain in terms of parallel distributed processing (PDP) is both a heuristic framework from which to view neural organization and a formal set of models within cognitive science. The formal elements of PDP involve the relationship of neural science and computer science and have been applied to the development of models of language, vision, motor learning and memory. As a heuristic framework, the notion that

**Figure 15.1** Brodmann's cytoarchitectural map of the human cerebral cortex, lateral view; each symbol represents a distinct area of the cerebral cortex, numbered as shown. (Source: Brodmann K [1909] *Vergleichende Lokalisation lehre der Grosshirnrinde ihren Prinzipien dargestellt auf Grund des Zellenbaues*. JA Barth, Leipzig.)

higher cortical functions are best described as parallel and distributed is quite influential to most current thinking in the cognitive neurosciences.

## Memory

Memory functioning – broadly defined as the storage and recall of past experience – is of major interest and importance in cognitive neuroscience. The intensity of research in the area of memory has been especially great in the past decade, when the fields of cognitive psychology and neuropsychology converged to offer unified models of memory functioning on the basis of experimentation in normal and brain-damaged humans, as well as lesion studies in animals. Functional neuroimaging has also begun to yield valuable insights into the patterns of neuroanatomical connectivity involved in aspects of memory. Because this field is relatively

massive, the reader is referred to comprehensive sources for further details (Christianson, 1992; Squire and Butters, 1992).

Historically, the debate between the localizationist and holistic views of neural processing has been nowhere sharper than in the search for regionally specific entities involved in memory. The search for the “engram” or memory trace led Lashley (1950) to conclude that memories are distributed throughout the brain, not localized within a discrete or unitary structure. The debate has been given a more sophisticated focus with the realization that although there is regional specificity in aspects of memory, the complexity of the processes requires multiple brain regions, probably operating in a parallel fashion.

The initial contributions to the present knowledge of memory were from two methodologies. These are the lesion analytical method and cognitive studies of normal individuals. The lesion analytical method has contributed the most to an understanding

of both the cognitive and neuroanatomical aspects of memory functioning.

In the last 10 years, functional neuroimaging techniques (particularly positron emission tomography [PET] and functional magnetic resonance imaging [fMRI]) have become increasingly popular and provide an alternative method of studying human cognition. These techniques have the dual potential to validate existing models of memory and to suggest newer theories based on patterns of anatomical connectivity observed during the performance of memory tasks. Furthermore, unlike the lesion analytical method, they afford the ability to observe cognitive processes in healthy human brains. Neither PET nor fMRI directly measures neural activity; rather, they rely on changes in regional cerebral blood flow (rCBF) that result from the metabolic demands of neural activity. As neural activity occurs, the demand for oxygen causes an increase in the relative concentration of deoxyhemoglobin in the surrounding region.

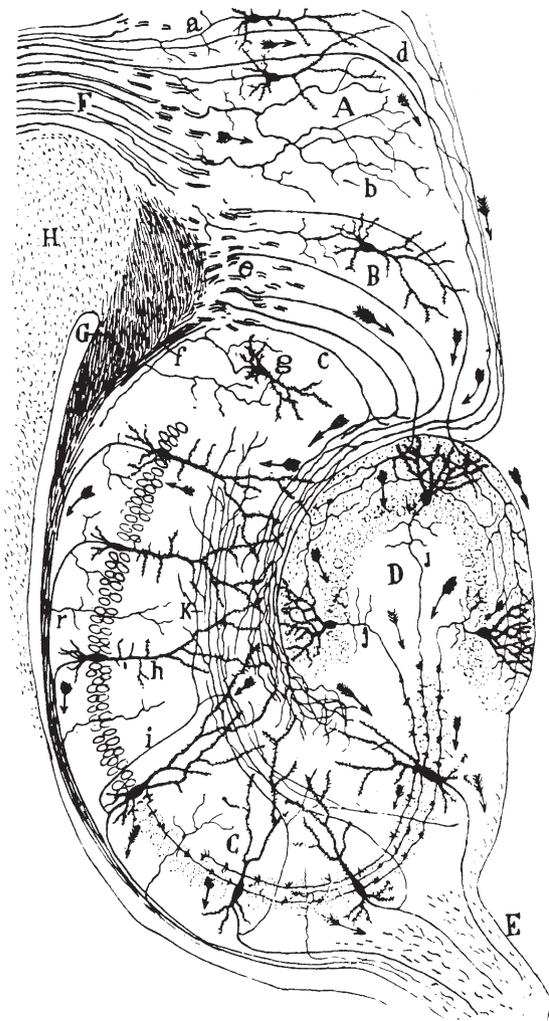

There are several things to keep in mind when considering findings from neuroimaging studies. First, it is important to remember that PET and fMRI are based on relative blood flow. Therefore, the baseline task subtracted from the events of interest must be tightly controlled to ensure that the finding is as specific as possible. Furthermore, although functional neuroimaging can suggest brain regions functionally involved in performing a cognitive operation, blood flow studies cannot suggest what is unique about that brain region. Also, when distributed brain regions are simultaneously activated, the technique itself does not immediately reveal the functional connectivity between those regions. Unlike the electrophysiological studies of working memory, imaging cannot suggest whether a brain region is in a sense storing information or transmitting information or is in some other way involved in the performance of an operation.

### Cellular Basis of Memory

On the basis of lesion analytical studies, the hippocampus and related structures have been implicated as a site for the consolidation of memory. The question naturally arises out of the properties of the neurons in this area that might permit the association of information. Neuroanatomically (Figure 15.2), the hippocampal formation consists of the fields of Ammon's horn (regions CA<sub>1</sub>, CA<sub>2</sub>, CA<sub>3</sub>), the dentate gyrus and the subiculum. Afferent pathways from the entorhinal cortex project to the hippocampus via the perforant pathway and synapse on the granular cells in the dentate gyrus. The entorhinal cortex itself receives cortical inputs from polysensory associational regions in the frontal, temporal and parietal lobes. Within the hippocampal formation, the granule cells in region CA<sub>3</sub> also project to the CA<sub>1</sub> region through the fimbria fornix, which also projects to the subiculum. The subiculum is the major efferent pathway, projecting to a number of cortical regions but also projecting back to the entorhinal cortex, completing the loop.

For learning and memory to occur, there must be plastic changes such that the structure and functional characteristics of nerve cells and their interconnections are altered. Much of the research into the processes of synaptic plasticity underlying learning and memory has been conducted in invertebrates (Kandel *et al.*, 1983; Kandel, 1991) through examination of reflexive learning processes (habituation, sensitization and classical conditioning).

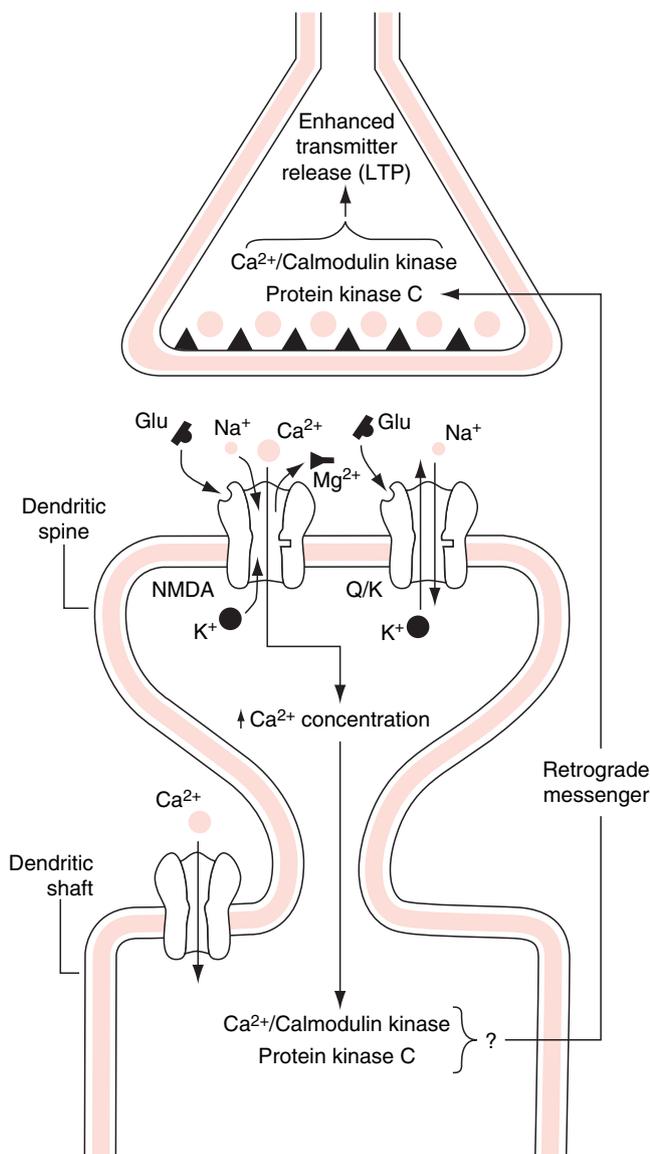

Regarding the mammalian brain, Bliss and Lomo (1973) were the first to demonstrate that repeated stimulation of the

**Figure 15.2** Some of the structure and connections of the hippocampus (Ammon's horn) as drawn by Ramon y Cajal. A, Entorhinal cortex; B, subiculum; C, hippocampus; D, dentate gyrus; E, fimbria of fornix; F, fibers of the cingulum entering the entorhinal cortex (A); K, Schaffer collaterals; a, axons entering the cingulum; b, fibers of the cingulum terminating in the entorhinal cortex; c, pyramidal cell of the subiculum; h, pyramidal cells of the hippocampus; i, ascending collaterals from the hippocampal pyramidal cells; j, granule cell axons; r, collaterals from axons in the alveus. (Source: Ramon y Cajal S [1911] *Histologie du Système Nerveux de l'Homme et des Vertébrés*. Maloine, Paris.)

afferent pathways to the dentate granule cells of the hippocampus of the rabbit produced an excitatory potential in the postsynaptic hippocampal neurons lasting for hours. Recording in intact animals has shown potentials that lasted for days and weeks. They termed this increased facilitation as a result of repeated stimulation long-term potentiation (LTP).

With respect to area CA<sub>1</sub> of the hippocampus, studies have shown that LTP occurs only when a number of input pathways have been stimulated. This is known as the criterion of cooperativity. When distinct weak and strong excitatory inputs impinge on a pyramidal nerve cell, the weak input becomes potentiated through association with a strong input. This is known as the criterion of associativity. Finally, the criterion of specificity refers to

**Figure 15.3** The events surrounding the induction of LTP are portrayed. As a result of the tetanic stimulation of the postsynaptic membrane, depolarization relieves the magnesium ( $Mg^{2+}$ ) blockade of the NMDA channel allowing sodium ( $Na^+$ ), potassium ( $K^+$ ) and calcium ( $Ca^{2+}$ ) to flow through the NMDA channel. The increase of calcium in the dendritic spine then triggers calcium-dependent kinases, which induce LTP. The maintenance of transmitter release is thought to occur by release of a retrograde messenger that acts on the presynaptic terminal. The voltage-dependent calcium channels in the dendritic shaft remain closed. (Source: Adapted from Kandel ER [1991] *Cellular mechanisms of learning and the biological basis of individuality, in Principles of Neural Science, 3rd edn.* [eds Kandel E, Schwartz JH, and Jessell TM]. Appleton & Lange, Norwalk, CT, pp. 1009–1031. Copyright, the McGraw-Hill Companies, Inc.)

the fact that strong repeated stimulation in one synaptic pathway is specific only to that stimulated pathway. Unstimulated synapses on the same cell do not demonstrate LTP.

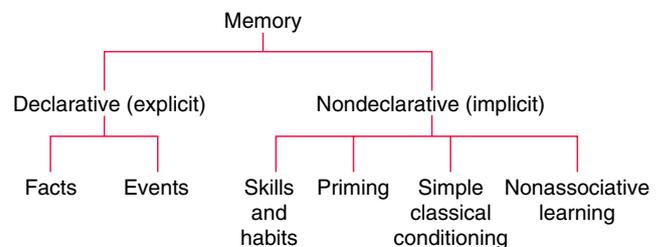

The events surrounding LTP are schematically described here (Figure 15.3); the reader is referred to a detailed explanation of the cellular and molecular aspects of LTP (Kandel, 1991;

Shepherd, 1994). Studies of the  $CA_1$  region of the hippocampus reveal that LTP is mediated by the neurotransmitter glutamate.

LTP has been stressed as a cellular mechanism of informational connectivity in the hippocampus. Brief mention should also be made of long-term depression (LTD). LTD is the opposite of LTP and refers to “use-dependent long-lasting decreases in synaptic strength” (Linden and Connor, 1995). LTD may have a number of advantages and work in parallel with LTP with respect to memory functioning. LTD may help reset synapses that have been potentiated by LTP, to prevent saturation. It may serve as a cellular mechanism of forgetting (Tsumoto, 1993) and, finally, may also form an active inhibitory system to attenuate signals from adjacent potentiated synapses. The specific role of LTD in the coordination of memory is still unclear. For a detailed description of the potential cellular and molecular mechanisms involved in LTD, the reader is referred to other sources (Linden and Connor, 1995; Linden, 1994). The phenomena of LTP and LTD provide an example in which neural cytoarchitecture and the underlying cellular and molecular levels may actually conform to the principles of association and connectivity. Computational models have been developed to further our understanding of the manner in which learning and memory emerge from the properties of synaptic plasticity embodied in the circuitry of the hippocampus (Churchland and Sejnowski, 1992; Traub and Miles, 1991). The attraction of computational models is that they may clarify the link between aspects of LTP and LTD within local networks of associated neurons at the cellular level and the events at the behavioral level.

### Major Subdivisions of Memory Systems

Current research on the cognitive neuroscience of memory has considered memory from the perspective of multiple systems rather than a unitary system. Figure 15.4 illustrates the subdivisions between memory systems. A number of systems have been proposed, and the distinction between these systems is not impermeable. The most basic distinction between memory systems is that of explicit versus implicit memory. Explicit memory is also referred to as declarative memory and implicit memory is also known as nondeclarative memory. What is considered explicit about this type of memory is that it requires conscious awareness of past experience (Cohen and Squire, 1980). There are two major components of explicit memory: episodic memory and semantic memory. Episodic or autobiographical memory is the

**Figure 15.4** Subdivision of major memory systems. Declarative (explicit) memory requires conscious awareness of past experience; nondeclarative (implicit) memory refers to the effects of previous experience on current behavior without conscious recollection. Reprinted with permission from Squire LR and Zola-Morgan S [1991] *The medial temporal lobe memory system. Science* 253, 1380–1386. Copyright 1991, American Association for the Advancement of Science.

ability to remember personal events over time. This refers to the individual's ability to remember not only that something occurred but also the context in which it occurred. Semantic memory, in contrast, refers to knowledge without context. Another type of explicit memory system that involves the short-term registering of information is termed working memory, which will be discussed in the executive functions section of this chapter. Memory systems research in the past several years has also focused on implicit memory. Implicit memory does not involve conscious awareness. It refers to the effects of previous experience on current behavior without conscious recollection.

On the basis of cases of medial temporal lobe damage in humans, it has been concluded that the medial temporal lobe, including the hippocampus, and adjacent anatomical structures enable the formation of explicit memories. In humans, it has been shown that a lesion confined solely to the hippocampus (field CA<sub>1</sub> of the hippocampus) can produce a mild amnesic syndrome (Zola-Morgan *et al.*, 1986). It would then appear that the parahippocampal and perirhinal cortical regions are also necessarily involved in explicit memory. According to Zola-Morgan and Squire (1993), the medial temporal lobe system essentially coordinates the organization of information that originated in other brain regions. The medial temporal lobe system may thereby act as a temporary site to store information that is cortically distributed until the information is permanently coded.

### Diencephalon and Explicit Memory

Neuropsychological studies of patients with Wernicke–Korsakoff disease have yielded insight into the contribution of the diencephalon (dorsal and anterior thalamic nuclei and the mamillary bodies of the hypothalamus) to memory. Wernicke–Korsakoff disease is usually associated with a thiamine deficiency and is typically seen in individuals with alcoholism, nutritional deficiencies, infections and brain tumors (Markowitsch and Pritzel, 1985). The memory deficit is characterized by impairment of explicit memory as seen by dense anterograde amnesia and variable retrograde amnesia. These patients are also frequently apathetic and indifferent and have diminished initiative.

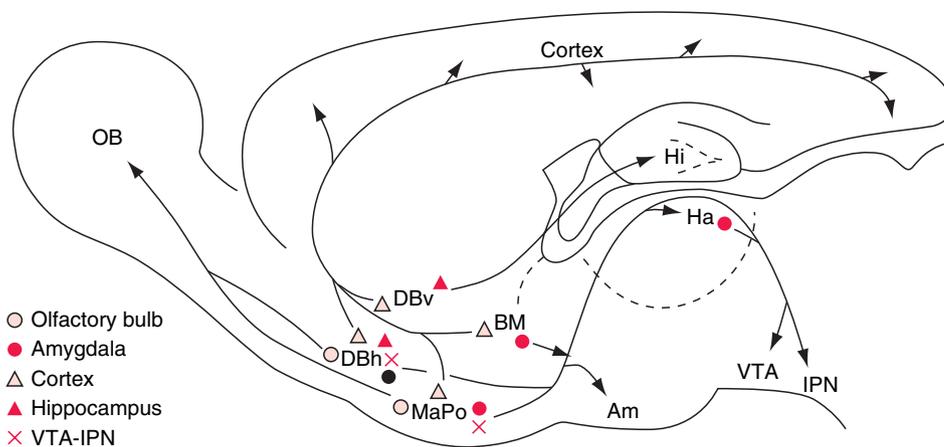

The effects of damage caused by alcoholic and nonalcoholic lesions to the anterior and medial thalamic nuclei as well as to the mamillary bodies are diverse. The diencephalic region is connected with the hippocampal region; the mamillary bodies are connected to the hippocampus via the fornix and to the anterior thalamus via the mamillothalamic tract. The mediodorsal thalamic component of the system is also interconnected with the frontal lobes. Patients with Korsakoff's disease typically manifest frontal lobe damage, which is seen in the phenomenon of confabulation. Aside from this frontal component, which is often seen in alcoholism and may represent an independent lesion, the diencephalic amnesia is largely similar to the kinds of memory deficits observed with damage to the medial temporal lobe system. This suggests that, at least at a functional level, anatomical damage in this subcortical system produces an impairment in the consolidation of information.

### Basal Forebrain and Memory

Another neuroanatomical region that plays a direct role in explicit memory is the basal forebrain. The basal forebrain region is located where the diencephalon meets the cerebral hemispheres and includes a number of brain structures such as the septal area, diagonal band of Broca, nucleus accumbens septi, olfactory tubercle, and substantia innominata. Figure 15.5 illustrates the rostral cholinergic projections in the rat brain. The contribution of this brain region to memory has been a relatively recent discovery. The cholinergic system plays a role in memory (although its full role is not clear at this time), and is implicated in normal and pathological aging, but is only one locus in the network of brain regions involved in memory.

### Affective Valence and Neuromodulatory Systems

Memory functioning requires a system for establishing valence between memorable events. That is, some events are more memorable than others. Affect and its associated chemical neuromodulators probably serve a valence capacity by facilitating the storage of emotionally charged experiences. The underlying

**Figure 15.5** Sagittal view of some projections of the rostral cholinergic column in the rat. The symbols ([Page No. 371]) refer to the origin within the rostral cholinergic column of afferents to the olfactory bulb, amygdala, and so on. Am, Amygdala; BM, nucleus basalis; DBh, horizontal limb of diagonal band; DBv, vertical limb of diagonal band; Ha, habenula; Hi, hippocampus; IPN, interpeduncular nucleus; MaPo, magnocellular preoptic area; OB, olfactory bulb; VTA, ventral tegmental area. Copyright, Lipincott Williams and Wilkins (1987).

assumption here is that emotionally tinged experiences activate neurobiological pathways that facilitate their storage. In evolutionary terms, it is highly adaptive to remember experiences that are learned under arousing conditions. Neuroimaging studies have provided evidence for the role of the amygdala in forming declarative memories. A number of neuromodulators play a role in affective responding and also influence memory storage. Chief among them is the noradrenergic system. The central noradrenergic system involves the locus coeruleus in the midbrain reticular formation, the amygdala and the stria terminalis (a major afferent and efferent pathway to the amygdala). A number of findings have converged to suggest that central norepinephrine (NE) receptors in the amygdala are involved in the postlearning consolidation of information (Liang *et al.*, 1986).

Overall, the role of the noradrenergic and other systems, such as GABA and opioid peptides, in memory may lie in the release of adrenal epinephrine after stressful or emotional stimuli. Activation of NE in the locus coeruleus–amygdala system, which ultimately has extensive connectivity with a number of brain regions, then serves to consolidate the storage of these memories. On a cellular level this may occur by the production of LTP, because noradrenergic compounds have been found to enhance LTP (Gold *et al.*, 1984).

### Frontal Lobe Contribution to Explicit Memory

It is probable that interactive processing between the medial temporal lobe system and the frontal lobes is necessary for explicit memory. The frontal lobe provides an executive input to the medial temporal lobe system, imbuing memory with “intelligence” (Moscovitch, 1992). The frontal lobes, through their extensive reciprocal connectivity with the hippocampal formation, probably provide input to ordering and placing experience in a spatial–temporal context. The frontal lobes in a sense add goal orientation to memory.

### Implicit Memory

As defined earlier, implicit memory refers to the influence of past experience on current behavior that is not conscious or intentional. In other words, retention of linguistic, visual, or motor information can occur in the absence of explicit retrieval of that information. An example of the manner in which explicit memory and implicit memory can be dissociated is given by the results of a fragment stem completion task (Tulving *et al.*, 1982), which illustrates the priming effect. Priming refers to the increased facilitation of identifying a stimulus that occurs as a result of having had prior exposure to that stimulus (Schacter *et al.*, 1993), even though the individual may have no conscious recollection of the exposure. On the basis of numerous studies with brain-damaged and normal individuals, it is probable that the perceptual representation subsystems for priming are a visual word form system representing the orthographical features of words, a system that represents structural relations among parts of objects, and an auditory word form system that mediates phonological or acoustic information. The likely brain regions associated with each of these subsystems are the extrastriate cortex, inferior temporal region and perisylvian cortex.

Although the priming effect is the most extensively studied aspect of implicit memory, it is important to note that the learning of motor skills and habits and the phenomenon of classical condi-

tioning fall under the rubric of implicit memory. These processes may be considered as part of implicit memory because behavior changes and learning occur without conscious. This behavioral dissociation between priming and skill learning suggests that the latter may be mediated by the corticostriatal loop that mediates motor programming, namely the basal ganglia, thalamus, and motor, premotor and sensorimotor cortex (Heindel *et al.*, 1991).

### Executive Functioning and the Frontal Lobes

Most researchers now agree that the study of frontal lobes represents an important aspect of attempts to understand of humans’ higher mental functions, such as planning, decision-making, reasoning and judgment, which are often referred to as executive processes.

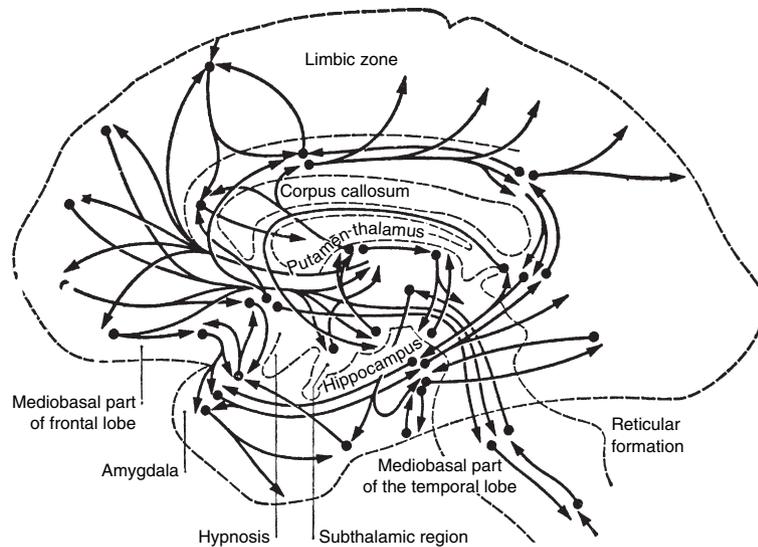

The frontal lobes of the human brain comprise all the tissue anterior to the central sulcus. Four major subdivisions of the frontal lobes have been suggested: 1) the motor area; 2) the premotor area; 3) the prefrontal area, and 4) the basomedial portion of the lobes (Walsh, 1994).

Two prefrontal areas, namely, the orbitomedial prefrontal cortex and the dorsolateral prefrontal cortex, have been targeted in much of the research concerning executive processes. The functional role of the frontal system in providing executive control to behavior is probably related to the extensive reciprocal anatomical connectivity between the frontal lobes and other brain regions involved in information processing. Numerous afferent and efferent connections of the frontal lobe have been demonstrated. The extracortical and transcortical connections of the frontal lobes are exceedingly complex, especially where the prefrontal cortex is involved (Kolb and Wishaw, 1990). In general, brain connectivity encompasses three major types: cortical–cortical, thalamic–cortical, and subcortical–cortical (Figure 15.6). For a detailed review of brain connectivity, the reader is referred to the works of Pandya and Yeterian (1984) and Goldman-Rakic (1988).

Cortical–cortical connections of the frontal lobes take on a number of distinct forms (Kolb and Wishaw, 1990). First, as previously mentioned, connections within the frontal lobes themselves involve projections from tertiary cortex in the prefrontal areas to the premotor cortex and to the motor cortex. Secondly, there are reciprocal connections between the prefrontal cortex (Brodmann’s areas 8, 9 and 46) and the temporal, auditory and visual association regions, as well as the medial temporal lobes. Thirdly, there is another set of reciprocal connections connecting the prefrontal areas and the anterior and medial temporal regions. Fourthly, there are connections between prefrontal areas and the limbic system, including a reciprocal connection between the amygdala and the frontal lobe.

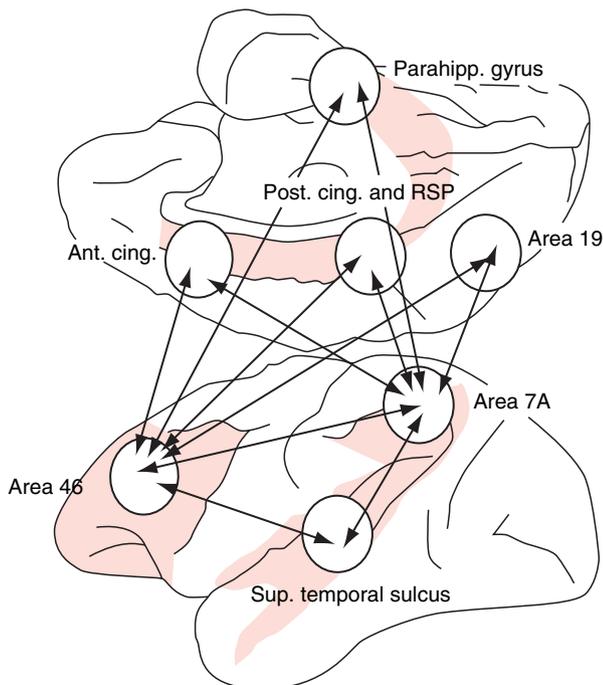

Thalamic–cortical connections include projections to the prefrontal lobe from the pulvinar, anterior nuclei and dorsomedial nucleus of the thalamus. In addition, via the dorsomedial nucleus, information from limbic areas and the hypothalamus is relayed to the frontal lobes for processing of emotions and internal states.

Subcortical–cortical connections include projections from the frontal cortex to various subcortical structures including the caudate nucleus, superior colliculus and hypothalamus. Particular attention has been paid to the interconnectivity of the frontal lobe and basal ganglia via the corticostriate projection system. Lesions in either area are associated with similar cognitive impairments, such as decreased cognitive flexibility or set switching (Eslinger and Grattan, 1993).

**Figure 15.6** Illustration of some of the patterns of frontal lobe connectivity. (Source: Luria AR [1973b] *The Working Brain: An Introduction to Neuropsychology*. Penguin Books, London, p. 85.)

Examination of the connectivity of the frontal lobes has revealed that the pattern of connectivity is best viewed from within the context of a parallel and distributed anatomical network (Figure 15.7).

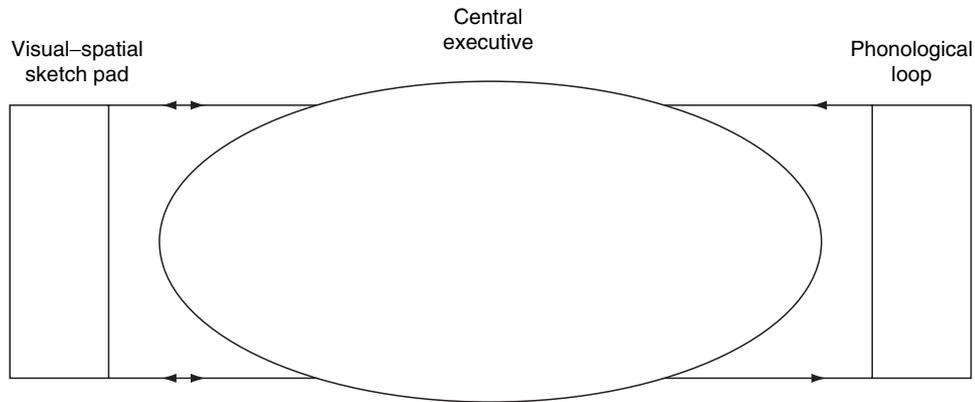

**Figure 15.7** Illustration of the parallel connectivity of the frontal and parietal regions. Area 46 and area 7A project to more than a dozen common targets; five of these areas are illustrated. (Source: Goldman-Rakic PS [1988] *Changing concepts of cortical connectivity: Parallel distributed cortical networks*, in *Neurobiology of Neocortex* [eds Rakic P and Singer W], p. 187. ## Working Memory

We have previously discussed in general terms the frontal contribution to memory at the level of encoding and retrieving. However, memory researchers believe that the frontal lobes modulate the use of memory in executive functions such as planning and decision-making. This kind of memory is referred to as “working memory” (Miller *et al.*, 1960). In their recent comprehensive review of working memory models, Miyake and Shah (1999) proposed that working memory “is those mechanisms or processes that are involved in the service of complex cognition, including novel as well as familiar, skilled tasks”. This definition differentiates working memory from short-term memory because it suggests that working memory goes beyond simply keeping information “in mind”; rather, working memory brings or keeps information online in a goal-directed fashion. Baddeley and Hitch (1974) were the first to provide a human cognitive model for the concept of working memory, and the neuroanatomical localization of this to the frontal lobes has been largely advanced by the extensive work of Goldman-Rakic and colleagues (Goldman-Rakic, 1987, 1988; Baddeley and Hitch, 1974).

Figure 15.8 illustrates the major components of the Baddeley and Hitch model of working memory. This model (Baddeley and Hitch, 1974) provides for a dynamic system of temporary and limited storage. It is composed of a central executive and two “slave” systems, a visual-spatial sketchpad, and a phonological loop.

The central executive aspect of the working memory system appears to exert control over the flow of activity between the slave systems and provides the input to long-term memory. However, this is also the least well-understood component of working memory. The interaction of slave systems with the central executive probably reflects the interplay between the frontal lobe mechanisms of executive control of input received from parietal, temporal and occipital systems of perception and association. Although the detailed role of the central executive remains unclear, evidence from the animal and human experimental literature suggests that the prefrontal cortex is specialized with respect to working memory.

**Figure 15.8** A simplified representation of the Baddeley and Hitch (1974) working memory model. Reprinted with permission from *Working memory*. ### Anatomical Evidence of Working Memory

The prefrontal cortex may be a kind of multipurpose working memory center, with each area concerned with a different domain. The prefrontal cortex would then function as the coordinating element in a parallel distributed cortical–cortical network.

### Theories of Frontal Lobe Functioning

Some of the influential theories of the role of the prefrontal cortex and behavior are shown in Table 15.1. All theories impute to the frontal lobes a functional role as an executive control

system for other cognitive and motor processes. The theories differ with respect to the specific mechanisms involved and the extent to which cognitive and neuroanatomical parameters are delineated.

### Assessment of Frontal Lobe Functioning

#### Neuropsychological Assessment

There is an extensive literature concerning the evaluation of frontal lobe functioning with various neuropsychological assessment

**Table 15.1** Theories of Frontal Lobe Functioning

Basis	Author	Description
Psychological assessment	Miller <i>et al.</i> (1960)	Postulated test-operate-test-exit feedback loops by which the frontal lobe organizes and coordinates behaviors transferred from the posterior brain.
Psychological assessment	Teuber (1964)	Postulated that anticipatory discharges travel from the frontal lobe to the posterior brain influencing motor system and sensory functions.
Psychological or anatomical	Luria (1973a)	Postulated three brain units, each unit having different neuroanatomical representation. Unit 3 is located in frontal lobes and exerts regulatory functions over the behavior of the other two units in the posterior brain through interactive and sequential processing.
Psychological or information processing	Norman and Shallice (1986)	Postulated that the frontal lobes primarily function as an SAS over cognitive units and schemas during nonroutine behavior.
Anatomical or animal studies	Fuster (1989)	Postulated that frontal lobes generally function in the temporal integration of behavior through three subordinate functions: anticipation, provisional memory and control of interference.
Neuroanatomical or animal studies	Goldman-Rakic (1987)	Postulated that prefrontal cortex maintains a representational memory of symbolic, mnemonic, and sensory information from nonprefrontal areas. These memory units exert inhibitory and excitatory influences on behavior through PDP.
Neuroanatomical or computational neuroscience	Mesulam (1990)	Postulated that the frontal lobes, through interconnectivity with other brain areas, exert executive control over neural networks subserving different information processing capacities via PDP.

techniques. The majority of these studies are based on assessment of individuals with known frontal lobe damage or animals with experimentally induced lesions. Dubois and colleagues (1994) suggested that the skills needed for the elaboration, control and execution of goal-directed behaviors form the basis of studies involving the prefrontal cortex. These abilities would necessarily include planning, mental flexibility, impulse control, working memory and evaluation of one's behavior, that is, executive processes.

Evaluation of executive processes is fraught with numerous obstacles. First, there are few assessment procedures that allow enough flexibility in response or ability to consider alternative ways of thinking, which are central elements of executive processing. Consider the paradox of having to structure an examination technique that assesses the ability of subjects to make structure for themselves (Lezak, 1995). Secondly, executive functioning is the final stage of a processing sequence, relying heavily on information provided by other brain areas. It follows that successful execution of the frontal lobe functions depends, in great part, on the integrity of the remainder of the brain. Effective executive processing is an unlikely occurrence if the information needed from nonfrontal lobe regions is missing or inaccurate. Thirdly, frontal lobe functioning encompasses a number of abilities, making a complete assessment of such processes an arduous, if not impossible, task at best. Fourthly, many of the neuropsychological instruments used in the assessment of executive processes are weakly constructed and insensitive to obscure changes in the

presence of compensatory strategies that occur after frontal lobe damage. Despite these obstacles, the quest better to understand the cognitive processes that belie the functioning of the frontal lobes, as well as the desire to prognosticate level of adaptive functioning in patients with known impairment, has maintained the strong interest in employing neuropsychological assessment techniques. Many of these neuropsychological tasks have also been used in the context of functional neuroimaging to better delineate cognitive and neuroanatomical correlates. Table 15.2 details several of the assessment procedures used to evaluate the integrity of the frontal lobes in performing cognitive operations.

### Behavioral–Neuroanatomical Correlates

Disrupted neurobehavioral functioning in a number of psychiatric and neurological disorders has revealed several interesting aspects of the role of the frontal lobes in behavior. Studies involving dementias of the frontal lobe type, particularly Pick's disease, have provided some information concerning the role of the frontal lobes. Pick's disease is quite distinguishable from the better known Alzheimer's type in that in the former basic memory functions are relatively spared early in the disease course. The initial presentation of Pick's disease largely involves the presence of striking changes in personality and social appropriateness. Memory dysfunction, if apparent, is secondary to motivational or attentional factors rather than faulty learning. Patients with Pick's disease consistently perform poorly on a wide variety of tests sensitive to frontal lobe dysfunction.

Many of the studies involving the association of affective disorders and frontal lobe functioning have emerged from the literature on stroke. Starkstein and associates (1987) have found that the left frontal opercular region is the area most frequently damaged in patients suffering from poststroke depression. Similarly, using computed tomography, Robinson and Szetela (1981) have demonstrated that the closer the lesion is to the frontal pole, the more severe the ensuing depression. After reviewing the relationship between frontal lobe impairment and affective dysfunction in poststroke depression, Baxter and colleagues (1989) concluded that left prefrontal hypometabolism was the most consistent and severe finding in major depression, bipolar depression and obsessive–compulsive disorders.

A surge in the study of schizophrenia has provided a wealth of knowledge concerning the functioning of the prefrontal cortex. It is generally agreed that cognitive abnormalities associated with schizophrenia often involve difficulties in executive processing. Some of the earliest and best known studies involving neuroimaging techniques in the assessment of cognitive abilities in this population were carried out by Weinberger and colleagues. Many other studies employing rCBF (Buchsbaum *et al.*, 1984; Weinberger *et al.*, 1988; Sagawa *et al.*, 1990) and functional brain imaging (Buchsbaum *et al.*, 1990) have found evidence to support the “hypofrontality” hypothesis in schizophrenia. However, not all studies have found frontal hypometabolism in patients with schizophrenia (Gur *et al.*, 1985; Berman *et al.*, 1988). The heterogeneous nature of schizophrenia probably accounts for these contradictory findings. A number of researchers including Volkow and colleagues (1987) and Andreasen and associates (1992) have found that hypofrontality was most related to patients with a predominance of negative symptoms.

### Attention

In view of what is known about the role of the prefrontal cortex, it is readily apparent that the primary role of this brain region

**Table 15.2** Tests Commonly Used to Assess Executive Functions

Function	Test
Abstract thinking	Comprehension subtest of Wechsler Adult Intelligence Scale–Revised, Gorham's Proverbs Test
Concept formation, social judgment	Similarities subtest of Wechsler Adult Intelligence Scale–Revised
Concept formation and cognitive flexibility including establishing, maintaining and shifting cognitive set	Wisconsin Card Sorting Test Halstead Categories Test

Cognitive set maintenance and impulse control	Stroop Color–Word Test
Planning and impulse control	Porteus Maze Test
Visual–spatial working memory and problem solving	Tower of London
Cognitive productivity	Controlled Oral Word Association Test (verbal fluency) Ruff Figure Fluency Test (design fluency)

involves the integration and modulation of cognitive functioning. Given the onerous task of managing vast amounts of incoming and outgoing information, it stands to reason that attentional abilities are of great importance to frontal lobe functioning.

The area of attention as it relates to the frontal lobes has provided a rich field of study. Like many of the other general areas of cognition (e.g., memory, language), attention represents a vast and complex phenomenon. This is, in part, due to the many facets of attention itself. Underlying all cognitive activity, there must be some tonic form of activation that provides the background in which all other cortical activity occurs. Luria (1973a) referred to this capacity as his first functional brain area and noted that the reticular activating system in the brain stem provided the core structure subserving brain activation. In general, this is referred to as alertness or wakefulness. However, one's ability to pay attention to specific stimuli is thought to be subserved by higher cortical areas, including the prefrontal cortex. The psychological process of attention can broadly be defined in terms of divided, focused and sustained abilities. Divided attention occurs when multiple stimuli are attended to simultaneously. We can often find ourselves participating in divided attention tasks at parties when we tune into two different conversations at one time. Focused attention refers to the ability to inhibit irrelevant stimuli in the service of attending to a particular stimulus. Often this type of attention requires one to inhibit automatic responses that conflict with the task at hand. Sustained attention requires the ability to maintain attention over time.

As suggested earlier, Mesulam (1990) has proposed a neurocognitive network of attention involving a number of neural circuits participating in PDP. According to this model, interactive, multifocal neural pathways that are both localized and distributed give rise to multiple possibilities and flexibility with respect to attentional behavior. Much of this model is based on neglect behavior, which can be separated into perceptual, motor and limbic components. In general, the perceptual component refers to the diminished awareness that a sensory event has occurred within the neglected field, the motor component refers to the diminution or absence of exploratory behaviors, and the limbic component refers to a devaluation or amotivation of the neglected hemispace. According to Mesulam, neglect behavior in both humans and monkeys consistently follows lesions to one of three areas: the dorsolateral parietal cortex, the dorsolateral premotor–prefrontal cortex and the cingulate gyrus. These three areas provide local networks that provide the basis for a large-scale neural model of attention. Each local network or component participates in mapping the environment in slightly different ways. For example, in the case of visual hemineglect, Mesulam suggested that the posterior parietal cortex provides sensory (visual) awareness, the prefrontal area provides a map of exploratory movements (i.e., eye movements), and the cingulate gyrus provides a map for assigning value to the spatial coordinates. Within these areas, specific cytoarchitectonic structures interact through extensive reciprocal and monosynaptic connections. In the area of the dorsolateral prefrontal cortex, the frontal eye fields (Brodmann's area 8) play a critical role in directed attention. Although lesions in other brain regions, such as subcortical structures, are known to cause neglect, these areas have been found to connect to at least two of the three central components.

## Language

Language as a species-specific ability in humans is intrinsic to the development of knowledge and understanding. It endows us with a capacity unique to the human species to structure and organize experiences through the manipulation of categorical and abstract

concepts. With increasing internalization of language comes the capacity for disengagement from the environment so that concepts exist independently of their immediate context, as internal representations. Through this capacity to organize and form internal representations of experiences, a stable construction of reality is made possible (Bunowski and Bellugi, 1970; Guidano and Liotti, 1983).

Language is thus an integral part of mentation. Language is also central to modes of communication. Both of these aspects of language have been subjects of study for many disciplines, including philosophy, psycholinguistics, psychology and cognitive sciences. Furthermore, the disconnection of language from other cognitive processes and the disruptions in its communicative functions have been subjects of investigation in the fields of neurology, neurosurgery, neurophysiology and neuropsychology. Multidisciplinary efforts have led to a burgeoning body of research on language in normal and brain-damaged individuals, and the converging findings have greatly advanced our understanding of language as a complex human ability.

Regardless of the discipline within which the study of language is attempted, its essential features are common. Language is governed by a set of rules that link its various components. The basic units of a sound-based language (e.g., as opposed to a sign-based language) are classified in terms of phonemes, morphemes, lexicon, syntax, semantics, prosody and discourse. Phonemes are the smallest units of sound; morphemes are the smallest meaningful word units that when combined form words; syntax refers to the relational features by which words are combined, that is, grammar; lexicon refers to the words or vocabulary of a language; semantics refers to the meaning of words and sentences; prosody means the inflection and rhythm of utterances; and discourse involves the combination of sentences within any given context and constitutes narratives (Damasio and Damasio, 1992).

## Important Issues in Language Research

From a historical standpoint, one of the earliest questions about language has pertained to the concept of cerebral dominance and differential lateralization. A second area of investigation that has gained considerable interest because of cross-disciplinary research efforts is concerned with structural and functional localization of language. Researchers are concerned with whether specific regions of the brain are specialized for specific linguistic functions, including speaking, comprehending, reading and writing. Furthermore, with the growing influence of cognitive neuroscience, researchers are investigating whether specific language operations are localized in different levels of processing (e.g., phonological, orthographical, lexical, syntactic) and studying specific neural substrates associated with these processing networks. They are also interested in studying the patterns of connectivity between these neural networks. A third area that continues to generate great interest relates to neurodevelopmental aspects of language. Some of the questions in this area deal with the acquisition and development of language, as well as with the organization of the brain for language abilities in children.

The centrality of these issues to an understanding of language is reflected in the emergence of different models for language, which are described in greater detail in later sections. Briefly, these models can be broadly classified into traditional and current models when placed in a historical context. The traditional models were essentially localizationist (Wernicke, Broca, early contributions of Geschwind); the current models are more "hybrid" (Mesulam, 1990) in that they reflect a conceptualization of language processing as being both localized and distributed.

Because a great deal of what is understood about language and continues to intrigue investigators has emerged from studies of deficits and their neuroanatomical correlates in the various language disorders, especially aphasia, a description of these is important and is provided next. For more detailed reviews of language disorders, the reader is referred to other sources (Benson and Geschwind, 1985; Heilman and Valenstein, 1993).

### Acquired Language Disorders: The Example of Aphasia

The longstanding finding of different patterns of language impairment linked with specific neuroanatomical sites has led

to several classification schemes for organizing clinical and research data on aphasia. Classifications based on syndromes or clusters of symptoms have been most favored. The major aphasia subtypes that are now widely accepted are presented in Table 15.3. The subtypes of aphasia have been further subdivided in terms of their neuroanatomical loci into perisylvian (Broca's, Wernicke's, conduction and global) and extrasylvian (transcortical-motor, transcortical-sensory, mixed, anomic and subcortical) aphasias (Benson and Geschwind, 1985). The impairment and preservation of the ability to repeat appear to coincide with this dichotomy. Figure 15.9 depicts some of the regions of the left cerebral cortex that are involved in language functioning.

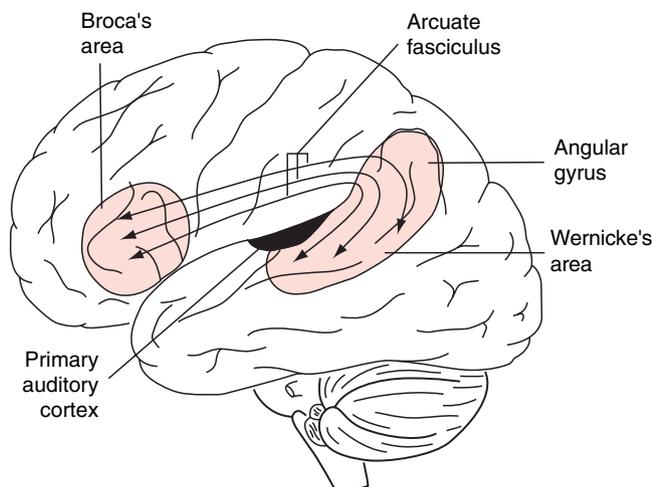

**Table 15.3** Clinical Features Associated with Subtypes of Aphasia

Type of Aphasia	Speech or Verbal Output	Repetition	Comprehension	Naming	Other Features*	Regions Involved
Broca's	Nonfluent	Impaired	Largely preserved	Often impaired	Right hemiparesis; may be depressed	Left posterior inferior frontal
Wernicke's	Fluent; paraphasic	Impaired	Impaired	Impaired	May be agitated; ambiguous; paranoid	Left posterior superior temporal
Conduction	Fluent; paraphasic	Impaired	Impaired	Often impaired	†Right hemisensory defect †Right arm and facial weakness	Left supramarginal gyrus or left auditory cortex
Global	Nonfluent	Impaired	Impaired	Impaired	Right hemiparesis; right hemisensory defect	Left frontal parietal temporal
Transcortical motor	Nonfluent	Intact or largely preserved	Impaired	Impaired	‡Right hemiparesis	Left frontal, anterior or superior to Broca's area
Transcortical sensory	Fluent; paraphasic	Intact or largely preserved	Impaired	Impaired	†Right hemiparesis	Left temporoparietal areas surrounding Wernicke's area
Anomic	Fluent	Intact or largely preserved	Largely preserved	Impaired	No definite motor signs	Left temporoparietal or frontal
Subcortical*	Fluent or articulatory disturbances may be present	Intact or may be impaired	Impaired	Intact or impaired	†Right hemiparesis	Caudate; thalamus

\*Variable symptoms depending on subcortical area affected;

†sometimes present;

‡often present.

**Figure 15.9** Left cerebral hemisphere showing areas of particular relevance to language processing. Reprinted from Burt AM [1993] *Textbook of Neuroanatomy*. WB Saunders, Philadelphia, p. 469. Copyright 1993, with permission from Elsevier.

Computed tomographic studies have linked aphasia with left-sided lesions in areas lying outside the cerebral cortex. This finding suggests that language is also subserved by subcortical areas. Subcortical aphasia is characterized by mutism in the early stage of the disorder, followed by articulatory disturbances and paraphasic output. Paraphasia appears to resolve when the patient has to repeat sentences. Comprehension is commonly impaired, and other language disturbances may also be involved. One distinguishing feature of this type of aphasia is the transient nature of the severe language defects seen in the early stages (Benson and Geschwind, 1985). The neuropathology in subcortical aphasia has been found to vary in terms of localization. Most commonly, subcortical aphasia is associated with lesions in the thalamus, caudate, and putamen (Naeser *et al.*, 1982).

Some inconsistent findings have raised questions about the role of subcortical damage in aphasia. For example, it has been noted that aphasia can resolve even in the presence of persisting subcortical abnormalities. Conversely, in some cases, aphasia does not follow damage to subcortical areas. In some instances, evidence from functional neuroimaging studies has been used to understand such discrepancies. PET studies reveal that structural damage in an area might result in hypometabolism in distant, intact areas. Metter and coworkers (1987) found that aphasia was associated with the presence of cortical hypometabolism after structural lesions in subcortical areas. Thus, there is some suggestion that changes in cortical hypometabolism accompanying subcortical lesions might be a factor associated with the presence or absence of aphasia rather than the lesion in the subcortical region.

## Concepts of Neuroanatomical Dominance and Localization in Language

### Dominance

As previously noted, Broca's discovery of the connection between aphasia and damage to the left hemisphere was the precursor of all contemporary investigations of the structural and functional organization of the brain. Broca pointed out the significance of the left inferior frontal area, and Wernicke predicted the importance of the left temporoparietal region. In the past

two decades, functional mapping studies of language disorders have clearly established dominance of the left hemisphere for language functions through the use of radiological techniques. Studies of the relationship between handedness and dominance for language have suggested that in about 98 to 99% of right-handed individuals the left side is dominant for language. About 1 to 2% of right-handed individuals show right side dominance (Gling *et al.*, 1969). This reversed pattern of dominance (i.e., right side dominance) is therefore considered to be exceptional and has been reported in a few studies (Fischer *et al.*, 1991).

### Localization

Although the issue of neuroanatomical dominance for language abilities in right-handed adults has been more or less settled for many years, the debate over localization has evolved into new directions. One classical approach to localization has been syndromic, with attempts made to find structural substrates for each of the subtypes of aphasia. This method involves lesion-syndrome correlations (Cappa and Vignolo, 1983).

An approach to localization that has yielded an extensive literature on neuroanatomical correlates of language focuses on specific linguistic functions and processes. This approach uses data from lesion-deficit correlational studies and functional neuroimaging techniques have further made it possible to identify brain regions that are activated during the performance of language tasks even in normal individuals. In the past few years, investigations into the neural correlates of specific functions, such as naming, comprehension and reading, have led to the well-established conclusion that these functions are not unitary. Rather, they are complex language processes that involve various components of language, including phonology, lexicon, syntax and semantics. Thus, the new direction in localization research involves attempts to find the loci for specific language operations within the various component processes and, in turn, to map these components onto brain regions.

Evidence from various sources has clearly established that linguistic functions are multifaceted in terms of both neural mechanisms and components of processing. As a result, impairment of a function does not involve global loss; instead, there are selective patterns of dissociation even between aspects of a specific linguistic function. This finding has given rise to the view that the various aspects of a function have corresponding neural mechanisms that are localized in different regions of the brain. The different regions are interconnected in ways that are thought of as forming neural networks. A breakdown in their connections results in selective patterns of dissociation. Because these networks can involve distant regions of the brain, the earlier ideas of localization of a function in terms of dichotomous subdivisions such as anterior versus posterior and sensory versus motor regions are now considered untenable. In addition, the patterns of dissociation suggest differential breakdown of the interconnections between levels of processing. Some of the patterns of dissociation observed in functions such as word finding and comprehension are presented to elucidate the involvement of different regions.

### Model of Language

In the past two decades, neurolinguistic research has been greatly influenced by the application of cognitive theories and computational models to the study of language processes. Combined with functional neuroimaging techniques, these methodologies have enabled the analyses of much smaller units of language processing. The evidence has led to the development of the current

information-processing or PDP model for language that has supplemented the traditional Wernicke–Geschwind model as well as earlier cognitive models of language.

The traditional Wernicke–Geschwind model was more anatomically based and reflected a view of language functioning in terms of interconnections and disconnections between hierarchically arranged regions of the brain. According to this view, language was processed through a serial flow of information in the interconnecting pathways and cortical regions. For example, in a simple repetition task, the information flows through the following pathways: auditory input received by the auditory apparatus passes through the medial geniculate nucleus, primary auditory cortex (Brodmann’s area 41), and higher order auditory cortex (area 42) to the angular gyrus (area 39) and Wernicke’s area (area 22). Thereupon, the arcuate fasciculus transfers the information to Broca’s area, where syntactic processing and articulatory programming for production take place.

The application of cognitive theories to neuropsychological processes led to the development of information-processing models for language (as for other mental activities). However, the earlier models also tended to posit that information traversed across regions and across levels of processing (phonological, syntactic, semantic) in a serial fashion.

Within the framework of the current PDP model, linguistic operations are considered to be performed in more complex ways. One feature that characterizes this model is that any given task is thought to involve many operations that are localized within the various components of language (e.g., orthographical, semantic, phonetic, syntactic). These components, in turn, are subserved by different regions in the brain; that is, they are distributed (Paulesu *et al.*, 1993). Investigations in this area therefore entail two stages: first, an attempt is made to locate the operations within the components or levels of processing; secondly, attempts are made to map these components onto specific brain areas. A second feature of this model is that it posits a view that the various linguistic operations that constitute performance are carried out interactively through various routes in a parallel, concurrent and simultaneous fashion. At least, in normal or near-normal performance this is the case. In defective language processing, the flow of information through the expected routes is disturbed. As suggested earlier, the concept of parallel processing emerged from a realization that the notion of a serial transfer of information did not account for the rapidity with which mental processes are carried out.

Given the complexity of linguistic phenomena and the technical and methodological limitations involved in applying a heuristic computational model to the empirical analyses of language processes, this field of inquiry is still in its infancy.

## Neurodevelopmental Aspects of Language

Any description of the relationship between the brain and language would be incomplete without considering some neurodevelopmental aspects of language. As a comprehensive discussion of this subject is beyond the scope of this section, the focus here is on presenting central theoretical issues. Some of these issues help shed light on the ways in which the brain is organized for language in children. For discussions of language disorders in children, the reader is referred to Yule and Rutter (1987).

## Language Acquisition

One central issue addresses the notion of the innateness of language. Interest in this concept was stimulated by the pioneering

work of Chomsky (1988), who espoused the view of an innate human capacity to know the universal rules of grammar. Chomsky drew attention to the fact that despite differences in the languages of the world, all human languages have the same universal features. Consequently, learning a language is something that “happens” to a child (Goldberg, 1989).

The fact that there are universal regularities in the acquisition of language supports the notion of an innate capacity. Thus, according to Lenneberg (1967, 1969), an infant’s language capabilities are linked with physical maturation and there is therefore a correlation between language development and motor development. Thus, by about 15 months of age, when the motor milestone of self-propulsive gait is attained, an infant has a vocabulary of three to 50 words; by 18 to 24 months, when a child begins to run (with falls), many two-word utterances are observed (Lenneberg, 1969; Brown, 1973). By about 3 to 4 years of age, a child acquires the capability for many fully grammatical utterances (Stromswold, 1995).

In the literature dealing with the issue of language acquisition, much consideration has been given to the relative influences of genetic and environmental factors. Individual differences in performance raise questions about the relative contributions of these factors in language acquisition. On the one hand, it has been thought that if language is indeed an innate capacity with associated neural mechanisms, then language functions and malfunctions must also have a genetic basis.

Evidence for a genetic basis has come from many sources, especially from research in the area of developmental language disorders. Based on a review of relevant studies, Stromswold (1995) reported the finding of a higher incidence of language impairment in families of children with developmental disorders than in families of children without such impairment.

With respect to the view of language as an innate capacity, it is generally believed that language can be acquired without explicit instruction. For example, Stromswold (1995) reported that even children who are unable to speak and therefore cannot be corrected are capable of acquiring normal receptive language. In addition to the evidence that supports genetic contributions to language functions and dysfunctions, there is indirect support for the role of environmental exposure from studies of individuals raised in severely deprived environments. Studies of “wild” children raised in conditions of extreme linguistic, social and emotional deprivation essentially suggested an innate hypothesis for language acquisition but also suggested that the environment can have some modifying influences.

## Brain Organization and Language Development

It is thought that if language is indeed an innate capacity, there must be a neural basis for this capacity that is present from birth. In this regard, there has been some debate about the concepts of equipotentiality and differential lateralization at birth.

Equipotentiality of the brain for language means that both sides are capable of performing linguistic functions. Equipotentiality also suggests plasticity of the brain and a capacity for reorganization even after injury so that language functions can be transferred from one hemisphere to the other. Indeed, lesion data for childhood aphasia and earlier reports of hemispherectomy studies have suggested functional recovery with respect to language until puberty, as evidenced by ipsilateral and contralateral transfer of linguistic functions. Thus, it has been reported that if there is damage to the left side in infancy but

the right side remains intact, the child can still develop normal language (Curtiss, 1989; Dennis and Whitaker, 1976).

In early childhood, after the onset of language but before age 4 years, damage to the language areas results in transient aphasia. After puberty, by about age 14 years, the prognosis begins to worsen, and similar lesions in adulthood can cause irreversible deficits (Lenneberg, 1967, 1969). Some authors, such as Lenneberg (1967), have taken these findings about the capacity for transfer of function in young children to mean that the brain is symmetrically organized to begin with and only gradually becomes asymmetrically specialized, resulting in a diminished capacity for recovery with age. However, there is now increasing evidence that the brain is asymmetrical with respect to linguistic ability from birth.

If the brain is lateralized for linguistic functions from birth, a question arises about the evidence for greater recoverability of language when damage occurs early enough in life. One interpretation of this recoverability is that there is greater neuroplasticity in the young brain, as evident from the capacity of surviving neurons to make new synaptic connections even after injury.

Lenneberg's view of the critical period for language development (from birth to the early teens) was that both hemispheres are involved in language functions at first, but by puberty the left becomes more specialized. A later view relates the concept of critical period to the notion of neural plasticity. In any case, it is thought that the critical period is correlated with innate mechanisms, and that language development is most susceptible to the limiting effects of both biological and environmental factors if these extend beyond this critical period.

## Conclusion

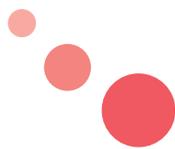

The focus of this chapter has been the cognitive neuroscience of memory, language and executive functions. As stated earlier, the term cognitive neuroscience does not refer to a single discipline; it connotes the integration of work from several fields examining brain-behavior relationships as they subservise specific mental processes. The exciting research that has emanated from *in vivo* functional imaging, especially with respect to memory, holds promise for further understanding of the manner in which the brain is specialized to process and store information.

Within the realm of theory, we have also stressed the growing consensus that neural processing and the emergence of cognition occur in a parallel and distributed fashion. Although this idea may be heuristically tenable, the specific mechanisms allowing simultaneity in information processing are difficult to model, from both cognitive and neuroanatomical perspectives. Work in computational neuroscience, aided by functional imaging and electrophysiological techniques, should permit the development of increasingly realistic and integrated models of cognition and brain. Rather than localizing whole functions to discrete areas of damage (as was the earlier tradition), the current emphasis continues to be on the contribution of a discrete area to a particular functional network. This approach characterizes present research on language, in which the role of regional specificity is understood within the context of a distributed functional and neuroanatomical system. The frontal lobes and executive control of behavior have proved to be an area that is rich in theory, but delineating the specific role of the frontal lobes in behavior and underlying neuroanatomical mechanisms has proved somewhat elusive. Advances in characterizing frontal circuitry and the specialized role of the prefrontal cortex in such functions as representational memory have elucidated the complex contribution of this region to the regulation of behavior.

# Cognitive Psychology: Basic Theory and Clinical Implications

---

A number of factors, including the development of complex learning theories, discussions regarding language development, use of computers as a metaphor for human information processing and practical applications needed during World War II, all contributed to the cognitive revolution in psychological research during the 1950s and 1960s. Cognitive psychology is now one of the major areas of psychological inquiry alongside experimental, developmental, social and personality, and clinical psychologies.

The major synthesis of cognitive psychology with clinical practice has been forged by cognitive–behavior therapists. There are, however, other major applications and implications of cognitive psychology regarding attention, memory and higher order cognitive processes such as problem solving, schema construction and modification, and automatic processing.

The purposeful allocation of one's finite mental resources is a process known as attention (Ashcraft, 1994). Attentional processes have profound implications regarding adaptive functioning, inasmuch as it falls to the attentional system to identify and select the most salient pieces of information in need of processing at each moment. Inefficient or erratic allocation of attention may engender maladaptive behavioral responses. Furthermore, it has been noted that a subset of cognitive processes appears to occur in the absence of attentional focus; such processes are often referred to as automatic (Posner and Snyder, 1975). Dysregulations of the attentional system appear to play a central role in several clinical disorders, such as Generalized Anxiety Disorder (GAD), Major Depressive Disorder (MDD), Attention-Deficit/Hyperactivity Disorder (ADHD) and Borderline Personality Disorder (BPD). Consequently, efficacious cognitive–behavioral interventions for these disorders have accorded considerable attention to the development of strategies designed to facilitate more efficient and adaptive functioning of the attentional system.

Human memory is the central, essential ingredient in an information-processing system. Human cognition supports operations more diverse by far than those of a computer, ranging from complex mathematical and spatial reasoning, to artistic and literary endeavors, to athletic prowess and interpersonal awareness. During the past century, empirical research has led to an increasingly refined understanding of the interlocking mechanisms of human memory. This understanding has now been applied to the domain of clinical assessment and psychopathology. Researchers have documented the role of memory deficits and biases in several mental disorders, including (but not limited to) depression and PTSD. The results of these investigations have suggested that memory, just as it plays an essential role

in adaptive human functioning, may also play a central role in maladaptive, pathological functioning. The cognitive perspectives on psychopathology place an emphasis on the role of schematic memory bias in its contribution to various forms of psychiatric disorder, and corresponding psychotherapy techniques have been developed to address bias in memory (Beck, 1976; Beck *et al.*, 1979).

Problem solving is the complex mental process of using previously learned information to identify solutions to new problems. Although specific empirical links between basic research and clinical practice have been sparse, the conceptual connections have provided several clinical procedures that are identifiable within self-control, cognitive–behavioral and interpersonal psychotherapies.

Cognitive psychologists studying memory developed the concept of schema, which can be understood as templates used to make sense of and draw conclusions about new sensory affective, of cognitive information. The schema construct was formulated to explain how memory is organized and why it produces the inaccuracies and incompleteness often observed in human recall. The incorporation and abstraction of new experiences into relevant schemata serve to influence the interpretation of future experience and thereby the encoding and recollection of new memories. Schemata, therefore, affect all levels of human cognitive processing and may well be the most significant regarding a theoretical model contribution to date in cognitive psychology. The development and modification of schemata are central to Beck and others' models of cognitive–behavioral conceptualizations of psychopathology and therapeutic change.

Finally, material is frequently processed automatically while conscious processing occurs on a parallel cognitive track. This raises intriguing questions regarding the similarities and differences in various conceptualizations of the unconscious. Answers to questions raised about automatic processes may well be the most significant future contributions cognitive psychology and neuroscience integration can offer clinical practice.

Piaget's work in the mid-20th century helped delineate the subsequent areas of inquiry about human psychological functioning and adaptation, and to some extent it has influenced the mainstream of cognitive psychology; however, his greatest legacy is clearly his seminal contributions to the study of human development and developmental psychology, of which cognitive development is only a portion. The focus of Piaget's theory was also considered cognitive when set in apposition to Freud's focus on emotion in his theory of psychosexual development. This chapter focuses on major areas of cognitive psychology: attention, memory and several of the most important “higher order”

cognitive processes. Neisser (1967) provided a seminal summary of cognitive psychology reviewing in detail information-processing approaches, findings from related models, and empirical data regarding internal mental processes of human functioning.

Although the information-processing paradigm is still dominant in cognitive psychology, two new paradigms became influential during the last 10 to 15 years of the last century. The more established one is called **connectionism** (or parallel distributed processing, see Chapter 16) (McClelland *et al.*, 1986). This approach addresses an inherent limitation of the traditional computer metaphor of the mind – the fact that the brain’s information processing operations differ dramatically from those of serial symbol-processing computers, inasmuch as the former occur within a distributed architecture of parallel interconnected elemental (neural) arrays. In other words, the connectionist approach attempts to gain insights into human information processing by attending closely to the manner in which the brain’s own neurons process information. Accordingly, this approach uses neural network computational modeling techniques (simulations) as useful theoretical tools in the specification of the actual neural mechanisms and processes that underlie human cognition.

An even newer cognitive paradigm is the so-called ecological approach, although it is not yet as well established or as conceptually coherent as are the information-processing and connectionist paradigms. The ecological approach emphasizes that cognition does not occur in isolation from larger environmental (e.g., cultural) contexts, and argues that it is essential to study cognition in the natural context in which it occurs.

In the following sections, we review the general findings regarding attention, memory and higher order cognitive processes and give examples of their application to various areas of psychopathology and treatment interventions. Figure 16.1 provides an overall schematic of the interactions of the cognitive processes that are discussed.

## Attention

The purposeful allocation of one’s finite mental resources is a process known as **attention** (Ashcraft, 1994). Attentional processes have profound implications regarding adaptive functioning, inasmuch as it falls to the attentional system to identify and select the most salient pieces of information in need of processing at each moment. Inefficient or erratic allocation of attention may engender maladaptive behavioral responses. Furthermore,

it has been noted that a subset of cognitive processes appears to occur in the absence of attentional focus; such processes are often referred to as automatic (Posner and Snyder, 1975). Some automatic processes may also be etiologically involved in certain forms of psychopathology to the extent that automatic thoughts, which occur without the benefit of attentional inspection, turn out to be aberrant or distorted (Beck, 1976). Dysregulations of the attentional system appear to play a central role in several clinical disorders.

The following sections examine various ways in which the functioning, or malfunctioning, of attentional processes may be involved in four relatively common psychiatric disorders: anxiety disorders (AD), major depressive disorder (MDD), attention-deficit/hyperactivity disorder (ADHD) and borderline personality disorder (BPD).

## Anxiety Disorders

An individual in an anxious state gives heightened attention to threat-related cues (MacLeod *et al.*, 1986; Matthews and MacLeod, 1985; Brosschot *et al.*, 1999; Bradley *et al.*, 2000; Fox *et al.*, 2001; Lundh and Oest, 2001; Bradley *et al.*, 1999; Mogg *et al.*, 2000), as such cues are usually particularly salient to the feelings of anxiety; this selectivity process may in turn filter out and discard information not congruent with the anxious mood state. Such a mood-congruent attentional bias helps orient the individual to the source of danger, which may in turn help ensure that the individual formulates an appropriate response to the threatening situation. To the extent that there is a reasonable goodness of fit between the level of anxious arousal and the level of genuine threat posed to the individual by the environment, the mood-congruence attentional bias serves an adaptive function. When the level of anxiety is consistently incommensurate with the environmental context, however, a state of pathological anxiety ensues.

Barlow’s (1988) anxious apprehension model suggests that pathological anxiety, such as that observed in GAD, may arise from a chronic misapprehension or overestimation of the level of threat posed by a wide array of situations, many of them benign. It is further proposed that, once the anxious arousal of a patient with GAD is triggered by the misapprehension of threat, there is a narrowing of external attention to the perceived danger, concurrent with a ruminative internal self-focus on negative expectancies regarding the situation’s

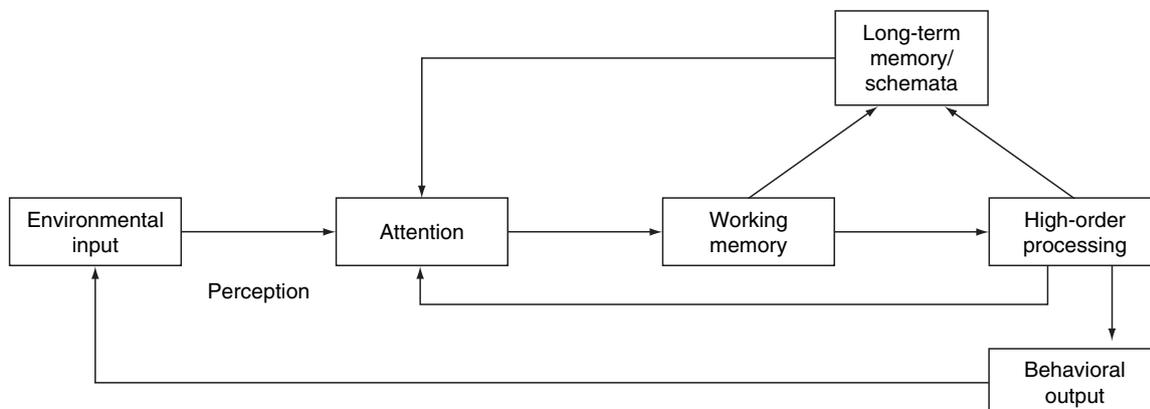

Figure 16.1 Human cognition.

outcome. Two deleterious consequences of such an attentional bias predictably ensue: 1) the patient disregards or discounts information that could serve to correct the original misapprehension of threat and 2) the patient's attentional resources are so thoroughly consumed by the focus on negative expectancies that few resources are available for constructive problem solving and adaptive responding.

A somewhat related cognitive model of pathological anxiety has been proposed by Beck and Emery (1985) in the schema theory of anxiety. Central to this theory is the mechanism of cognitive appraisal, with anxiety as the feeling state resulting from the appraisal of threatening stimuli. The appraisal process, in turn, is believed to be influenced by cognitive structures known as schemata, which consist of stored information abstracted from previous experience (Dombek and Ingram, 1993; Dibartolo *et al.*, 1997). Schema-guided appraisal is held to take place automatically.

Schema theory views pathological anxiety as the result of faulty schemata that lead to habitual, and largely automatic, overappraisal of danger; pathological appraisal often takes place automatically without benefit of the scrutiny that accompanies attentional focus. Accordingly, Beck's therapeutic approach to ameliorating pathological anxiety involves helping the patient allocate more attentional resources to the appraisal process, as a corrective to faulty schematic processing. Applications from cognitive psychology to the treatment of anxiety disorders are presented in Table 16.1.

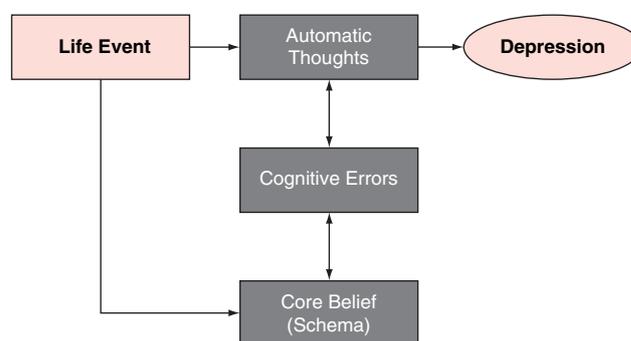

Figure 16.2 Beck's model of depression.

### Major Depressive Disorder (MDD)

It has been consistently observed that individuals suffering from major depression are prone to a negativistic bias in cognitive processing. Within Beck's influential cognitive model of depression (Figure 16.2) (Beck, 1976; Beck *et al.*, 1979), these depressotypic negative thoughts are held to be centrally involved in the onset and maintenance of the depressive episode (Figure 16.2). In addition, Beck's model proposes that many depressive thoughts occur automatically, in the absence of attentional awareness. In a manner similar to that observed with anxiety disorders, it appears that the attention of depressed patients is selectively focused on environmental cues congruent with the depressed state (Engel

Table 16.1 Prominent Clinical Exemplars of Cognitive Psychology

DSM Syndrome	Relevant Cognitive Psychological Finding	Clinical Application*
Major depressive disorder	Mood-congruent bias in recall and encoding of memory	CBT: Patient is trained to examine noncongruent memories (positive or neutral) to compensate for schematic distortion.
	Occurrence of negativistic automatic thoughts regarding self, world and future	CBT: Patient is directed to challenge automatic thoughts and to generate rational alternatives and is subsequently taught to challenge underlying negative beliefs.
	Deficits in problem solving	IPT: Patient is instructed in the use of problem-solving techniques, primarily in the interpersonal domain.
Generalized anxiety disorder	Heightened attention to environmental threat cues	CBT: Patient is directed to use relaxation techniques as means of ameliorating the anxiety state, thereby attenuating attentional bias.
	Overestimation of environmental threat	CBT: Patient is trained to undertake rational evaluation of all relevant environmental stimuli.
	Schematic bias in retrieval of threat-related memories	CBT: Threat-related schemata are modified via integration of successful coping experiences.
DSM Syndrome	Relevant Cognitive Psychological Finding	Clinical Application*
Borderline personality disorder	Poor regulation of emotion secondary to lack of attentional control	DBT: Patient is trained in the use of numerous attentional control techniques (e.g., core mindfulness; see Linehan, 1989).
	Deficits in problem solving secondary to attentional dyscontrol	DBT: Patient is directed to shift attention from rumination over difficulties to discovery of more adaptive responses to problem. Also, patient receives direct training in social problem-solving skills.

\*CBT, Cognitive-behavioral therapy; IPT, Interpersonal psychotherapy; DBT, Dialectical behavioral therapy.

and DeRubeis, 1993), such as cues related to themes of failure or rejection.

Rehm (1974) has identified another prominent dysregulation of the attentional system in MDD in the self-control model of depression, in which it is noted that depressed patients often devote excessive attentional focus to ruminative appraisal of self. By extension, self-management therapy for depression (Rehm, 1984) assists patients in shifting attentional focus away from self, thereby freeing up mental processing resources for the formulation of more effective behavioral responses.

### Attention-deficit/Hyperactivity Disorder

In general, it appears that the attentional system of children with ADHD frequently functions inefficiently, so that relevant stimuli often go unidentified, irrelevant stimuli (distractors) are accorded disproportionate attention, and even on occasions when attention is paid to appropriate environmental information, such attention is often broken off prematurely; that is, the children frequently respond to environmental stimuli before consideration of all relevant data (Douglas, 1980).

These attentional difficulties seem to be strongly related to problems with behavioral inhibition (Barkley, 1999), a finding that still obtains even when global intelligence, reading achievement and comorbid psychopathology are taken into account (Chhabildas *et al.*, 2001; Nigg *et al.*, 1998; Nigg 1999; Seidman *et al.*, 1997). Within this perspective, treatments need to include components which address the fundamental problems regarding behavioral inhibition.

Various stimulant medications, most notably methylphenidate, have been shown to be efficacious in the acute treatment of ADHD. As noted by Kendall and MacDonald (1993), there are limitations to stimulant therapy that highlight the need for also developing effective psychosocial interventions for ADHD: 1) some children with ADHD do not respond to stimulant medication; 2) medication appears to be limited in its effect on some higher order cognitive processes, such as problem solving; 3) medication may not ameliorate longstanding deficits in social skills; 4) some children experience difficulties complying with medication regimens; and 5) gains made during medication therapy are often not maintained after termination of treatment. Cognitive-behavioral treatment interventions for ADHD, therefore, would appear to constitute a potentially valuable supplement and/or alternative to medication.

### Borderline Personality Disorder

Inability to regulate emotional states has been identified as one of the hallmarks of BPD (Grotstein, 1987; Linehan, 1993a; Herpertz *et al.*, 2001). The significance of this finding for the present discussion lies in the fact that there exists a strong reciprocal relationship between emotion regulation and attentional focus: an increase in emotional arousal narrows attention to a focus on emotion-relevant stimuli. Conversely, the ability to shift attention away from affect-inducing stimuli may be central to the process of emotion modulation. Therefore, it has been hypothesized that the characteristic difficulties with emotion regulation of the patient with BPD may be directly linked to a relative lack of attentional control (Linehan, 1993a; Coolidge *et al.*, 2000).

Linehan's (1989, 1993a) dialectical behavior therapy (DBT) has been shown in a series of clinical trials to be effective in ameliorating many of the more serious symptoms of BPD, including

parasuicidal behavior and impulsive angry outbursts (Linehan *et al.*, 1991, 1993; Shearin and Linehan, 1994; Koons *et al.*, 2001). Significantly, the DBT protocol includes numerous interventions that seek to address the dysregulations in attention characteristic of patients with BPD.

A central goal of DBT is the cultivation of core mindfulness, a frame of mind described by Linehan as “[being] in control of attentional processes – that is, what one pays attention to and how long one pays attention to it” (Linehan, 1993b, p. 65). The patient with BPD is taught to recognize the connection between attentional fixation on distressing stimuli and a commensurate escalation in affective arousal, especially problematical negative affective states such as rage and depression. Thus, in DBT there is explicit recognition that enhanced attentional control is a primary treatment goal.

### Memory

The second major area of study in cognitive psychology involves the investigation of memory. In the most generic sense, memory refers to the components of an information-processing system that support the encoding, storage and retrieval of information over time. Memory is the central, essential ingredient in the human information-processing system. Human cognition supports operations more diverse by far than those of a computer, ranging from complex mathematical and spatial reasoning, to artistic and literary endeavors, to athletic prowess and interpersonal awareness. Memory is the substrate of these many skills and the foundation for human consciousness. To the extent that we are each more than the sum of our biological components, it is in large part the texture of our own unique memories that makes us so.

Over the course of the past century, the empirical efforts have led to an increasingly refined understanding of the interlocking mechanisms that constitute human memory. This understanding has begun to be applied to the domain of clinical assessment and psychopathology. Researchers have documented the role of memory deficits and biases in several mental disorders. The results of these investigations have suggested that memory, just as it plays an essential role in adaptive human functioning, may also play a central role in maladaptive, pathological functioning. The cognitive perspectives on psychopathology place an emphasis on the role of schematic memory bias in its contribution to various forms of psychiatric disorders, and corresponding psychotherapeutic techniques have been developed to address bias in memory (Beck, 1976; Beck *et al.*, 1979).

For the purposes of this discussion, it is necessary to point out that the study of memory has become a useful adjunct to the cognitive perspectives on psychopathology. The central theme of these perspectives is an emphasis on maladaptive thinking in the genesis and maintenance of psychiatric disorders. Once granted the premise that dysfunctional thoughts and/or cognitive biases may play a pivotal role in the dynamics of psychopathology (Beck, 1976, 1983; Beck *et al.*, 1979), it follows that memory may serve as a cognitive mediator in many forms of mental disorders; an extensive empirical literature has developed through efforts to test this premise.

The following sections of this chapter present a brief discussion of memory-related research for two particular psychiatric disorders, MDD and post traumatic stress disorder (PTSD). Because researchers have substantially documented the memory deficits associated with these disorders, a review of the findings may prove useful for clinical and diagnostic purposes.

## Clinical Depression, Memory and Schemata Bias

Depression (clinical and subclinical) has been linked to impaired performance in a variety of memory experiments, and additional research has suggested that the effect may partly reflect deficits in the recognition or employment of informational structure in stimulus materials. It remains to be demonstrated conclusively whether similar impairments obtain for implicit memory processes (in which the subject is unaware of any conscious recollection). There is a different line of research, however, that bears more directly on depression and automatic (or unconscious) memory processes. According to the theory of depression of Beck and colleagues (Beck, 1976; 1983; Beck *et al.*, 1979), the depressed individual is prone to make negativistic inferences and generalizations and prone to consequent biases in recall and recognition memory (e.g., through selective abstraction, overgeneralization, magnification, minimization). These memory biases have been more broadly described as mood-congruent recall, referring to distortions in memory based on current mood state. Mood-congruent recall is an implicit, automatic memory process (to the extent that mood state may exert a systematic effect on the content of memory retrieval, without conscious awareness or intention on the part of the individual).

For clinical purposes, two generic findings from cognitive research on depression are important to remember. First, depression is associated with general impairment for explicit memory tasks (recognition and recall). Secondly, depression is also associated with a mood-congruent memory bias. Taken individually, either of these symptoms may interfere with adaptive coping, because accurate memory is necessary for adaptive and intelligent behavioral responses. In combination, the two memory difficulties can have a substantial impact on an individual's perceptions of the self, the world and the future (Beck's cognitive triad [Beck, 1976; Beck *et al.*, 1979]), serving both to impair behavior and to maintain depressive affect. In consequence, memory disturbance in depression can be an important focus for clinical intervention (Beck *et al.*, 1979), and it should ideally be considered in the formulation of a comprehensive treatment package.

## Posttraumatic Stress Disorder, Repression and Memory Impairment

Survivors of PTSD suffer from a persistent and aversive tendency to reexperience the traumatic event, as manifested by symptoms of intrusion, dissociation and hyperarousal. These symptoms can include recurrently intrusive images or dreams, hallucinatory flashbacks, intense psychological distress (caused by symbolic re-exposure), blunted affect, social withdrawal, hopelessness, amnesia, avoidant behavior, irritability, insomnia, hypervigilance and impaired concentration. When experienced in combination, these symptoms may often result in a highly debilitating syndrome that operates to the exclusion of adaptive coping behavior.

PSSD by definition involves a pathological response to memories that are so traumatic as to be at once unforgettable (hence the intrusive symptoms) and intolerable to remember (hence the dissociation). The resulting heterostasis is posited to lead to emotional and physical dysregulation and presents a challenge to fundamental beliefs regarding security, efficacy and prospect for future well-being (Herman, 1992).

It is currently unclear whether PTSD memory deficits derive from some (unidentified) neuropsychological sequelae of

extreme stress exposure or are simply concomitant to prolonged symptoms of hypervigilance, emotional distress, or comorbid depression. It is clear that PTSD is associated with significant proactive interference in memory, such that survivors are impaired in their ability to encode and to retrieve new information.

The second type of memory deficit in PTSD involves symptoms of amnesia for, and intrusion of, memories for the initial traumatic event. These symptoms represent a functional deficit in memory, such that the survivor is alternately confronted with emotionally disturbing recollections and unable to access the traumatic memory.

In addition to deficits in memory, individuals with PTSD complain about the intrusion of memories for the traumatic event. In a pattern similar to that observed in MDD, individuals with PTSD appear to demonstrate both overgeneral autobiographical recall and a negativistic memory bias.

Questions about the accuracy (or inaccuracy) of repressed memory are difficult to address. Although the prevalence of amnesic and dissociative symptoms in PTSD has been validated by studies of trauma survivors (Herbst, 1992; Zimering *et al.*, 1993), these studies do not address the validity of more controversial cases that reportedly involve complete (and asymptomatic) repression over long periods. Empirical efforts to document long-term traumatic repression continue to meet with significant methodological and conceptual criticisms (Williams, 1994; Loftus *et al.*, 1994).

The practicing psychiatrist must recognize the possibility of suggestibility and bias in retrieval of traumatic memories (Loftus, 1993; Berliner and Loftus, 1992; Gutheil, 1993), while maintaining a stance of openness and compassion in helping trauma survivors to clarify and to reintegrate their memories of traumatic events (Alloy *et al.*, 1990). In sum, PTSD is a disorder of unbearable and inescapable recollection, and both research and therapy will continue to focus on the elucidation of memory for trauma.

## Higher Order Cognitive Processing

### Problem Solving

Newell and Simon (1972) exemplified the modern approach to the study of problem solving. Their methodology involved the extensive analysis of verbal protocols, that is, subjects' verbalizations as they attempted to solve (often lengthy) mental problems. Their in-depth analyses of human mental processes ultimately led Newell and Simon to their most important conceptual contribution – the idea that human thought could be conceived of as internal symbol manipulation, or the processing of information. Their analogy to algorithmic information processing in computers proved useful; data input was similar to perception, data representation was similar to memory and data manipulation was similar to problem solving.

Goldfried and Davison (1994, p. 186) concluded that “much of what we view clinically as ‘abnormal behavior’... may be more usefully construed as ineffective behavior with its negative consequences, such as anxiety, depression, and the creation of secondary problems”. Deficits in problem solving have been documented as nonspecific deficits associated with many psychiatric disorders (e.g., schizophrenia). Problem-solving techniques are considered standard cognitive-behavioral interventions with applications to such diverse problems as depression, suicidal behavior, anxiety, marital problems and adolescent social prob-

lems (D’Zurilla, 1986; Nezu *et al.*, 1989; Nezu and D’Zurilla, 1980; Robin, 1981). Applications with children have focused on reducing aggressive behavior (Camp and Bash, 1985), reducing impulsive behavior (Kendall and Braswell, 1985), and teaching social competence in prevention programs (Kirschenbaum and Ordman, 1984).

In the current practice of problem-solving therapies, there is general agreement on the five steps central to most problem-solving applications. These steps may be traced to observations derived from empirical work on problem solving in cognitive psychology, although actual explicit empirical links have never been established. These five steps, first enumerated by D’Zurilla and Goldfried (1971), are: 1) developing a general orientation or set to recognize problems, 2) defining the specifics of the problem and what needs to be accomplished, 3) generating alternative courses of action, 4) deciding among the alternatives by evaluating their consequences, and 5) verifying the results of the decision process and determining whether the alternative selected is achieving the desired outcome. If the outcome is not satisfactory, the process is repeated. These basic steps of clinical problem solving, at times combined with components of Spivak and Shure’s (1974) program (e.g., taking the perspective of other persons), have formed the core of the empirically validated problem-solving therapies that are usually identified as a type of cognitive-behavioral therapy.

### Schema Theory and Reasoning

Beck and colleagues (1979) suggested that new information about particular experiences or situations is processed through the medium of an established, organized, cognitive structure based on abstractions from relevant prior experience. This organized, cognitive structure is called a **schema**, and it has become one of the primary elements in the cognitive perspective on depression (as well as the cognitive perspective on other forms of psychiatric disorders). Cognitive schemata are believed to exert their influence at many different levels of information processing. Schemata are hypothesized to direct the selectivity of attention, as well as the interpretation of ambiguous information, and the integration of new experiences into an existing cognitive matrix. For this reason, schema theory can be used as an overarching, explanatory framework for much of the clinical psychopathology research on attentional mechanisms, memory biases and reasoning processes.

The application of schema theory to the study of psychiatric disorders represents one of the important elements in the cognitive perspective on psychopathology. Although Beck is most widely known for his theories about depression, he has also written about the cognitive bases for other emotional disorders including anxiety and anger (Beck, 1976), as well as the cognitive bases for personality disorders (Beck and Freeman, 1990). In all of these theories, the central credo involves the influence of schematic bias in the interpretation of new information and the encoding of new memory. Thus (for example) in depression, the overgeneralized operation of negativistic schemata is hypothesized to lead to faulty and depressogenic inferences about events and experiences in an individual’s life (Beck *et al.*, 1979). Another example of the role of schemata in psychopathology is observed among personality disorders, wherein an individual is hypothesized to suffer from a self-perpetuating and treatment-resistant “early maladaptive schema”, which essentially involves a dysfunctional set of assumptions and interpretations regarding oneself in relation to other people and/or the environment (Young, 1990). Cognitive theory can be extended, by analogy, to many of the other forms of psychiatric disorders.

### Automatic Versus Conscious Processing

As noted previously, mental processes exist that appear to occur in the absence of attentional focus and thus outside conscious awareness; these processes are frequently described as being automatic (Logan and Klapp, 1991; Posner and Snyder, 1975; Shiffrin and Schneider, 1977). It was further noted that complex mental processes, such as driving to work, initially require considerable attentional focus but may eventually become automatic as a result of overlearning (Craighead *et al.*, 1994). Automatic cognitive processes often facilitate adaptive functioning, inasmuch as they permit the individual to engage in numerous cognitive operations concurrently (i.e., parallel processing). However, it has also been suggested that some automatic thoughts, such as appraisals, may turn out to be aberrant or distorted (Beck and Emery, 1985), and because such thoughts are not subjected to the scrutiny that accompanies conscious attentional focus, aberrant automatic thoughts are unlikely, under most circumstances, to be corrected. We know that schema-based inferences fill in the gaps in memory of prior events so that humans reconstruct that which they cannot completely recall. Thus, what is recalled is integrated in memory with that which is reconstructed and the relevant schema is thereby modified, many times in a self-defeating or negativistic manner by patients. Although this is an efficient mechanism that facilitates functioning in our complex world, it can lead to schematic errors of which the individual may not have full awareness – she or he only is aware of the outcome and not the process. One of the fundamental goals of cognitive-behavioral therapy is the development of the understanding of both the content and functioning of such automatic processes.

This model of automatic cognitive processes has been implicated in the etiology and maintenance of numerous forms of psychopathology, most prominently GAD (Wolpe, 1958; Barlow, 1988) and MDD (Beck, 1976; Beck *et al.*, 1979). For example, the patient with GAD is hypothesized to engage in automatic overestimation of potential threat in a variety of environmental contexts, many of them benign (Beck and Emery, 1985). This automatic misappraisal is believed to be influenced, in large measure, by the operation of faulty schemata, cognitive structures that represent the preprocessed distillation of various threat-related experiences stored in long-term memory. Likewise, depressed patients have been observed to engage frequently in a variety of negativistic automatic thoughts, presumably influenced by the operation of schemata concerning themes of rejection and failure.

Social psychology, defined broadly as the study of social influences on psychological functioning, is highly relevant to a biopsychosocial perspective in that it focuses on understanding the person–environment relationship. Environmental factors are presumed to influence psychological functioning. Individuals are defined as active interpreters of the environmental contexts in which they live such that individual construals of events influence psychological life and behavior.

The chapter begins with a discussion of how social factors influence the psychological processes of the individual, including self-functioning and social cognition processes. This is followed by a review of interpersonal processes. Next, attention is turned to the functioning of social groups, including the family. Finally, the influence of culture is considered.

## The Self

### Theory and Research Findings

#### Historical Precedents

Current social psychological efforts to understand the self in the context of the person–environment relationship, particularly the social world of the individual, are not without significant historical precedence. For example, James (1890/1981) posited that one component of the self was a social self determined in part by relationships with significant others. James maintained that because one's social roles and impact on others are varied, each individual has multiple social selves (e.g., self at work, self with family) with varying degrees of integration and internal consistency. Cooley's (1902) concept of the looking-glass self referred to the idea that the self emerges from one's interpretations of the reactions of important others in the social environment. Similarly, Mead's (1934) symbolic interactionism approach posited that self-knowledge derives from a process of taking the role of the other in social interaction. According to this view, the individual internalizes norms and expectations of the social group (the generalized other) in the course of social interaction. This internalization of the generalized other provides the basis for self-reflection, including the capacity to evaluate one's gestures and deeds, and anticipate others' responses to one's behavior. Social psychological inquiries into the self in the middle decades of the 20th century were sparse, but over the past 20 years interest in self-functioning has dramatically increased, in part spurred by social cognition research (Taylor, 1998). While a comprehensive review of this now voluminous literature is beyond the scope of this discussion, a sampling of representative, contemporary social psychological perspectives on self is presented here.

#### Social Psychological Models of Self

Consistent with trends toward systematic examination and articulation of the person–environment relationship in personality functioning as a whole (Baumeister, 1999; Curtis, 1991; Mitchell, 2000), social psychological models presume that self-functioning is influenced both by intrapersonal and situational context factors (Baumeister, 1998; Tesser *et al.*, 2000). From this perspective, self-functioning may be understood in terms of personal traits and dispositions (individual self), interpersonal roles and relationship patterns (relational self), and larger group identifications (collective self) (Sedikides and Brewer, 2001).

Investigations of the self have produced myriad conceptualizations of self-functioning. To organize the diverse strands of theory and research on self, Baumeister (1998) has proposed three dimensions central to the construction of self, including reflexive consciousness, interpersonal being and executive function. Reflexive consciousness refers to the human capacity to reflect on personal thoughts, feelings and behavior, and is the mechanism that makes possible the construction of self-conceptions and self-knowledge. Interpersonal being connotes the relational component of self that develops within ongoing interpersonal transactions and serves the vital psychological function of negotiating the relational world. Executive function refers to the capacity for agency, decision-making and initiative in living, and is the basis for active engagement with the environment. Social psychological models of self-functioning typically presuppose and/or focus on one or more of these dimensions of self.

To illustrate current social psychological thinking with regard to self-functioning, a few examples of recent social psychological theories of self are outlined briefly in the table: the self-verification theory, self-evaluation maintenance, self-discrepancy theory and self-determination theory (Table 17.1). Each of these models represents a significant contribution to the social psychological perspective on self, and although not clinically derived, has significant relevance to the clinical situation.

#### Self-presentation, Impression Management and Personal Identity

Along with specific theoretical models of self, social psychology has examined the impact of self-presentation and impression management on self-functioning. Specifically, people are invested in presenting themselves in certain ways (performing) in social situations and endeavor to control the impressions that others have of them in those situations (Goffman, 1959; Leary, 1995). These modes of self-presentation have some degree of influence on

**Table 17.1 Theories of Self: Representative Examples**

Model	Basic Tenets
Self-verification theory	Individuals use their social relationships to validate core aspects of their self-concepts.
Self-evaluation maintenance	Regulation of self-regard is influenced by the performance of others in one's social environment.
Self-discrepancy theory	Persons seek a state of affairs in which their self-concept (qualities that oneself/others presume that one possesses) is perceived to be congruent with how they and others believe they should or ought to be.
Self-determination theory	Behavior is directed by a core self-organization consisting primarily of intrinsic motivation, innate needs, and integrative psychological functions.

self-definition and personal identity (Tice and Baumeister, 2001). Successful impression management requires an awareness of social expectations regarding behavior in a specific situation, a desire to act within social expectations, and a capacity to present oneself in such a way that the desired impression is conveyed. One's behavior in social interactions also is guided by the impressions one forms of others. Generally speaking, it is adaptive to be cognizant of others' views of oneself and to portray oneself in particular ways because these interpersonal strategies can enhance one's capacity to comprehend, regulate and anticipate social interaction patterns (Schlenker and Pontari, 2000). In deciding how to present themselves in a social interchange, people stress the commonalities between themselves and what is expected of them and present a personally and socially desirable public image to assure social compatibility, solidarity with others and social approval.

### Self in Health and Illness

Issues of physical health and illness influence both one's self-definition and the quality and nature of one's interpersonal world. In turn, one's self-definition influences how one responds to health-related concerns. Self-efficacy (Bandura, 1997), which connotes beliefs regarding one's capacity to perform a required action, is an especially important variable in predicting individual responses to health-related concerns (Salovey *et al.*, 1998). To heighten the extent to which individuals can exercise control over their own health behaviors and associated environmental stresses, individuals may be taught self-management and self-control techniques. Learning the array of cognitive and behavioral coping strategies that increase people's ability to manage their illness and associated affective responses also enhances self-efficacy and overall capacity for effective self-regulation.

### Mental Health Implications

Mental health professionals increasingly have appreciated the need to understand self-functioning in a relational context. This shift in focus has been influenced by attachment theory (Bowlby, 1982), interpersonal psychiatry (Sullivan, 1953), psychoanalytic object relations theory (Greenberg and Mitchell, 1983), feminism (Jordan, 1997) and family systems theory (Gurman and Kniskern, 1981, 1991). For example, Sullivan's (1953) clinical theory included a characterization of the self-system as composed of the good-me bad-me and not-me personifications, with the self-system defined interpersonally on the basis of perceived responses of significant others beginning early in life. Within the psychoanalytic tradition, adherents to object relations theory (Fairbairn, 1954; Guntrip, 1969; Winnicott, 1965), self-psychology (Kohut, 1977), and relational psychoanalysis (Mitchell, 2000) have underscored the importance of the interpersonal contributions to self-development and functioning. Each of these approaches emphasizes that the nature and quality of the relationship between the therapist and patient is centrally relevant to helping the patient make changes in self-functioning.

### Models of Self and Clinical Intervention

Based on a synthesis of theoretical models and empirical research findings, Deaux (1992) has developed a social psychological model of relationships between self and mental health that revolves around self-definition and the impact of challenges to self-definition on mental health functioning. In the model, self-definition is conceptualized as consisting of 1) specific domains of functioning (e.g., social and personal identities, life tasks) rather than as a global entity; 2) goals and aspirations as motivational elements; and 3) active interpretations of experience and personal meaning constructions. Demographic and socio-cultural variables, social structure and socialization processes are viewed as distal influences on self-definition. Although the self-definition is presumed to be relatively stable, it is subject to challenge by internal factors (e.g., perceived discrepancies between the self-definition and internally defined expectations for oneself, negative social comparisons) and/or external factors (e.g., illness, change of employment status, changes in significant relationships). Challenge triggers a self-evaluation process to deal with information that is inconsistent with one's predominant self-definition. Self-evaluation results in regulation and reconstruction activities focused internally on the self (e.g., self-esteem maintenance, self-affirmation, self-esteem protection, activities associated with alterations in self-definition) and/or externally on the external world (e.g., self-verification, self-monitoring, behavioral disconfirmation activities associated with presentation of the reformulated self-definition in the social world). Negative outcomes of the self-evaluation process are presumed in the model to be associated with adverse mental health outcomes.

Drawing from myriad theories and concepts from within social psychology, Deaux's (1992) model acknowledges the centrality of self-regulation processes in the maintenance of overall mental health as individuals respond to challenges to existing self-definitions. Self-regulation processes are a core element of the social psychological theories of self summarized herein, including self-verification theory (Swann, 1983, 1997), self-evaluation maintenance (Tesser, 1991; Beach and Tesser, 1995), self-discrepancy

theory (Higgins, 1987; Moretti and Higgins, 1999) and self-determination theory (Deci and Ryan, 2000; Ryan and Deci, 2000). Each of these models provides insights for the clinical understanding and treatment of mental health problems as they relate to challenges to self-definition and the self-evaluation processes that ensue in response to such challenges. Examples of the clinical relevance and utility of these models for clinical work now will be considered.

### Self-presentation and Impression Management in Clinical Perspective

While the maintenance of a specific social image through impression management can yield psychological benefit, certain patterns of self-presentation can also have a negative psychological impact. For example, preoccupation with presenting oneself as competent in a particular pursuit when realistic appraisal suggests otherwise can give rise to pursuit of goals for which one is not suited, generating impractical expectations for self and precipitating associated frustration and disappointment. Extreme efforts to present oneself in a particular light can lead to maladaptive states of mind, response patterns and relationships (Shepperd and Kwavnick, 1999).

Impression management also has implications for the self-relevant social emotions of guilt and shame. Both guilt and shame are responses to perceived transgressions on the part of the self, but differ in that guilt involves condemnation of a particular behavior and is accompanied by remorse or regret, whereas shame involves condemnation of one's self and is accompanied by feelings of being exposed as objectionable and bad (Tangney and Salovey, 1999). Both guilt and shame are emotional experiences tied to one's perceived failure to maintain a positive self-presentation, and each propels specific patterns of impression management. For instance, guilt tends to spark interpersonal efforts to make reparation for one's behavior, whereas shame may prompt social avoidance associated with a wish to hide the self from view (Tangney and Salovey, 1999). Although guilt and shame are expectable emotional dimensions of everyday psychological life, their problematic manifestations can adversely affect both self-regulation and interpersonal relationships, and therefore must be considered in clinical evaluation and treatment of psychological dysfunction.

### Social Cognition

Social cognition – the ways social events are interpreted, analyzed and mentally represented – provides an information-processing framework for understanding how construals of self and others affect social discourse and psychological life (Fiske and Taylor, 1991). Social cognition concepts have influenced traditional areas of social psychological theory and research, including attribution processes, person perception, and attitude formation and change. Over time, the information processing emphasis of social cognition has been integrated with concepts of motivation and emotion to create a fuller view of the individual in relation to the social world (Taylor, 1998).

### Attribution Processes

Attribution processes refer to causal explanations generated by an individual to account for why a particular event or set of outcomes has occurred. People use attributions to make sense of their own behavior and that of others, and, therefore, attribution processes influence individual actions, affective experiences and

**Table 17.2 Attribution Theories: Representative Examples**

Model	Basic Tenets
Heider's model	Individuals attribute the causes of events to dispositional or situational factors.
Jones and Davis' model	Individuals make inferences about the dispositions of an actor based on observations of the noncommon effects of the actor's behavior.
Kelley's model	Individuals attribute the causes of behavior to the actor, the entity, or the circumstances. Consensus, consistency and distinctiveness information are used to formulate an attribution to one of these three sources.  Causal schemas also influence attributions when one or more of these types of information is not available.
Achievement model	Affective responses in achievement situations are influenced by the extent to which success or failure is attributed to internal/external causes, stable/variable causes and controllable/uncontrollable causes.
Depression model	Risk of depression increases as a result of attribution of negative events to internal, stable and global causes.

interpersonal behavior (Weiner and Graham, 1999). Attribution theory (Table 17.2) and research has been a mainstay of social psychology and has led to important clinical mental health applications (Bell-Dolan and Anderson, 1999; Forsterling, 2001; Graham and Folkes, 1990).

### Attribution Biases

Based on the proliferation of research stimulated in the 1970s by social psychological models of causal attribution, three major types of attribution biases in everyday social interactions were illuminated: the fundamental attribution error (Ross, 1977), the actor–observer bias (Jones and Nisbett, 1971) and the self-serving (hedonic) attribution bias (Bradley, 1978) (Table 17.3).

The fundamental attribution error – a bias toward attributing behavior to dispositional factors in the actor while underestimating the influence of situational variables – typically occurs in the context of understanding the behavior of others.

**Table 17.3 Major Attributional Biases**

Bias	Description
Fundamental attribution error	A bias toward attributing behavior to dispositional factors and underestimating situational influences on the behavior in question
Actor–observer bias	A bias toward attributing one’s own acts to situational factors while attributing others’ behavior to dispositional factors
Self-serving (hedonic) bias	A propensity to attribute one’s own successes to dispositional factors while attributing failures to situational factors

The actor–observer bias refers to instances in which individuals attribute their own acts to situational factors and minimize the role of dispositional qualities, attributing the others’ behavior to dispositional factors. Actor–observer differences may be a function of greater self-knowledge than knowledge of others, or related to differing perspectives between actors and observers that lead to different causal interpretations. The self-serving (hedonic) attribution bias involves a propensity to attribute one’s successes to dispositional factors and one’s failures to situational causes. Specifically, the self-serving bias reflects a wish to present oneself in the best possible light. People tend to extend this attribution bias to important others in their interpersonal sphere (e.g., spouse). Multiple explanations have been offered in the literature regarding the causal underpinnings of these attribution biases (Forsterling, 2001).

### Attributions in Health and Illness

Given that attribution processes tend to be activated by negative, unanticipated, or ambiguous events, it is logical to assume that attribution theory would have a useful role in conceptualizing how people come to understand the causes of their illness as well as processes of stress and coping with illness (Amirkhan, 1990; Salovey *et al.*, 1998). Empirical evidence supports this view, as exemplified in a recent meta-analytic study that suggested that attributions influence illness-related coping and adjustment (Roesch and Weiner, 2001). Attributions influence one’s self-definitions in relation to the illness, as well as one’s perceptions of control over illness-related contingencies and outcomes. However, associations between specific attributions and illness should not be interpreted to mean that certain attribution patterns cause illness, but rather that they may be among a complex set of factors affecting responses to illness.

It is clear that causal attributions are important in facilitating health promotion and positive health practices (Rodin and Salovey, 1989; Salovey *et al.*, 1998). To the extent possible, treatment interventions with medically ill persons should incorporate a focus upon enhancing the individual perceptions of control over health and treatment regimens with the aim of increasing adherence to medical regimens and improving adjustment to medical procedures and conditions. Existing research also underscores

the importance of considering locus, stability and controllability dimensions of the attribution process in understanding illness-related attribution processes and their role in predicting patient perceptions of medical treatment (Amirkhan, 1990).

### Mental Health Implications: Attribution Processes

Theoretical models and research have significant implications for mental health treatment (Bell-Dolan and Anderson, 1999; Forsterling, 2001; Weiner and Graham, 1999). Presumably, attribution models can be instructive for designing interventions that target causal inferences associated with problematic emotion states (e.g., guilt), moods (e.g., depression) and behavioral constellations (e.g., social avoidance) (Bell-Dolan and Anderson, 1999). The application of attribution models to depression is illustrative of this point.

### Hopelessness Theory of Depression

The use of attribution concepts, including the notion of attributional style, in understanding learned helplessness and depression led to the formulation that the presence of a pessimistic attributional style increased the risk that an individual would experience helplessness, hopelessness and depression (Abramson *et al.*, 1978). This attribution dimension was later incorporated as a key component of the hopelessness theory of depression (Abramson *et al.*, 1989; Gotlib and Abramson, 1999). This model predicts that an individual is at risk for hopelessness depression to the extent that negative events are attributed to internal, stable and global causes, and that these causes are perceived as both likely to prompt other negative consequences and to be reflective of deficiencies or shortcomings of self. The model also posits that a given individual’s causal attributions are a function of both situational factors and individual differences in attributional style. Further, cognitive vulnerability to hopelessness depression is conceptualized as a function of individual differences in attributional style as well as the propensity to infer negative consequences and negative self-evaluation in response to adverse events (Gotlib and Abramson, 1999).

### Person Perception and Implicit Personality Theories

Person perception, also referred to as social perception, pertains to the ways in which people formulate impressions of others (Leyens and Fiske, 1994). Person perception can be conceptualized broadly as involving three sequential processes: 1) the identification of meaningful acts by observation of overt actions based on the actor’s intentions or traits; 2) the formation of attributions about the acts; and 3) the integration of attribution inferences into a unified impression of an individual (Gilbert, 1998). Social psychologists have long suggested that people formulate implicit personality theories that consist of general beliefs about human characteristics and patterns of covariation among personality traits (Schneider, 1973). These knowledge systems facilitate rapid formation of inferences about the enduring personality qualities of other people in everyday life by using assumptions about interrelationships among dispositional qualities to draw conclusions about observed behavior. More recently, schema concepts in social cognition have been investigated in order to specify cognitive processes through which individuals organize and represent coherent and meaningful impressions of others (Leyens and Fiske, 1994).

Although person perception variables per se have not been explicitly discussed in the context of health issues, one particularly useful application of this literature is in understanding relationships between patients and their health care providers. The doctor–patient relationship is influenced in part by the affective and cognitive evaluations that each make regarding the other. These person perception variables affect interaction styles between physicians and their patients which, in turn, may influence the nature and quality of medical care. Patients’ perceptions of their physicians as paternalistic, interested in mutuality in decision-making regarding care, or expecting them (the patient) to have primary responsibility for decision-making will contribute to differential doctor–patient interaction dynamics (Shelton, 1998). Similarly, the degree to which the physician’s impression of the patient is that of a passive novice, informed partner, or the consumer in charge of care will affect doctor–patient interactions.

Person perception has clinical relevance for the cognitive interpretation of interpersonal situations. Many of the cognitive distortions (e.g., overgeneralization, magnification and minimization) observed in depressed persons (Beck *et al.*, 1979), anxious individuals (Beck *et al.*, 1985), and people with personality disorders (Beck and Freeman, 1990) influence person perception in a maladaptive fashion. Thus, while person perception research has demonstrated a normative tendency to make rapid evaluations of others and interpersonal situations based on limited information, this process is apt to become problematic when cognitive distortions are operative. For example, the depressed person with low self-esteem and a pessimistic attributional style who, based on a few experiences of being criticized, perceives others as judgmental in virtually every interpersonal interaction is overgeneralizing based upon limited data (i.e., “others are always critical of me”). This is likely to interfere with the development of trusting relationships.

Implicit personality theories and schemas in social cognition are clinically applicable to understanding chronically maladaptive person perception processes. This may have particular relevance for the clinical understanding of personality disorders. For example, the patient with paranoid personality disorder may hold a pervasive view of others as potentially attacking, blaming and controlling (Benjamin, 1996). The patient with borderline personality disorder may perceive others as simultaneously rejecting, abandoning and needing dependent others (Benjamin, 1996). The patient with obsessive–compulsive personality disorder may believe that others expect perfection regardless of the individual’s own wants and needs (Benjamin, 1996). To address these maladaptive implicit personality theories, schemas and associated interaction patterns, effective psychotherapy helps patients identify dysfunctional person perceptions, develop an affective and cognitive awareness of the etiology of these beliefs and the functions they serve, and form more adaptive schemas of self in relation to others (Benjamin, 1996). Additionally, therapists’ awareness of problematic schemas and implicit personality theories early in treatment can assist in assessment and identification of interpersonal patterns that are likely to be enacted in the therapeutic relationship.

## Attitudes

Attitudes refer to evaluations made by people along a continuum from positive to negative about specific entities called attitude objects (e.g., ideas, concrete things, life events, social

groups, classes of behavior, persons) (Eagly and Chaiken, 1998). Individual attitudes consist of three elements: cognitive (beliefs about attitude objects), affective (emotions elicited by attitude objects) and behavioral (action intentions or overt behavior directed toward attitude objects). Additionally, individual attitudes may be associatively or logically linked to form broader inter-attitudinal structures consisting of two or more attitudes (Eagly and Chaiken, 1998). Attitudes provide a framework for rapid appraisal and evaluative interpretation of one’s world, thereby allowing one to formulate responses to the complexities and ambiguities of daily living in an economical fashion, often without the need for deliberate, conscious processing (Cooper and Aronson, 1992). Fundamentally, attitudes serve an important adaptive function by virtue of their evaluative properties involving distinctions of good stimuli presumed to enhance well-being from bad stimuli that could endanger well-being (Eagly and Chaiken, 1998).

## Attitude Theories

Attitude theory and research has a rich history as one of the great areas of inquiry within social psychology (Eagly and Chaiken, 1998; Petty and Wegener, 1998). However, this voluminous and intricate literature can be encapsulated only briefly here. Theoretical frameworks developed in the 1950s, 1960s and 1970s that laid the foundation for later social psychological inquiries into attitudes (Table 17.4).

Learning and reinforcement theories of attitude formation and change, founded on principles of behaviorism, were derived

**Table 17.4 Attitude Theories: Representative Examples**

Model	Basic Tenets
Learning and reinforcement theories	Environmental contingencies, including conditioning and association processes, determine the formation, maintenance and alteration of attitudes.
Social judgment theory	Attitudes are most likely to be influenced by information that is similar to one’s own attitudinal set, may be influenced by information about which one’s attitudes are not clearly defined, and are least likely to be influenced by information that is inconsistent with one’s attitudinal set.
Consistency theories	Attitude formation and change are organized by a need to impose structure and order on one’s understanding of the environment.
Functional theories	Individuals form and maintain attitudes that are consistent with their needs and motives.

from basic experimental psychology. Two major examples are conditioning (Staats and Staats, 1958) and associationist (stimulus–response) (Hovland *et al.*, 1953) perspectives. These approaches emphasize the influence of stimulus pairing and stimulus–response patterns in attitude formation (Eagly and Chaiken, 1998).

Social judgment theory emphasizes the interplay of cognitive and affective attitudinal components and posits that perceptions and judgments mediate attitude change (Sherif *et al.*, 1965). According to this approach, attitudes are most likely to be influenced by information that is similar to one's existing attitudinal set (i.e., latitude of acceptance), may be influenced by information about which one's attitudinal set is not clearly defined and affectively neutral (i.e., latitude of noncommitment), and least likely to be influenced by information that is inconsistent with one's attitudinal set (i.e., latitude of rejection).

Consistency theories posit that attitude formation and change are organized by a need to impose structure and order on one's understanding of the environment. Cognitive dissonance theory (Festinger, 1957) posited that discrepancies between simultaneously held attitudinal cognitions (dissonance) produced psychological tension, requiring attitudinal changes to reestablish consistency (consonance). The degree to which this dissonance causes psychological tension is a function of the personal importance of the cognitions and the number of dissonant cognitions relative to consonant cognitions.

An alternative approach that proposed to account for research findings regarding dissonance was self-perception theory (Bem, 1972). According to this perspective, individuals infer their attitudes through observing their own behavioral responses and the conditions under which they occur. From this view, attitudes are formed on the basis of self-attributions (Cooper and Aronson, 1992).

The final group of attitude theories – functional theories – hold that individuals form and maintain attitudes consistent with their needs and motives (Katz, 1960; Kelman, 1961; Smith *et al.*, 1956). For example, particular attitudes may be adopted for adjustment, instrumental, or utilitarian purposes, as they maximize rewards and minimize punishments. Attitudes also may serve a value expression function. Ego-defensive or externalizing functions of attitudes allow for maintenance of desired views of self and the world, while protecting the individual from acknowledgement of unpleasant realities. Attitudes serving a knowledge function assist people in formulating meaning about events in their world. Functional models suggest a complex interplay among different attitudinal beliefs, necessitating different change strategies based upon the function of the attitude being targeted for change (Eagly and Chaiken, 1998).

Interest in enhancing precision in the prediction of behavioral responses from attitudinal beliefs prompted efforts to develop models of the attitude–behavior relationship (Table 17.5). Two broad types of models include those focusing on attitudes toward targets of behavior and those focusing on attitudes toward behavior (Eagly and Chaiken, 1998).

### Attitudes in Health and Illness

People's attitudes affect whether or not they practice adaptive or maladaptive health behaviors. Accordingly, it has been suggested that information aimed at promoting behaviors that reduce health risk should focus on attitudinal and normative beliefs influencing the behavior in question. The goal of such

**Table 17.5 Models of Attitude–Behavior Relationships: Representative Examples**

Model	Basic Tenets
Reasoned action model	The strength of intentions to act is determined by one's attitudes toward the behavior and perceptions of the social desirability of the behavior.
Cognitive dissonance model	Individuals alter attitudes in a manner consistent with their behavior to reduce dissonance.
Self-perception model	Individuals infer their attitudes through observation of their own behaviors and the conditions under which they occur.

interventions is to bolster intentions to engage in or abstain from the target behavior.

Although not an attitude theory per se, the health belief model (Rosenstock *et al.*, 1988; Strecher *et al.*, 1997) is a well-known social psychological model explicitly formulated to understand health-related behavior practices. The health belief model posits that individuals are motivated to respond to perceived threats of illness, with threat defined in terms of perceptions regarding seriousness of and personal susceptibility to an illness. Behavioral responses to health-related threats are influenced by expectations regarding the ability to minimize such a threat, including perceived benefits and problems associated with a given response pattern. Sociocultural and demographic factors as well as personal and environmental cues regarding appropriate courses of action also are considered in the model. The model predicts that people are likely to take steps to minimize the risk of contracting a medical problem if the following conditions occur: 1) they view themselves as vulnerable to a particular health condition; 2) they deem the condition to be personally consequential; 3) they believe that a specific course of action would minimize vulnerability to the condition and that limitations associated with such actions are outweighed by the potential benefits to be accrued; and 4) they perceive themselves as capable of performing these actions (i.e., self-efficacy). Researchers have examined the utility of the health belief model in informing prevention and intervention approaches for medically ill individuals and those at risk for specific illnesses (Salovey *et al.*, 1998).

Attitudes can have an important impact on psychological outlook and functioning. Whereas individuals who evidence positive mental health possess flexible attitudes that are adaptive to the context, persons with psychological difficulties evidence rigidly held maladaptive attitudes that impair their capacity to cope effectively with life's challenges. This suggests that helping patients identify and modify maladaptive attitudes about self and others can be an important component of psychotherapeutic intervention (Cooper and Aronson, 1992).

## Interpersonal Processes

Recent multidisciplinary trends in theory and research on interpersonal phenomena have converged in scientific efforts to elucidate relationship dynamics, including their antecedents and consequences (Reis *et al.*, 2000). Underlying these efforts is the assumption that, since human behavior takes place within a relational context, a comprehensive scientific understanding of human behavior requires careful study of interpersonal relationships (Reis *et al.*, 2000). Although there have been differences of opinion regarding how to define the term relationship, there is loose agreement that a relationship involves an interaction between relational partners that affects the subsequent behavior of each partner in the interaction (Berscheid and Reis, 1998).

The study of interpersonal relationships spans a multitude of behavioral domains relevant to social psychology. Although recognition of the limits of the traditional individualistic focus of social psychological theory and research recently has prompted calls for a more systemic conceptual approach to research on interpersonal relationships, the vast majority of work to date has examined relationships between individual variables and relationship experiences (Reis *et al.*, 2000). It is important to emphasize that the nature and qualities of human social interaction are not attributable solely to evolutionary and biological influences and processes and are not directly parallel to animal behavior (Hinde, 1987). Further, while an evolutionary perspective can provide useful insights, adoption of such a viewpoint does not imply strict genetic determinism or unmodifiability of evolved behavioral patterns (Buss and Kenrick, 1998).

## Attachment

Bowlby (1982) regarded attachment between infants and caregivers as an innate relational pattern that evolved in order to ensure the survival of the infant. Attachment phenomena are common in birds and mammals, with extended dependency periods in which offspring are fed, cleaned, sheltered and protected by the parent. In many species, attachment is enhanced by imprinting (Lorenz, 1970), a learned attachment that forms at the earliest phases of development. Imprinting is most likely to occur during specific, critical periods of development. If imprinting is not achieved during those times, it is difficult to attain. Attachment facilitates survival of the offspring, and investment in parental care for offspring is theorized to involve a cost–benefit trade off; the increased likelihood that offspring will survive is weighed against potential costs of parental care.

Attachment theory has as its cornerstone a system of reciprocal interactions that facilitate psychological safety and security (i.e., attachment behavioral system) (Bowlby, 1973, 1980, 1982). According to Bowlby's theory of attachment, as a consequence of evolutionary processes, children possess emotional and behavioral systems that organize and direct them to seek proximity and to bond with their primary caretakers when they feel distressed or threatened. The nature and quality of parental response in such instances influences the child's development. Children's internal working models of the attachment figure and the self in relation to this figure (i.e., self- and object-representations and schemas of interaction patterns between self and attachment figures) influence their attachment style and the quality of their interpersonal relationships (Bretherton and Munholland, 1999).

The bulk of attachment research has been conducted with young children and their primary caretakers. This research reveals four attachment bonds types (i.e., secure, avoidant, anxious/ambivalent, disorganized/disoriented) most noted when

**Table 17.6** Types of Childhood Attachment Bonds and Behavioral Correlates

Attachment Bond	Behavioral Hallmarks
Secure	Social, freely explore the environment, respond with resilience to stress
Avoidant	Anxious with primary caretaker, angry or attention-seeking with others
Anxious/Ambivalent	Fearful, affectively unstable, excessive clinging behavior
Disorganized/Disoriented	Disorganized and contradictory behaviors, particularly upon reunion with primary caretaker

infants and their primary caretaker are reunited following a brief, experimentally controlled separation (Ainsworth *et al.*, 1978; Hesse and Main, 2000; Main, 2000) (Table 17.6).

Securely attached children are social, able to explore their environment freely, and resilient when faced with stressful situations. In contrast, avoidant children tend to be anxious with their primary caretaker(s) and angry or attention-seeking with others. Anxious/ambivalent children typically are fearful of the environment, affectively unstable, and cling inordinately to others. Finally, disorganized/disoriented children often exhibit signs of disorganization and contradictory behaviors, particularly upon reunion with their primary caretaker. Longitudinal research shows that attachment behavior patterns are stable over time, predictive of school behavior and peer interactions, and consistent with the quality of parenting received and parental attachment style (Bowlby, 1988; Sroufe, 2002; Sroufe *et al.*, 1990).

## Adult Attachment

Recently, clinicians and researchers have begun to turn their attention to attachment patterns in adults (Sperling and Berman, 1994; West and Sheldon-Keller, 1994). Similar to infant attachment patterns, adult attachment is presumed to be rooted in evolutionarily significant biological adaptation processes (Hazan and Diamond, 2000) and is characterized by a strong interest in the other, a desire to remain physically close to and spend time with the other, reliance on ongoing access to the other, dependence upon the other for support in the face of physical or emotional threats, and feelings of discomfort and distress upon separation (Feeney, 1999; Shaver and Hazan, 1993; West and Sheldon-Keller, 1994). However, unlike attachment patterns in children, the primary adult attachment objects typically are peers, adult patterns of relating are more reciprocal, and attachment figures often also are sexual partners (Feeney *et al.*, 2000). Adult attachment is influenced significantly by working models of the attachment object and self that have their origins in childhood attachment experiences with primary caretakers (Bartholomew and Horowitz, 1991). Work in adult attachment theory addresses the establishment and maintenance of primary emotional partnerships in adult life, the effects of early and current attachment experiences on the development of psychopathology, and the use of attachment theory to guide therapeutic interventions.

Among the most compelling questions in research on close relationships are those that pertain to relationship satisfaction and stability. Work in this area has been influenced (see Table 17.7) heavily by the social exchange tradition, which assumes that the exchange of rewards and costs is a key influence on relationships (Berscheid and Reis, 1998). Specifically, social exchange theory suggests that people are motivated to maximize rewards and minimize costs, with the favorability of relational outcomes being defined by the relative balance of rewards and costs for each relationship participant. Within the social exchange framework, interdependence theory (Thibaut and Kelley, 1959; Rusbult and Van Lange, 1996) has been especially useful in making predictions about relationship satisfaction and stability. This model posits that people evaluate relationship satisfaction according to expectancy standards for relationship outcomes (comparison level), and that relationship satisfaction is a function of the extent to which outcomes meet or exceed these expectancy standards. The model also posits an additional evaluative standard employed by individuals to determine whether or not to stay in a given relationship (comparison level for alternatives). This standard is relevant to predicting relationship stability, as it represents the minimal acceptable relationship outcome level for remaining in a given relationship when outcomes associated with available alternative relationships are taken into consideration. According to the model, therefore, relationship stability is related to the combined influence of relationship attractiveness and the availability of desirable alternatives external to the relationship. Relationship stability is likely to be compromised to the extent that relationship attractiveness is lower than the appeal of available relationship alternatives. In general, relationship stability is influenced by degree of commitment to the relationship, availability in the social environment of viable relationship alternatives, perceived approval for the relationship by the social networks of the respective partners, and partner perceptions of the relative equity/inequity in gains as a result of being in the relationship (Berscheid and Reis, 1998).

Sexual behavior is an important channel of expression in certain types of interpersonal relationships (e.g., romantic relationships) and its patterns of expression may symbolize underlying relational dynamics (Mason, 1991). While some social psychological perspectives have explored sexuality as it relates to romantic love, much of the extant theory and research related to sexuality has focused on mate selection (Berscheid and Reis, 1998). Evolutionary psychology, in particular, has examined mate selection in detail (Buss and Kenrick, 1998).

In humans, sexual behavior serves more than the purely biological functions of procreation and physiological release, as it is also an important means of expressing love, closeness and the need for human contact. Sexual behavior is manifested in diverse ways determined by a complex interplay among one's relationships, life situations and the broad sociocultural context. Although normative sexual behavior has received systematic empirical study, beginning with the survey research of Kinsey and colleagues (1948, 1953) and continuing to the present day (Janus and Janus, 1994), much of the emphasis of psychological research has been on sexual dysfunction and its treatment (Kaplan, 1974; Masters and Johnson, 1970).

Considerable evidence has accrued that social integration in general, and social support in particular, are related both to enhanced health and lowered risk of mortality (Berscheid and Reis, 1998; Stroebe and Stroebe, 1996). Both main effect models and

**Table 17.7** Attraction Theories: Representative Examples

Model	Basic Tenets
Cognitive-consistency theories	Attraction is influenced by the need for internally consistent beliefs.
Reinforcement theories	Attraction is influenced by patterns of reinforcement and punishment.
Exchange theories	Attraction is influenced by mutuality of rewards.
Developmental theories	Attraction occurs according to a sequence of deepening involvement from casual contact to increased degrees of intimacy.

stress-buffering models have been employed to explain observed relationships between social support and health factors (Stroebe and Stroebe, 1996). Main effect models assume that a specific factor, such as social influence, may directly affect health and well-being via its impact on health beliefs, attitudes and behavior. By contrast, stress-buffering models presume that social support confers health benefits only to the extent that an individual is experiencing stress. According to this perspective, social support may provide health benefits indirectly by serving as a resource to help the individual cope with health-related stress.

Several factors influence the likelihood of social-support provision. Among these are social-exchange processes and social norms surrounding provision of help for individuals in ill-health, as well as causal attributions made about the recipient of social support (Stroebe and Stroebe, 1996). For example, social psychological research suggests that a curvilinear relationship exists between degree of distress and likelihood of an individual receiving social support, with moderate distress eliciting the greatest degree of supportive actions by others. Further, individuals perceived by others as responsible for their plight may be less likely to receive social support than those whose ill-health is perceived by others as caused by uncontrollable circumstances. Additionally, social support may be withheld if individuals are perceived as not trying hard enough to manage their illness or are not showing sufficient improvement in response to social support provision. These patterns may have unfortunate implications for individuals with disease syndromes that cause high stress levels, are highly stigmatized, and/or are chronic or progressive, as they may find themselves socially isolated at times of high need for social contact.

As has already been mentioned, there is a vast scientific literature in support of the idea that relationships contribute both to physical and mental well-being (Berscheid and Reis, 1998; Reis *et al.*, 2000; Stroebe and Stroebe, 1996). This empirical base complements the widespread clinical regard for the treatment relationship as a primary tool of influence and therapeutic change (Mitchell, 2000). As such, social psychological theory and research on relationships can contribute substantively to current thinking about how to structure the clinician–patient relationship to maximize mental health treatment benefit (Derlega *et al.*, 1991).

## The Treatment Relationship

Derlega and colleagues (1991) have delineated specific mental health applications of social psychological research on interpersonal relationships. For instance, they suggest that principles from social exchange theory can be applied to clinical formulation of the patient–therapist relationship dynamics, including the influence of rewards and costs on decisions to initiate a therapy relationship, levels of satisfaction with and commitment to the relationship, and the overall quality of an ongoing therapeutic relationship. They also point out that application of findings from interpersonal attraction research can enhance clinical understanding of the goodness of fit and working alliance between a therapist and patient. For example, patient attraction to the therapist may be influenced by the extent to which the therapist is perceived as similar on domains that the patient considers highly significant (e.g., gender, cultural background, beliefs and values, personality style). The therapist’s experience of rapport with the patient may be similarly influenced. The attraction between therapist and patient is likely strengthened by the extent to which time is shared, as increased experience allows for greater mutual understanding, which in turn enhances the experience of interpersonal attraction and compatibility. Different types of therapeutic alliances tend differentially to influence the course and nature of the treatment. Finally, Derlega and colleagues (1991) point out that social psychological models of relationship development, such as social penetration theory, can provide some insight into the understanding of how therapeutic relationships unfold and deepen.

The benefits of social support for psychological well-being have been clearly established in the research literature (Stroebe and Stroebe, 1996). It follows, therefore, that an important objective of therapy is to assist patients in building adequate social support. Further, it is useful also to conceptualize the therapeutic relationship itself as a source of social support for the patient. Among the therapist activities that can be regarded as aspects of social support are the communication of positive feelings toward the patient, attending to patient feelings and beliefs, encouraging patient expression and providing help with solving problems and completing tasks (Derlega *et al.*, 1991).

Attachment theory and the associated empirical findings have useful clinical implications for assessing and treating dysfunctional parent–child, peer, dyadic romantic and family relationships, and for understanding therapist–patient relationships (Doane and Diamond, 1994; Sperling and Berman, 1994). Attachment theory also provides a meaningful framework for conceptualizing various psychiatric disorders in individuals and families (Doane and Diamond, 1994; Sperling and Berman, 1994). In an attachment theory based approach to psychotherapy, the therapist provides new and more adaptive models of relating such that individuals may move from insecure and/or anxious attachments to the development and maintenance of secure attachments (West and Sheldon-Keller, 1994). This process is facilitated by the therapist’s provision of a secure base, examination of relationships and expectations of significant people in the patient’s life, exploration of the therapist–patient relationship, reflection on links between parental expectations and the patient’s working models of relationships, and development of an understanding of the appropriateness of these working models for guiding current and future relationships (Bowlby, 1988).

## The Egoism–Altruism Debate

Historically, the Western perspective has been that human beings tend to be motivated by self-interest (egoism). It is therefore not surprising that investigators concerned with prosocial behavior have debated the veracity of the concept of altruistically motivated prosocial acts in which others are benefited with no apparent short-term or long-term benefits for the helper. A model proposed by Batson (1987, 1998) is intended to account for altruism without invoking self-serving motives by establishing empathy as a key factor that drives altruistic behavior. According to this empathy–altruism hypothesis, empathy provides a vehicle for adopting the perspective of the other in need that then motivates the helper to act with the goal of benefiting the other. Because empathic emotion is distinguished from that of a distress response, it is argued that helpful acts resulting from empathic determinants are carried out with the intention of enhancing the welfare of the other rather than the self. Three types of self-serving motives have been proposed to challenge the empathy–altruism hypothesis, including the prospect of self and social rewards for providing help, avoidance of self or social punishment for failing to help, and reduction of aversive arousal associated with feelings of empathy. In reviewing existing research, Batson (1998) concluded that none of these self-serving motives could adequately account for the relationship between empathy and helping behavior, and that, on balance, empirical findings generally support the empathy–altruism hypothesis that there are instances of altruism that can be distinguished from helping behavior involving self-serving motives. Batson (1998) further proposed a general model involving four categories of prosocial motivation, each of which is linked to specific values. These include egoism (valuing self-enhancement), altruism (valuing other-enhancement at the level of the individual), collectivism (valuing other-enhancement at the level of the social group), and principlism (valuing maintaining faithfulness to specific moral ideals). Although ideally these four categories of prosocial motivation operate in cooperative and complementary ways, they also may at times come into conflict. In investigations of helping behavior, factors that influence whether or not an individual will engage in helping others, focus on characteristics of the helper, the person who is in need of help, and the situation (Batson 1998) (Table 17.8).

The high value placed on aiding those in ill-health is ubiquitous in human life, exemplified at the cultural level by health care professions and health care institutions entrusted to care for those in need of medical intervention. Although multiple factors

**Table 17.8 Factors Influencing Helping Behavior**

Mood of the helper
Empathy for the needs of the one in need of help
View of the one in need of help as similar to oneself
Perception of the one in need of help as attractive and likeable
Attribution processes
Diffusion of responsibility
Ambiguity regarding whether or not the situation is one in which help is needed
Concerns that one might do more harm than good
Evaluation apprehension

contribute to the existence of health care institutions and personal decisions to work in health-related fields, prosocial motivations are key among them. At the level of the individual, the family and peer group, caring and empathy may propel the desire to help those who are ill by providing emotional and instrumental support. As myriad empirical investigations have shown, these prosocial acts of social support provide beneficial health effects for individuals who receive them (Stroebe and Stroebe, 1996).

Empathy engenders a sense of interest in and care for others (Batson, 1998). The capacity for empathy is an important part of healthy social relationships in that it enhances understanding of others and thereby facilitates social connection and the supportive dimensions of relationships. As such, clinical assessment should incorporate an evaluation of empathy skills, especially in instances where clinical difficulties stem from maladaptive relational patterns. Consideration of the balance of empathic versus self-serving interpersonal stances of the patient can be useful, not only in individual psychotherapy but also in work with couples seeking help in resolving conflictual relationship patterns.

The clinical relevance of empathy extends to the clinical practitioner. Therapist empathy is crucial to the understanding of the patient and to the maintenance of the therapist's concern for and desire to enhance patient well-being. It is, therefore, hard to imagine the practice of psychotherapy without empathic investment of the therapist (Watson, 2002). Although a powerful tool of therapeutic change, accurate empathy requires that the therapist bear witness to considerable emotional pain in the process of helping the patient. In some instances, the therapist may be overwhelmed by the clinical issues of a given patient, and in response may retreat from an empathic stance by distancing from, avoiding, or becoming numb to the experience of the patient. It has been suggested that this empathic retreat is a factor in the phenomenon of clinician burnout (Batson, 1998). As such, empathic availability is an important variable for therapists to attend to in their day-to-day work with patients.

## Aggressive Behavior

Multiple definitions of aggression have been proposed by social scientists (Baron and Richardson, 1994). This reflects both the diverging views regarding the nature and determinants of aggressive behavior and the social norms that provide a context for evaluating whether or not an aggressive behavior is socially sanctioned. For this discussion, aggressive action is defined as any verbal or physical behavior or set of behaviors emitted with the intention to harm or damage someone or something. Biological, affective, social cognitive, social learning, personality and sociocultural influences on aggressive behavior are reviewed here in the table (Table 17.9).

Aggressive behavior has implications both for overall public health and individual health. For instance, aggression as it relates to interpersonal violence has obvious public health implications. One clear example of this is family violence, which threatens the physical health and lives of those toward whom this behavior is directed. At the individual level, anger and hostility, which play some role in aggression (though are distinct from aggressive behavior), have been associated with specific health effects. The most well-known example is research showing increased risk of subsequent coronary heart disease in individuals with high levels of anger and hostility (Salovey *et al.*, 1998; Contrada *et al.*, 1999). Hypothesized mechanisms for these health effects include psychophysiological processes (e.g., blood

**Table 17.9** Factors that Influence Aggression

Factor	Behavioral Correlates
Biological	Instinctual processes and/or specific physiological systems influence aggressive behavior.
Affective	Aggression is a response to frustration or general negative affect states.
Social cognitive	Aggression is influenced by social cognition processes (e.g., attributions, attitudes).
Social learning	Aggression is influenced by one's history of reinforcement and modeling of aggressive behavior.
Personality	Aggression is influenced by dispositional factors in the actor.
Sociocultural	Aggression is influenced by social norms, laws, and customs.

pressure, stress hormone secretion, heart rate), health-compromising lifestyle patterns (e.g., poor self-care, cigarette smoking, limited exercise), and reactions to illness (e.g., compromises in adherence to medical treatment).

Multiple clinical techniques have been developed for helping individuals effectively modulate and manage aggression. These include exploring interpersonal patterns in which aggression arises, teaching cognitive restructuring techniques to address attribution processes (e.g., hostile attribution bias) that make aggressive behavior more likely to occur, employing family therapy approaches (e.g., functional family therapy; Alexander *et al.*, 1990) and parent management training, and utilizing cognitive-behavioral therapy techniques (e.g., problem-solving skills training, social skills training and aggression-related reinforcement contingencies). These techniques may be used individually or in combination, depending upon the clinical indications derived from a multidimensional assessment of factors contributing to aggressive behavior. Where indicated, addressing the role of psychoactive substance use in aggressive behavior is also important, given research suggesting that use of substances such as alcohol can be an antecedent to aggression (Baron and Richardson, 1994).

## Behavior in Groups

An individual's social world is comprised largely of group affiliations (Levine and Moreland, 1998). A group is a social unit in which members interact and are interdependent, such that there is mutual influence among the members. Groups vary across such dimensions as size, duration, purpose, tasks, goals, and patterns and rules of communication. Involvement in familial, work, social

and/or activity groups provides several potential benefits, including the satisfaction of survival, psychological, informational and identity needs. In some instances, however, the group dynamics and organization may compromise or hinder the gratification of these needs. As such, groups can both positively and adversely influence psychological adjustment (Forsyth and Elliott, 1999; Levine and Moreland, 1992).

Research on groups has revealed specific structural dimensions (Levine and Moreland, 1998). One such dimension is the status system, which reflects the power status of each group member relative to the other members. Additionally, groups are characterized by group norms, consisting of rules and expectations for behavior and interaction in the group. Individual group members typically adopt specific roles in the group *vis-à-vis* other group members and the group as a whole. Further, groups vary in their degree of cohesion, which refers to the extent to which group members experience a sense of connectedness to the group. Each of these structural dimensions affect the group culture, which can be broadly conceptualized as the group’s shared knowledge systems and customs.

The study of group influence on behavior has elucidated several dynamics of group influence (Table 17.10).

### Group Decision-making

An important function of many groups is that of decision-making (Levine and Moreland, 1998). It has been suggested that groups often are more effective than individuals in making decisions or solving problems, particularly when the collective and cooperative efforts of the individuals in the group are needed to accomplish the various components of the task at hand. In general, however, research suggests that the nature of a given task makes a difference in whether a group shows greater decision-making effectiveness than an individual. Successful group performance is aided

**Table 17.10 Group Influence Factors**

Factor	Description
Social facilitation	The presence of others enhances performance on simple or familiar tasks.
Social inhibition	The presence of others inhibits performance on complex or novel tasks.
Social loafing	The presence of others leads to lowered work effort when individual efforts are perceived to be anonymous and not subject to social evaluation.
Identity functions	Social identity may in part be defined by group affiliations.
Conformity	Uniformity of group opinion and/or behavior resulting from group pressure.
Minority influence	The influence of a minority faction in a group on the majority viewpoints.

**Table 17.11 Problematic Group Decision-Making Processes**

Group polarization	The tendency for groups to arrive at more extreme positions (i.e., more risky or conservative decisions) than would individual group members alone
Groupthink	A phenomenon in which cohesive groups make faulty decisions because intragroup dissent is discouraged.

by a cooperative, rather than competitive, group atmosphere in which members work together to attain goals that benefit the group as a whole. Group conflict may arise when there is disagreement about decisions, tasks, roles and objectives of a group, prompting the emergence of specific group processes to address group differences (e.g., negotiation, coalition formation) (Levine and Moreland, 1998). Groups are susceptible to specific social processes that may exert a potentially deleterious influence on the process of making thoughtful and productive decisions (Table 17.11).

### The Familial Group

The family is one of the most powerful and important group structures in our society (for a review of family theory, see Kaslow *et al.*, 1999), and there are many similarities between the functioning of familial and nonfamilial groups (McGrath, 1984). Further, one’s roles and functions in social groups are influenced by one’s roles and functions in one’s family of origin (i.e., parents, grandparents, extended family, siblings) and family of creation (i.e., partner, children, grandchildren).

General systems theory (von Bertalanffy, 1968), which provides the theoretical underpinnings of family systems theory, is also applicable to nonfamilial groups. According to systems theory, a system is a group of interacting elements. Family systems attempt to find a balance between change and homeostasis to facilitate adaptation of the family and its individual members across the life-cycle. Family systems exchange information via feedback loops, circular response patterns in which there is a return flow of information within the system. Interactions reflect circular causality, in which single events are viewed as both cause and effect. Families may be characterized in terms of their structure (i.e., organization) and function. The key structural property is wholeness (i.e., the whole is greater than the sum of its parts). Family units consist of interdependent subsystems that carry out distinctive functions to maintain themselves and sustain the system as a whole. Boundaries separate these subsystems and protect their integrity, while allowing interaction between subsystems. To maintain their structure, family systems have rules that enable them to function productively. Within each unit, individuals play a number of roles, exhibiting a predictable set of behaviors that may be influenced by family of origin, gender and generation within the nuclear family. All family behavior (e.g., roles, communication patterns, symptoms) is presumed to serve a systemic function.

Collaboration among medical providers is central to effective patient care. As medical providers routinely make important

decisions in the context of work groups, it is important for health providers to be cognizant of the dynamics of group behavior. Where decisions are being made about such matters as delicate health procedures that have life and death ramifications, efforts should be made to foster a group environment that minimizes the likelihood of faulty group decision-making stemming from group polarization or groupthink phenomena. This process will increase the chances that an integrated biopsychosocial strategy will be adopted and maintained.

Cognizance of group process also is important in family medicine, where major patient-care decisions often are best managed by involving patients, their families and health care providers in a collaborative process (McDaniel *et al.*, 1992). Given the systemic phenomena that typify family functioning as described above, the family context within which illness progression unfolds is a key component in developing and implementing effective treatment strategies as well as maximizing treatment adherence. Further, families can provide significant social support resources for patients living with illness-related challenges.

Groups can serve an important social support function for individuals with severe illnesses. One example is the peer-led support group. Such groups include members who share common concerns, and tend to be characterized by group autonomy, self-governance, freedom of expression, equal distributions of power and mutual helping, including problem-solving and support (Forsyth and Elliott, 1999). Clinician-led group psychotherapy also has been shown to benefit patients with diseases such as cancer, both in terms of emotional adjustment and health effects (Spiegel and Kimerling, 2001; Spira, 1997).

Given the profound influence of group involvement on one's sense of self and interpersonal relationships, it is reasonable to assume that membership in family groups, groups at work or school, or community-based groups are associated with the quality of one's mental health functioning (Forsyth and Elliott, 1999; Levine and Moreland, 1992). Group involvement often is sought as a means of gaining help in managing personal and social problems. In clinical mental health practice settings, various forms of both group therapy (Yalom, 1995) and family therapy (Gurman and Kniskern, 1981, 1991) have been employed routinely to treat psychiatric disorders.

Psychotherapy groups are organized for the specific purpose of dealing with intrapsychic, behavioral and interpersonal difficulties encountered in daily living. For illustrative purposes, a brief review of the interpersonal or transactional approach to group psychotherapy will be presented, as social psychological principles can be applied easily to understanding the nature and efficacy of this commonly used approach. Yalom (1995), who has contributed substantively to the understanding and implementation of psychotherapy groups, posits that groups provide an interpersonal context within which the members manifest their maladaptive interpersonal patterns, receive feedback about these patterns, and gain opportunities to learn new and more authentic modes of relating to others. In this regard, groups function as social microcosms reflecting each participant's social universe. According to Yalom, there are a number of therapeutic factors that facilitate change in group therapy. These include the instillation of hope, universality, imparting of information, altruism, corrective recapitulation of the primary family group, development of socializing techniques, imitative behavior, interpersonal learning, group cohesiveness, catharsis and existential factors. Forsyth (1991) has evaluated these change factors from a social psychological perspective, suggesting that social comparison,

social learning, self-insight, social influence and social provisions processes are all relevant to the understanding of change processes in therapeutic groups.

Many social psychological concepts regarding small group behavior may have particular applicability to group psychotherapy. For example, it is essential for the therapist to facilitate establishment of group norms that maximize the likelihood that the therapeutic factors associated with change will exert full influence. Such norms may pertain to group procedure (e.g., attendance, participation and communication rules, length, frequency and duration of sessions), communication of support and empathy, values (e.g., self-disclosure, honesty, acceptance) and goals (e.g., improved psychological adjustment, enhanced relationship satisfaction). Additionally, group cohesiveness is a key component to a successful therapeutic group in that group cohesion is associated with acceptance and support among group members, along with the formation of authentic intragroup relationships. Further, high levels of group cohesion are associated with more stable group functioning (Yalom, 1995).

The therapist's awareness of some potential pitfalls of group decision-making processes also is essential (i.e., group polarization, groupthink). For instance, the group polarization phenomenon (e.g., risky shift) may be addressed effectively by the presence of a cotherapy team rather than a single therapist, as the two therapists may assist group members in arriving at more moderate positions (Yalom, 1995). Careful attention to minimizing the conditions under which groupthink may occur also is important in order to sidestep potentially catastrophic group decisions. In this regard, it is crucial that group leaders monitor their own inclinations to dominate group processes and suppress intragroup dissent.

## Culture and Social Psychology

Social psychologists increasingly have appreciated the influence of culture on psychological functioning (Fiske *et al.*, 1998; Kim and Berry, 1993; Moghaddam *et al.*, 1993; Matsumoto, 2001). Consistent with this trend, Fiske and colleagues (1998) have proposed a mutual constitution of psychological and cultural life. Specifically, these investigators suggest that culture influences psychological functioning which in turn can change cultural expressions. They further argue that although the human tendency to form cultures sprang from evolutionary processes, culture, in turn, has exerted an influence on the subsequent course of evolution.

Myriad definitions of culture have been proposed by social scientists across a range of disciplines. Culture can be defined as a collective organization of behaviors, ideas, attitudes, values, beliefs and customs shared by a group of people, and socially transmitted across generations through language and/or other modes of communication. As this definition suggests, cultural processes are of core importance to individual psychological functioning, as they influence the cognitive, affective and behavioral aspects of a range of personal and social activities. Factors that influence the manner in which cultural patterns are manifested in interpersonal relationships include gender, ethnicity, race, socioeconomic status, educational background, neighborhood and geographic region of residence, country of origin, transmigration patterns, religious and political affiliations, and stage in the life-cycle.

Social psychological researchers have emphasized the importance of distinguishing culture-specific from universal

**Table 17.12 Social Psychological Factors Influenced by Culture**

Internal Processes	Interpersonal Processes
Self	Relationships
Person perception	Aggression
Social cognition	Group behavior

psychological findings (Triandis, 1997). This is illustrated by the conceptual distinction between **emics** (findings that differ across cultures and suggest culture-specific psychological principles) and **etics** (findings that apply across cultures and suggest universal psychological principles) (Matsumoto, 1994). Given cultural influences on psychological phenomena, a cross-cultural approach is presumed to be essential for the articulation of universal principles (Moghaddam *et al.*, 1993). Theorists and researchers who take a cultural perspective have argued persuasively that many findings from social psychological research in the USA reflect specific cultural dynamics and are not necessarily universally applicable (Moghaddam *et al.*, 1993; Triandis, 1997). Culture influences the understanding of self, social cognition, relationships and group behavior (Table 17.12).

Culture affects definitions and causal explanations of health and illness, as well as the nature and quality of help-seeking behavior (Kazarian and Evans, 2001; MacLachlan, 1997). Given that one's ethnomedical system influences one's involvement in the health care system as either patient or health professional, it is essential to inquire about the patient's "explanatory models" of health and illness and to be cognizant of the match between the doctor's and patient's world view *vis-à-vis* illness and its treatment (Kleinman, 1988). Further, it behoves health providers and patients to acknowledge that medicine as practiced in hospitals forms a subculture consisting of specific values, beliefs, and practices (i.e., the culture of medicine). In this regard, interactions between patients and health care providers can be viewed as cross-cultural communications, with all participants working to comprehend one another's world views.

Recent work emphasizing the understanding of psychological functioning from a cultural perspective has led mental health practitioners to recognize culture as central to the conceptualization, assessment, and treatment of clinically significant emotional and behavioral problems (Gopaul-McNicol and Armour-Thomas, 2002; Kleinman, 1988; Tseng 2001; Tseng and Streltzer, 2001). A cultural perspective has important implications for defining and conceptualizing normal and abnormal behavior, with some arguing that dichotomizing behavior as either normal or abnormal reflects historically Western scientific cultural constructions (Foulks, 1991). A cultural perspective is also important for developing and implementing culturally sensitive interventions. There is considerable evidence to suggest that culture influences many of the psychological and social variables typically associated with psychological development, including child-rearing practices and customs, constellation and structure of family life, communication and emotional expression, social support networks, frequency and quality of life stress, the ways in which difficulties are defined and managed, and values regarding help-seeking behavior for emotional distress (Foulks, 1991). As cultural differences across these domains vary, manifestations of psychological and personality dysfunction also will differ (Foulks, 1991). This particularly is

applicable to disorders that are thought to derive more from social and environmental influences than from biological factors.

Implicit in Western models of psychiatric nosology are a number of culture-bound assumptions regarding mental health and psychiatric disorder. Examples of North American culture-bound biases articulated by Lewis-Fernandez and Kleinman (1994) include: 1) an emphasis on individuality and autonomy (egocentric view of self) as opposed to a more interdependent emphasis (sociocentric view of self); 2) a view that psychopathological conditions have either an organic or a psychological etiology but not both simultaneously (mind-body dualism versus a more integrated somatopsychological view); and 3) an assumption that cultural effects on psychological functioning are epiphenomena underneath which can be found a universally knowable biological reality. The tendency to organize one's understanding of behavior according to these biases must be monitored carefully in work with patients. Further, clinicians and researchers need to contextualize behavior and experience, and use relevant cultural norms to understand behavioral difficulties and their adaptive value (Lewis-Fernandez and Kleinman, 1994).

The importance of cultural considerations in psychiatric diagnosis has increasingly been recognized (Mezzich *et al.*, 1996). Cross-cultural social scientists have investigated psychiatric epidemiology in different cultures, with particular attention to schizophrenia spectrum disorders and mood disorders. This work primarily has been conducted using an etic approach. Although there is considerable evidence that supports the universality of schizophrenia, cross-cultural differences in symptom expression and course have been reported (Kulhara and Chakrabarti, 2001). An additional area of work that approaches diagnostic classification from an emic perspective is that of culture-bound syndromes or folk diagnostic categories, defined as "... certain recurrent, locality-specific patterns of aberrant behavior and experience that appear to fall outside conventional Western psychiatric diagnostic categories" (Simons and Hugnes, 1993, p. 75). These disorders reflect symptom patterns that are linked to the cultural context within which they are embedded. Examples of culture-bound syndromes in Western societies include anorexia nervosa and the type A behavior pattern (Simons and Hugnes, 1993).

In addition to influencing assessment and diagnosis, cultural variables should be taken into account in psychotherapeutic endeavors. In this regard, cultural considerations are important in understanding the conditions under which mental health treatment may be sought, the type of approaches that would be most effective, the clinical stance of the therapist within the treatment setting, and the nature of the therapeutic relationship. Effective psychotherapy requires sensitivity to differences that may affect the therapist's and the patient's perspective on the problem, treatment method, and therapeutic process and objectives. Thus, it is important for therapists to be cognizant of the patient's culturally defined values and belief systems, definitions of normality and psychopathology, problem-solving styles, communication patterns, interpersonal customs and family role behaviors. This cultural perspective is essential when working with adults (Tseng and Streltzer, 2001), children (Canino and Spurlock, 1994; Vargas and Koss-Chioino, 1992) and families (McGoldrick *et al.*, 1996).

## Conclusion

Several basic assumptions, articulated cogently by Leary and Maddux (1987), guide the work of mental health professionals whose clinical activities incorporate a social psychological

perspective. First, emotional and behavioral dysfunction is understood within the interpersonal and sociocultural context within which it is embedded. Secondly, the social milieu and its associated norms and values contribute to definitions of normality and abnormality. Thirdly, clinical conceptualization, diagnosis and assessment involve the clinician's attribution and attitudinal processes, and those person perception operations that contribute to impression formation and maintenance. Fourthly, psychotherapeutic interventions with individuals, couples, families, or groups are conceptualized as quintessentially social relationships that have as major objectives the enhancement of both individual identity and healthy interpersonal relatedness, which are inextricably interwoven processes.

In a discussion of the place of social psychology in the "Decade of the Brain" (the 1990s), Cacioppo and Berntson (1992) proposed a multilevel analysis for understanding psychological phenomena, integrating various biopsychosocial variables and the interactions among them. In this regard, they maintained that "the level of organization of psychological phenomena can vary from the molecular, to the cellular, to the tissue, to the organ, to the system, to the organism, to the physical environment, to the sociocultural context" (Cacioppo and Berntson, 1992, p. 1020). This so-called social neuroscience approach assumes that the integration of neural and social standpoints on social psychological phenomena can lead to a more comprehensive set of psychological principles based on multiple levels of analysis (Cacioppo *et al.*, 1996; Ito and Cacioppo, 2001). The focus of this chapter has been to highlight the social, interpersonal and sociocultural tiers of this multilevel approach to understanding psychological functioning.

Psychoanalysis is a clinical therapy originally developed by Sigmund Freud (1856–1939) for the treatment of neuroses. The term refers as well to a theory of psychopathology underlying the therapeutic practice; a general theory of the mind based on the understanding arising from the clinical procedure and other sources, and a mode of research into mental life that is inherent in, and inextricably intertwined with, the therapeutic process. Although the contemporary practice of psychoanalysis derives historically from Freud's original contributions, it has evolved like any other discipline. Beginning with Freud and the inception of psychoanalysis, the section traces the important trends in the maturation of analytic theory and its current state of development.

## Development and Major Concepts

### Freud's Contributions

#### Dreams

Freud's study (1900, 1901) of dreams during his self-analysis and in his work with patients resulted in an elaborate understanding of the workings of the mind. The analysis of dreams continues to hold a prominent position in psychoanalytic practice. Dreams give expression to unconscious wishes in disguised form and generally represent their fulfillment or gratification. Analysis of dreams can provide conscious access to unconscious drives, wishes, fantasies and associated repressed infantile memories, providing what Freud called the "royal road to the unconscious".

The dream that is remembered on awakening is referred to as the **manifest dream**. Its component elements include sensory stimuli occurring during sleep, the **day residue** and the **latent dream content**. The day residue consists of experiences of events of the preceding day or days, often associated in the mind with unconscious wishes. The latent dream content is the set of unconscious infantile urges, wishes, and fantasies that seek gratification during the dreaming state of blocked motor discharge and regression.

Freud hypothesized a **dream censor** whose function is to keep the unconscious latent content from conscious awareness, thereby preventing the emergence of anxiety and awakening from sleep. The surreal and fantastic quality of the remembered manifest dream is a reflection of the influence of **dream work** and **primary process** unconscious mentation (Table 18.1): depiction of immediate gratifications, absence of the rules of logic of conscious thought, merging of past and present, absence of negatives, loss of distinction between opposites and representation of a whole by a part. The activity of the dream work involves a set of mental mechanisms designed to disguise and distort the latent content in keeping with the function of the dream censor.

**Table 18.1 Primary Process Thinking**

Does not follow rules of logic  
Spatial and temporal relationships are not preserved  
Thoughts and actions are equivalent  
"Dream language"

In psychoanalytic treatment, the analysis of dreams attempts to take this process backward, starting with the patient's narration of the dream and then observing the patient's associations to the manifest elements, with the goal of obtaining insight into the dreamer's unconscious wishes, memories and infantile fantasies, and processes of defense.

#### Childhood Sexuality

In his analyses of adult patients and observations of children, Freud (1905) became convinced of the influence of early sexual fantasies on the formation of neurotic symptoms and of the universality of sexual wishes throughout life including early childhood. The term **sexuality** is used in this context to refer not exclusively to adult genital sexuality but to a variety of body stimulations that are pleasurable and sensually gratifying. He postulated a developmental sequence of body zones that become primary foci of erotic sensations and mental organization (Table 18.2): oral, anal (including perianal and urethral) and genital (phallic). During development, there is a more or less orderly progression from one zone to the next, with pleasure being derived from sucking, biting, tasting, touching, looking, smelling, filling, emptying, penetrating and being penetrated. In the neuroses, the repressed component instincts become an unconscious source of symptom formation.

**Fixation** (Table 18.3) at a particular phase of development may occur if there is insufficient mastery of issues pertinent to that phase. Fixations result in continued manifestations of phase specific issues in a person's behavior, influencing later personality adjustment (e.g., the anal organization of the obsessional character). **Regression** (Table 18.3), a return to a less mature level

**Table 18.2 Freud's Stages of Psychosexual Development**

Oral: birth to 18 mo  
Anal: 18 mo to 3 yr  
Genital: 3 to 6 yr  
Latency: 6 yr to puberty  
Adolescence: puberty

**Table 18.3 Responses to Developmental Stress**

Regression
Use of behavioral and emotional solutions from a developmental phase earlier than the present conflict
Fixation
Overreliance on behavioral and emotional solutions from the phase in which the conflict occurs

of mental organization, may occur in the context of stressors or conflict that overtaxes the adaptive capacities of an individual.

The first of the phases described by Freud is the **oral phase** (Table 18.4), which encompasses approximately the first 18 months of life. During this phase, the mouth, lips and tongue are the primary sources of sensual gratification. The activities of sucking, swallowing, mouthing and biting, as well as the experience of being held during feeding, form a cognitive template for the organization of fantasy and relatedness to others. The infant at this stage is dependent on mother for nurturance, protection and sustenance. A favorable outcome of this stage is the establishment of a capacity to feel trust and safety in a dependent

**Table 18.4 Characteristics of Developmental Phases**

Oral
Urgency of needs
Extreme dependency
No consideration of others
Low frustration tolerance
Separation anxiety
Anal
Need for control and autonomy
Orderliness, obstinacy, punctuality
Beginning dyadic relationships
Conflict over autonomy and compliance
Guilt
Genital
Oedipus complex
Emergence of genital sexuality
Concerns about self-image
Shift from dyadic to triadic relationships
Latency
Waning of Oedipus complex
Decreased emphasis on sexual gratification
Focus on same-sex relationships
Emphasis on development of autonomous ego functions
Adolescence
Recapitulates early phases
Separation from family
Important bonds with peers
Revival of sexual interest
Identity formation

relationship, a sureness that needs will be recognized and gratified, and a minimum of conflict about aggressive wishes occurring during moments of frustration. Excessive neglect or deprivation during this period may result in adult feelings of interpersonal insecurity, mistrust, envy, depression, excessive dependency, anticipation of rejection by others and proneness to moments of diffuse rage.

The **anal phase** (see Table 18.4) emerges with the development of increasing neuromuscular control of the anal and urethral sphincters and takes place from about 18 months to 3 years. Fantasy organizes around anal pleasure and anal functions such as withholding, expelling and controlling. Because of the child's increased motor skills, language development and emerging autonomy, she or he is expected to take more of an active part in self-care activities, including using the toilet. Related to toileting, power struggles may ensue around the child's soiling or withholding. Anger is felt toward those in control of this educative process, but the child also wishes to please them. The child in the anal phase experiences considerable ambivalence around expelling versus retaining (giving versus keeping), obedience and submission versus defiance and protest, and cleanliness and orderliness versus messiness. Fixation at this stage results in a personality organized around anal erotism and its associated conflicts, characterized by wishes to dominate and control people or life situations, rigidity, defiance and anger toward authority, neatness, orderliness, messiness, parsimony, frugality and obstinacy.

The **phallic** or **phallic–oedipal** or **genital phase** (see Table 18.4) occurs from the ages of 3 to about 5 or 6 years. At the onset of this period, sensual pleasure has become most highly focused around the genitals, and masturbatory sensations more closely resemble the usual sense of the word **sexual**. The child at this time has become even more autonomous and has more sophisticated motor and language skills, conceptual capabilities and elaborate fantasies. The child is better able to recognize feelings of love, hate, jealousy and fear; has a more distinct recognition of the anatomical difference between the sexes; and appreciates that the parents have an intimate sexual relationship from which the child is excluded. Thinking about relatedness to others shifts from the largely dyadic (mother–child) quality of the prephallic phases to an appreciation of relational triangles.

Freud recognized in his patients' associations that there were regularly occurring incestuous fantasies and wishes toward the parent of the opposite sex that were involved in the formation of neurotic difficulties. He termed this phenomenon the **Oedipus complex**, in reference to the story of Oedipus, who unknowingly killed his father and married his mother. In the midst of the Oedipus complex, the child wishes to possess exclusively the parent of the opposite sex and to eliminate the parent of the same sex. The jealousy and murderous rage felt toward the same-sex parent are accompanied by fears of retaliation and physical harm. Because these fantasies are associatively linked to pleasurable genital sensations, the child has specific unconscious fears of being castrated, which Freud referred to as the **castration complex**. The oedipal phase proceeds differently in boys and girls.

Successful passage through the phallic phase includes resolution of the Oedipus complex and repression of oedipal fantasies. The child internalizes the parental prohibitions and moral values and demonstrates a greater capacity to channel instinctual energies into constructive activities. Excessive conflict or traumatization during this phase may lead to a personality organized

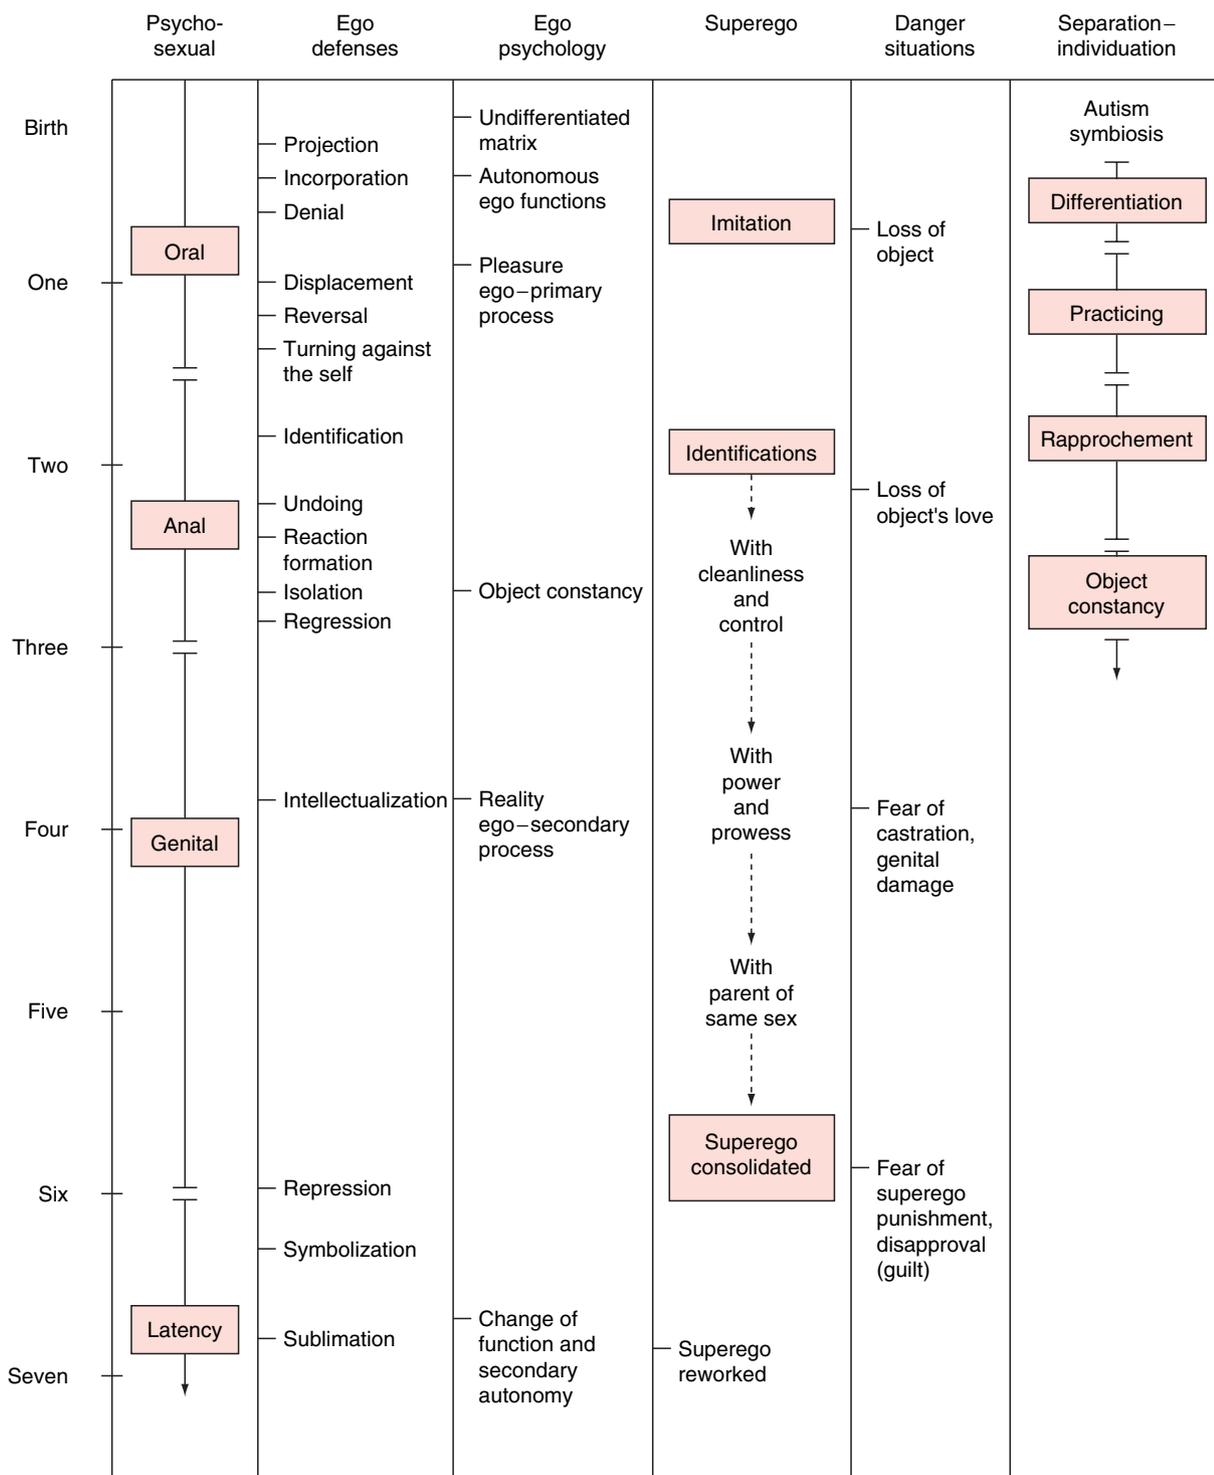

around oedipal fantasies and conflicts or a proneness defensively to regress to anal or oral organization.

During the **latency phase** (see Table 18.4), from age 6 years to puberty, play and learning take a prominent position in the child's behavioral repertory as cognitive process matures further. Although Freud believed that the sexual urges become relatively quiescent during this phase, observation indicates that they are expressed in derivative form in the

child's play. At puberty and through adolescence, genital urges once again predominate, but there is now a consolidation of sexual identity and a movement toward adult sexuality (Figure 18.1).

### Libido Theory

Freud's continued consideration of the sources and nature of the sexual drives led to his dynamic model of the mind referred to as

**Figure 18.1** Parallel lines of development. (Source: Inderbitzin LB and James ME [1994] *Psychoanalytic psychology*, in *Human Behavior: An Introduction for Medical Students*, 2nd edn. [ed. Stoudemire AJ]. JB Lippincott, Philadelphia, p. 131.)

**Table 18.5 Libido (Drive) Theory**

Assumes that biological “needs” (drives) fuel behavior  
 The aim of behavior is to gratify the drive  
 Drives are either sexual or aggressive in nature

**libido theory** (Table 18.5). This theory attempted to explain the observation that behavior and mental activity are not only triggered by external stimuli (as in the reflex arc) but also generated by primary internal processes. Freud defined instinct as “a concept on the frontier between the mental and the somatic, as the psychical representative of the stimuli originating within the organism and reaching the mind, as a measure of the demand made upon the mind for work in consequences of its connection with the body”. Regardless of the specifics of their origins, derivatives of the instincts are experienced mentally as compelling urges and a source of motivation.

Although Freud had given up the idea that sexual traumatization was always the cause of psychoneurotic symptoms, he maintained the view that the sexual instinct played an etiological role in the neuroses and that sexual stimulation exerted a predominant force on mental activity throughout life. Freud termed this force **libido**. The discharge of libido is experienced as pleasure; the welling up of libido without discharge is felt as tension or displeasure. According to the **pleasure principle**, the individual seeks pleasure (through the discharge of libidinal tension) and avoids displeasure. The primary process quality of unconscious mentation follows the pleasure principle as it maintains its focus on the gratification of wishes. As the mind develops, conscious mentation becomes more governed by the **reality principle** (Freud, 1911) involving a shift from fantasy to perception of and action on reality. The secondary process form of conscious thought follows the reality principle. Under the influence of the reality principle, gratification of wishes may be delayed with the aim of eventually achieving greater and/or safer pleasure.

The sexual instinct has four defining components: **source**, **pressure** (or **impetus**), **aim**, and **object**. **Source** refers to the biological substrate of the instinct. **Pressure** is the amount of force or “demand for work” of the instinct. The **aim** is the action designed to accomplish release of tension and satisfaction. An **object** is the target of desire, the person or thing through which gratification is accomplished. Although the libido theory has been criticized because it was based on 19th century German scientism, it has served as a useful metaphor to understand pleasure, attachments, and the dynamic processes of mental activity.

### From the Topographical to the Structural Model

According to the topographical theory, three regions or systems of the mind exist as defined by their relationship to conscious thought: the conscious, preconscious and unconscious. The **conscious** mind registers sensations from the outside world and from internal processes, and is the agency of ordinary wakeful thought. Conscious mentation follows the reality principle and uses secondary process logic. The **preconscious** includes mental contents that can gain access into consciousness by the focusing of attention. The **unconscious** is defined from three basic angles: descriptively, it consists of all mental processes and contents operating outside conscious awareness; dynamically, these

processes and contents are kept actively repressed or censored by the expenditure of mental energy to prevent the anxiety or repugnance that would accompany their conscious recognition; and as a mental system, it is a part of the mind that operates in accordance with the pleasure principle using primary process logic.

Over time, Freud encountered clinical phenomena that were not adequately accounted for by the topographical model. Freud revised his theory of mental systems to include the structural model, but the useful conception of the dynamic unconscious and the particular qualities of conscious, preconscious and unconscious mentation have been retained.

### Theory of Narcissism

In all mental functioning, it is possible to observe the balance between libido deployed toward objects and libido directed toward the self. For example, when a person is in love, much libido is attached to the loved object, even to the extent that the person feels himself or herself diminished (from decreased ego libido). During physical illness or hypochondriacal states, libido is pulled toward the ego so the person appears preoccupied with the body and uninterested in the world. According to the pleasure principle, the mind seeks to discharge libido, and if it is dammed up, symptoms will result. In neurotic persons, excess object libido has accumulated and, undischarged, produces anxiety. In psychotic persons, ego libido has been prevented from being discharged outward, so it is discharged inward, resulting in hypochondriacal anxiety and megalomania.

Internal judgmental processes and self-regard are also addressed by the theory of narcissism. In normal adults, most evidence of the operation of ego libido has been repressed. A new target of self-love has been constructed, the **ego ideal**, a forerunner of the superego concept, consisting of ideas and wishes for how one would like to be. Similarly, love objects may become the subject of idealization. Freud theorized a separate psychic agency, which he called the superego (see below), that attends to ensuring narcissistic satisfaction and measuring self-reflection, censoring and repression. Living up to the ideal, loving oneself and being loved, reflects attempts to restore a state comparable to the primary narcissism of infancy.

### Melancholia

In *Mourning and Melancholia* Freud (1917), developed a theory to explain processes of guilt, internal self-punishment and depression. To do this, he contrasted states of grief or mourning with the condition of melancholia, now called depression. Both have in common the experience of pain and sadness, and both are brought on by the experience of loss, but the person in mourning maintains her or his positive self-regard, whereas the person with melancholia feels dejected, loses interest in the world, shows a diminished capacity to love, inhibits all activities and exhibits low self-regard in the form of self-reproaches. In mourning, libido is gradually withdrawn from the object attachment; in melancholia, the ego feels depleted or comes under attack as though “one part of the ego sets itself over against the other, judges it critically, and as it were, takes it as its object”. This critical agency (again a theoretical forerunner of the superego) comes to operate independently of the ego.

The self-accusations of the person with melancholia seem to fit best with criticism that might be leveled against the lost object. In the case of suicidal impulses, the melancholic person

**Table 18.6** Structural Theory

Id
First to develop Completely unconscious Contains all drives Ruled by pleasure principle No awareness of reality
Ego
Second structure to develop Operates on reality principle Mediates conflict among id, ego, and superego Provides reality testing Monitors quality of interpersonal relations Provides synthesis and coordination Carries out primary autonomous functions Defends against anxiety
Superego
Third structure to develop Self-criticism based on moral values Self-punishment Self-praise based on ego ideal Most functions are unconscious

seems to be directing at himself or herself the sadism and murderous wishes felt toward the disappointing or lost other. Freud theorized that in the context of the loss of an ambivalently held object, the ego incorporates, or forms a narcissistic identification with, the object. Hostility originally felt toward the object is now directed at the self, giving rise to feelings of torment, suffering and self-debasement. A predisposition to melancholia may thus result from forming narcissistic object attachments and identifications.

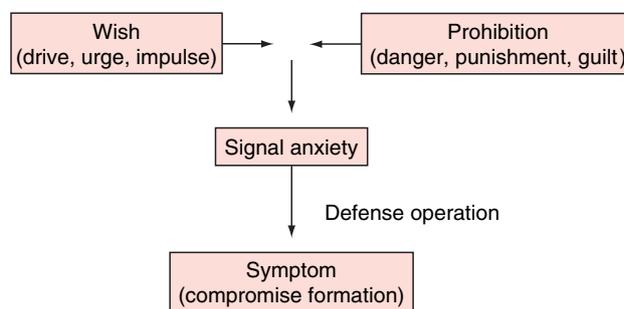

### Dual-instinct Theory

Freud had originally considered two types of instincts, the sexual and the ego (self-preservative) instincts, and considered sadism to represent a fusion of the two, with hostility occurring in the context of frustrated libidinal strivings. However, this theory did not adequately address psychological situations in which destructive tendencies seem to be operating independently of libidinal or self-preservative drives.

Freud concluded that there must be a separate instinct of aggression, whose aim is destructiveness. The aggressive drive is at work in impulses to harm, in the desire for control and power, in sadistic or masochistic behaviors, in guilt and depression, and in the persecutory fears of paranoid individuals.

### Structural Model

On the basis of the preceding considerations, Freud revised his theory of the mind into what is now known as the structural or tripartite model (Table 18.6). He conceived of three mental agencies operating in the psyche: the id, the ego and the superego. The **id** is the biological source of instinctual drives, operating unconsciously and following the pleasure principle. The activity of the

**Figure 18.2** Freud's theory of symptom formation.

id generates the motivational push for gratification of sexual and aggressive wishes.

The **ego** grows out of the id early in human development. Its functions include perception, interpretation of perceptions, voluntary movement, modulation of affects and impulses, cognition, memory, judgment and adaptation to reality. Subject to conflicting forces from the id, the superego and reality, the ego synthesizes mental compromises that provide gratification of instinctual wishes in accord with reality considerations and the moral demands of the superego.

The **superego**, which develops as an outgrowth of both the ego and id, consists of the moral standards, values and prohibitions that have been internalized throughout childhood and adolescence. It is the source of internal punishment, which is felt as guilt, and of internal reward. Early in development, the superego has a harsh and archaic quality. During maturation under optimal conditions, it becomes less harsh and comes to include loving components as well. In the structural model, the ego ideal (discussed earlier) is considered a component of the superego, accounting for feelings of shame and pride.

### Anxiety and Symptom Formation

With the elaboration of the structural theory, Freud progressively viewed the nature of anxiety and the origin of symptoms (Figure 18.2) differently. According to his original theory, anxiety resulted from the accumulation of undischarged sexual tensions caused by inadequate sexual activity in the actual neuroses or by inhibitions due to repression in the psychoneuroses. Later, it became clear that anxiety was more closely related to fear occurring in response to perceived dangers, either external or internal. This led to a focus on the ego, one of whose functions is to anticipate and negotiate danger situations. A dangerous or traumatic situation is one in which excessive stimulation threatens to overwhelm the ego's capacity for delay and compromise.

The ego has as one of its tasks the continual formation of **compromises** among id wishes, the prohibitions and moral standards of the superego, and the dictates of reality. If these

**Table 18.7** Typical Situations of Danger

Fear of instincts (traumatic overstimulation)
Fear of object loss
Fear of loss of love
Fear of castration (body injury)
Fear of guilt (moral anxiety)

**Table 18.8** Characteristic Defenses of Paranoid–Schizoid Position

Projection  
Introjection  
Projective identification  
Splitting  
Idealization  
Omnipotence  
Denial

compromises are successful, anxiety will operate predominantly on a signal level and behavior will be both sufficiently gratifying and acceptable in reality. A **symptom neurosis** occurs if these compromises are felt as uncomfortable, painful, or maladaptive.

## Post-freudian Ego Psychology

### Ego, Defense and Adaptation

Anna Freud laid out a categorization of defense mechanisms (1936) (Table 18.8). In discussing the preliminary stages of defense that are first used by the ego to avoid pain from the external world, she succeeded in integrating two main themes in the development of the ego concept: defense and relations with external reality. Anna Freud advocated a shift of the analyst's attention to the ego as the proper field for observation, in order to gain a picture of its functioning in relation to the other two psychic structures, **id** and **superego**. This more detailed methodical attention to the mind's surface, which includes manifestations of unconscious ego activities, provides a much clearer view of the actual workings of the mind. Her recommendation that the analyst listen from a point equidistant from id, ego and superego emphasized the importance of observing neutrally the influence of all three psychic agencies. The ego wards off not only derivatives of instinctual drives but also **affects** that are intimately connected with the drives. She advocated that priority be given to the interpretation of the defenses against affects, as well as defenses against instinctual drives.

## Other Psychoanalytic Perspectives

### Object Relations Theory

There is no unitary theory of object relations; rather, it is a variety of theories that differ from each other in important ways and are often contradictory. For some theorists, object relations refers primarily to interpersonal relations; others emphasize that the concept refers not to external interpersonal relationships but to specific intrapsychic structures. The concept of an inner world inhabited by mental representations of the self and of objects is central to all object relations theories. This inner world is constructed by the individual through the more or less successful integration of the internalized representations of real significant external figures with whom the subject has interacted.

### Melanie Klein

Klein's (Klein, 1937, 1946) theoretical formulations grew out of her observations of the psychotic children she treated. Although some of her controversial ideas have never gained acceptance in mainstream American psychoanalytic thought, her formulations

about the importance of aggression and envy, particularly in more primitively organized patients, as well as her understanding of primitive defensive operations have been central in the thinking of later object relations theorists.

Klein believed that fantasy exists from the beginning of life and is by definition the mental expression of the instincts. She conceptualized the neonate as having an active inner world of fantasy based on its innate libidinal and aggressive drives and their aims. The death instinct is central to Klein's theories. It finds its expression in earliest infancy in aggression against the object and the self.

Klein modified Freud's theories of psychological development drastically. As mentioned, she focused predominantly on infancy, describing two psychological "positions" during the first year of life (which was for Freud the oral stage of development). These are the paranoid–schizoid position (Table 18.8) during the first 6 months of life and the depressive position during the second 6 months. The paranoid–schizoid position is characterized by the defenses of projection, introjection, projective identification, splitting, idealization, omnipotence and denial (Klein, 1946).

These defenses are termed primitive defenses because they have their origin in early development, in contrast to the higher-level defenses that evolve later. **Projection** is the defensive externalization of a threatening internal impulse, ideal, or feeling. Because this is the predominant defense of earliest infancy, the young infant believes that the dangerous impulse, idea, or feeling, which actually originated from within as a manifestation of its own intense drives, is coming from an external source. Therefore, the feared threat is perceived as external rather than internal. This results in anxiety about being attacked from without, termed paranoid anxiety.

**Introjection** takes place when an external object is taken inside (in fantasy) and becomes part of the internal rather than

**Table 18.9** Erikson's Stages of Development

Psychosexual Stage	Psychosocial Crisis	Basic Strength
Oral–sensory (infancy)	Basic trust vs. basic mistrust	Hope
Anal–muscular (early childhood)	autonomy vs. shame and doubt	Will
Genital–locomotor (play age)	Initiative vs. shame and guilt	Purpose
Latency (school age)	Industry vs. inferiority	Competence
Puberty (adolescence)	Identity vs. identity confusion	Fidelity
Genitality (young adulthood)	Intimacy vs. isolation	Love
Procreativity (adulthood)	Generativity vs. stagnation	Care
Generalization of sensual modes (old age)	Integrity vs. despair	Wisdom

Source: Modified from Erikson EH (1982) *The Life Cycle Completed*. WW Norton, New York, pp. 32–33. Copyright 1985, WW Norton.

the external world. The paranoid position is characterized by projection and introjection taking place in cycles.

**Projective identification**, as conceptualized by Klein, is a complicated primitive defense that involves the projection of an internal object (usually a bad one) into an external object, followed by identification with the external object that is now experienced by the infant as having been contaminated by the bad object.

**Splitting** is the intrapsychic separation of the object into different partial objects. Typically, an unrealistically all-good (idealized) object and an equally unrealistically all-bad object are constructed. In the course of normal development, in the presence of adequate parenting that provides the consistent availability of predominantly benign external objects, the cycle of projection and introjection gradually results in the introjection of more benign aspects of the external object (parent or other caretaker), and the bad internal object is gradually detoxified.

### Donald W. Winnicott

Donald W. Winnicott was both a practicing pediatrician and a psychoanalyst for most of his professional life. He worked with many categories of patients – including regressed adults, disturbed and delinquent adolescents, and problem children – and treated mother–infant–toddler pairs. Working with such a diverse population of patients, he experienced the deficiencies of both the libido and the structural theories. The libido theory focuses on drives and anergic concepts; the structural theory concentrates on oedipal development and, in Freud's formulation, places the “narcissistic neuroses” (i.e., the psychoses) in a separate group without a framework for treatment. Although he found the existing theories to be problematic, Winnicott attempted to fit his ideas within them. He handled his disagreements with Freud's ideas by reinterpreting them to meet his need to deal with highly disturbed early relationships. For example, he reworked the Oedipus complex to emphasize Klein's conflict between love and hate, rather than Freud's conflict between instinctual desires and fear of castration. (Winnicott acknowledged his debt to Klein, particularly with reference to the depressive position; Winnicott, 1954–55). Another way in which Winnicott reinterpreted Freudian theory was to focus on the central function of an early maternal “holding environment”. This primacy of early bonding contradicted Freud's concept of “primary narcissism”, which held that the infant is at first not oriented toward others and that relationships become important only later, secondary to drive frustration.

Every individual, according to Winnicott (1960), develops **true** and **false selves**. Insofar as the mother is empathically attuned to her child, without intruding on the child, there is a core feeling of wholeness and goodness from which the true self develops. With appropriate “mirroring”, the child learns to play, to be creative and to be alone with comfort. Those developmental achievements create the **fundamental organizer**, the true self (at times also called the **ego** by Winnicott). However, insofar as there is a mismatch in the relationship, the child's development is stunted, and the child develops a false self. In healthy people, the false self is relatively minimal. It is represented by politeness and social manners; however, in extreme states of illness, it may be the main self-representation. A lifelong feeling of unreality and futility results, with a severely unempathic mother, in Winnicott's view. One positive function of the false self is that it protects the nascent true self from a damaging environment.

Winnicott's (1951) **transitional object** is a concrete, real external object (unlike the intrapsychic objects that we have been discussing). It is the infant's first “not me” possession and is imbued psychologically with attributes of both mother and infant. The transitional object evolves out of activities occurring in the “space” between infant and mother. These activities generally have close links to the mouth or the mother's body. For example, the child may at first put a fist or thumb in the mouth or stroke the corner of a blanket. The blanket gradually becomes special and essential to the child (the familiar security blanket). A stuffed toy such as teddy bear or even a hard toy may become a transitional object. This process is based on the facilitating, appropriate response of the mother. The blanket may become smelly, yet it must not be washed; and the teddy bear may become tattered, yet it must accompany the toddler everywhere. The evolution of the transitional object is the precursor of the child's ability to play. As an intermediary object, the transitional object also serves as a precursor of the ability to be alone. There is wide variation as to when the transitional object develops, but it usually evolves from about 4 to 12 months.

### John Bowlby

Bowlby began his study of the attachment of children to their caregivers in the late 1940s. The observations clearly confirmed that early separation produced extreme distress in children and that there were significant long-term adverse effects on the children as a result of even relatively brief separations. These initial observations, combined with the fact that there was at the time no adequate theoretical framework for understanding the profound effects of separation, led Bowlby to research and formulate theories about attachment, separation reactions, related anxiety, depression and psychopathological processes originating in disturbances in attachment.

Bowlby's major thesis was that the child's tie (attachment) to the object, for which he preferred the term **attachment-figure**, is primary and instinctive (in the sense of instincts shared by humans and animals rather than in Freud's sense of instinctual drives). This attachment is **not** secondary to the gratification of any drive. It is independent of the need for food and warmth and of any other striving. He strongly opposed the theoretical position that there is **ever** an early objectless state.

Bowlby went on to extend his observations of attachment behaviors and responses to separation across various cultures, citing anthropological observations. “No form of behavior is accompanied by stronger feeling than is attachment behavior. The figures towards whom it is directed are loved and their advent is greeted with joy. So long as a child is in the unchallenged presence of a principal attachment-figure, or within easy reach, he feels secure. A threat of loss creates anxiety, and actual loss sorrow: both, moreover, are likely to arouse anger” (Bowlby, 1969, p. 209). For Bowlby, the unpleasurable affects of anxiety, grief and anger were **secondary** to the thwarting of attachment.

### Margaret Mahler

According to Mahler (1975) the newborn does not differentiate internal from external stimuli; there is only tension and satiation. By the second month, the infant begins the “normal symbiotic phase”, in which there is a relationship characterized by an “omnipotent fusion”, a “delusion of a common boundary” with “the need-satisfying object”. From the infant's perspective, mother and child are a “dual unity”. If the symbiotic period progresses

normally, the infant begins to develop “memory islands” and a “core sense of self”, which are preparatory for the “hatching” that will occur at about 5 months. In her description of this period, Mahler used the concepts of libido theory but also referred to both Rene Spitz’s observations of the first months of life\* and to Winnicott’s concept of the holding environment.

What follows these earliest months, the period from about 5 months to beyond 3 years, is termed “the psychological birth of the human infant” by Mahler. During this time, the stages of the separation–individuation process occur. Mahler formulated a series of subphases of this process. In summary, the subphases are:

1. Differentiation: 4 to 8 or 9 months. During these months, there is the “first tentative” pushing away from “completely passive lap-babyhood”. The 5- to 6-month-old infant gradually begins to creep. During this time, transitional objects develop (a term coined by Winnicott and discussed earlier in this section). The infant soon begins differentiating, with more or less anxiety, the faces of strangers from primary caretakers.
2. Practicing
  - a. Early: 7 months to about 1 year. This subphase overlaps with differentiation. Infants begin to crawl and stand. They become upset if they end up too far away, frequently paddling back to mother for “emotional refueling”.
  - b. Practicing subphase proper: about 12 to 18 months. This subphase begins with walking and ushers in a “love affair with the world”. The children are frequently elated, curious and adventurous. They are delightful to observe but must be carefully watched because they are likely to dash blithely into precarious situations. They tend to be impervious to minor falls and other mishaps.
3. Rapprochement: gradually, from about 15 to 22 months or more, the carefree behavior gives way to anxiety about separation and fear of “object loss”. The toddler is learning that “the world is **not** his oyster” (Mahler *et al.*, 1975, p. 78). The child alternates between demanding, negativistic, challenging behavior and seeking love and approval by “wooing” behavior.
4. “The child on the way to object constancy”: 24 months to 3 years and beyond.

The optimal unfolding of phases depends on the emotional availability of the mothering person. If it is disrupted in the earliest months, the result can be the development of an infantile psychosis either because of lack of maternal availability or empathy or because, for constitutional reasons, the infant is unable to respond to the mothering. Regardless of whether the cause is environmental or constitutional, if the symbiotic mother–infant relationship fails to provide safe “anchoring” or discourages hatching, the separation–individuation process cannot proceed normally. Later phases may also be disrupted, for example, by overprotective mothering, which inhibits independence, or because of precocious motor development, which may lead the infant to separate physically from the mother before psychological readiness for that degree of separation. In addition, Mahler believed that the success or failure of the rapprochement subphase lays the foundation for subsequent relatively stable mental health or borderline pathology.

## Otto Kernberg

Kernberg’s major contributions have stemmed from his work on the psychoanalysis and psychotherapeutic treatment of

patients with severe character disorders, particularly those with borderline personality organization (Kernberg, 1968), as well as patients with narcissistic character.

The primitive defenses of splitting and projective identification, first described by Klein, are central to the diagnosis of borderline personality disorder as conceived by Kernberg (1979). His depiction of the landscape of the mind also owes some of its salient features to Jacobson, who first suggested that internal representations of self and object with an associated affect are the nuclei of the early development of the psyche. Kernberg’s depiction of the inner world of borderline and psychotic patients is, however, uniquely his own. Splitting breaks up the internal representation of objects and of the self into part object representations, each with an associated affect. The central feature of projective identification, a primitive defense according to Kernberg, is that it always involves the projection of an internal object relation with its associated affect. When projection is effective, the subject eliminates the unacceptable impulse or idea from any connection with the self. In contrast, in projective identification, the connection to the unacceptable contents is preserved along with the tie between the part self and the part object. The connection cannot be totally eliminated.

Kernberg envisioned the inner world of the borderline or psychotic patient as being populated by numerous unintegrated part self–part object dyads that are each linked by a predominant affect. These internal nuclei are kept separate by the defense of splitting. The borderline individual projects these pathological inner contents onto any significant other with whom he or she interacts. Which of these self-object–affect structures is active can shift from moment to moment; this results in the chaotic and shifting pattern of relationships that is the essence of what is observed clinically in patients with borderline psychopathological disorders (who can be described as being stably unstable).

## Erik H. Erikson

Erikson divided the entire life-cycle into eight stages, thus extending into adulthood Freud’s notion of infantile psychosexual stages while at the same time broadening Anna Freud’s concept of the developmental lines of childhood. As shown in Table 18.10, Erikson (1982) linked each **psychosexual** stage to a particular body zone or zones. In each stage, the individual negotiates a phase-specific **psychosocial** developmental task toward the achievement of specific strengths. In this model, each individual evolves a mode of interpersonal and intrapsychic functioning with emergent social capacities uniquely adapted to a particular social milieu. The crises of each stage are normative, not pathological ones, and the developmental tasks are never fully resolved in each stage but continue to be worked out throughout the life span.

Far from being a simple linear model, Erikson used his hierarchical schema to explore increasingly complex interactions between earlier and later stages over time and between internal and external factors that influence development. Erikson integrated so many separate components of the individual’s development and provided tools for their investigation in research models.

Erikson’s work has had a lasting impact on our understanding of adolescence and the concept of identity. Each of the developmental stages has a psychosocial crisis. For the adolescent it is an identity crisis. Whereas the term identity crisis has come into popular use to denote troubled teenagers with pathological antisocial behavior, Erikson’s original intention, as with

**Table 18.10 Erikson's Stages of Development**

Psychosexual Stage	Psychosocial Crisis	Basic Strength
Oral–sensory (infancy)	Basic trust vs. basic mistrust	Hope
Anal–muscular (early childhood)	Autonomy vs. shame and doubt	Will
Genital–locomotor (play age)	Initiative vs. shame and guilt	Purpose
Latency (school age)	Industry vs. inferiority	Competence
Puberty (adolescence)	Identity vs. identity confusion	Fidelity
Genitality (young adulthood)	Intimacy vs. isolation	Love
Procreativity (adulthood)	Generativity vs. stagnation	Care
Generalization of sensual modes (old age)	Integrity vs. despair	Wisdom

Source: Modified Erikson EH (1982) *The Life Cycle Completed*. WW Norton, New York, pp. 32-33). Copyright 1985 WW Norton.

the crises of each of the other developmental stages, was to designate a normative phase-specific internal conflict.

It is the concept of individual development within a social matrix and the interaction between the two to which Erikson gave his stamp. He had a complex view of this interaction, describing how at each stage of development the specific caretaker within the social matrix responds to the individual's stage and needs in accordance with the caretaker's own phase-specific capacities and needs. Thus, the developing individual and his or her caretaker mutually influence each other in a manner specific to each dyad. The paradigm of this mutual interplay can be used to describe the interaction between parents and children, children

and their teachers, psychotherapists and patients, societies and their members, or any one individual and another throughout the life-cycle.

Erikson concluded that every society responds to each developmental phase with institutions specific to that culture and so determines for each individual growing up in that culture the manner and extent of resolution of every developmental phase. Through this process, a given community preserves its own ecological balance.

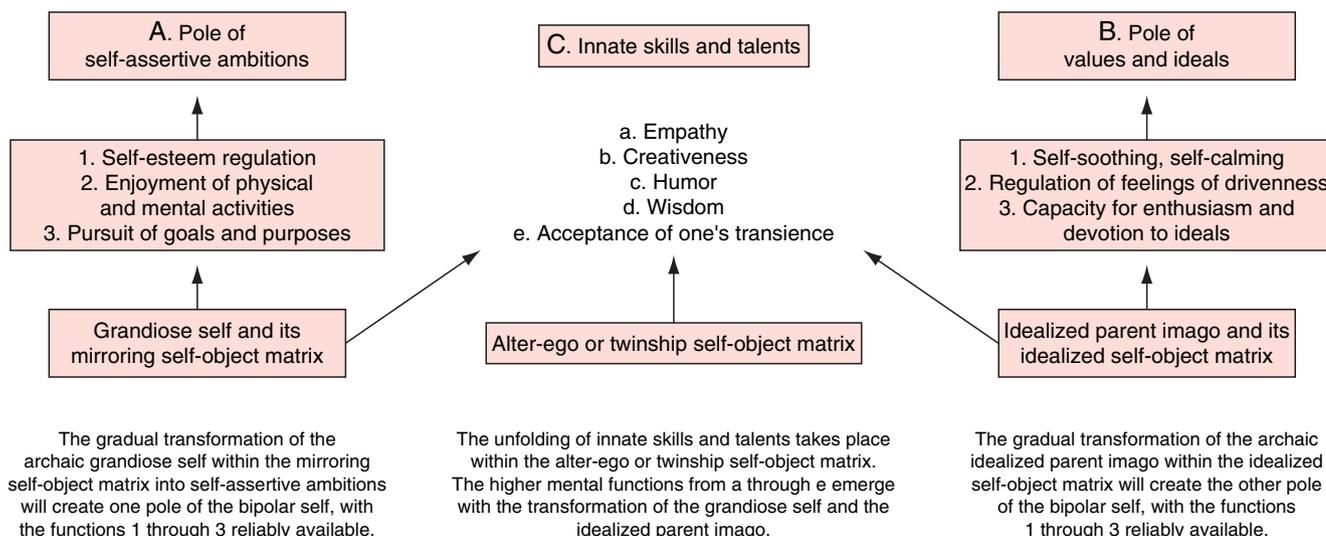

## Heinz Kohut: Self-psychology

### Conceptual Background

Freud and his followers tried to understand psychological life in terms of biology. Their ideal was scientific objectivity. They believed the analyst's human tendency to identify with the subjects of study impeded objectivity. In contrast, Kohut viewed empathic comprehension as the fundamental mode of psychoanalytic investigation. It is the knowledge of the other's experience, what it is like to be in that person's shoes. Empathy is the understanding of another's complex psychological experience as whole. Using this empathic method, Kohut attempted to create an "experience-near" psychology, explaining psychological events in terms of meanings and motives comprehensible from ordinary experience. He contrasted this to Freudian metapsychology with its postulated experience-distant forces, energies and structures.

The concept of **bipolar self** (Figure 18.3) refers to Kohut's metaphorical description of the self as having two poles, one of ideals and ambitions, the other a sense of the grandiose self. The former involves the sense of being vigorous and coherent because one is associated with what is good and powerful, for example, that an adult might have when working in accord with professional ideals. The grandiose pole of the self consists in the sense of being personally valuable and appreciated, as a child may feel by virtue of the glowing enthusiasm of parents.

Kohut's singular contribution was the idea of the **self-object**. Clinical observations led him to believe, like of object relations theorists, that the self could survive and prosper only in the context of experience with others. These experiences

**Figure 18.3** Structure and functions of the supraordinate bipolar self (normal development). (Source: Ornstein P and Kay J [1990] *Developments of psychoanalytic self-psychology: A historical-conceptual overview*. *Annu Rev Psychiatr* 9, 303–322.)

Kohut called self-objects, that is, objects (in the psychoanalytic sense of intrapsychic representation of other people) that are necessary for the well-being of the self. Kohut was speaking of intrapsychic experiences, not interpersonal relations. Intrapsychic experience may be contingent on interpersonal events. For example, the sense that one is appreciatively responded to usually requires some sort of active response from another person, but how that person's actions are experienced depends on many factors besides the actions themselves.

Kohut (1971) described two main types of self-object. **Idealized self-objects** embody what is admirable, strong and vigorous. The self feels alive and coherent by virtue of proximity to the idealized self-object. The youngster who feels like “a chip off the old block”, the student who is enlivened in the presence of a brilliant teacher, and the religious person who feels safe in God's presence have idealized self-object experiences. **Mirroring self-objects** contribute to the sense through their support of the grandiose pole of the self. Kohut described three major types of mirroring self-object:

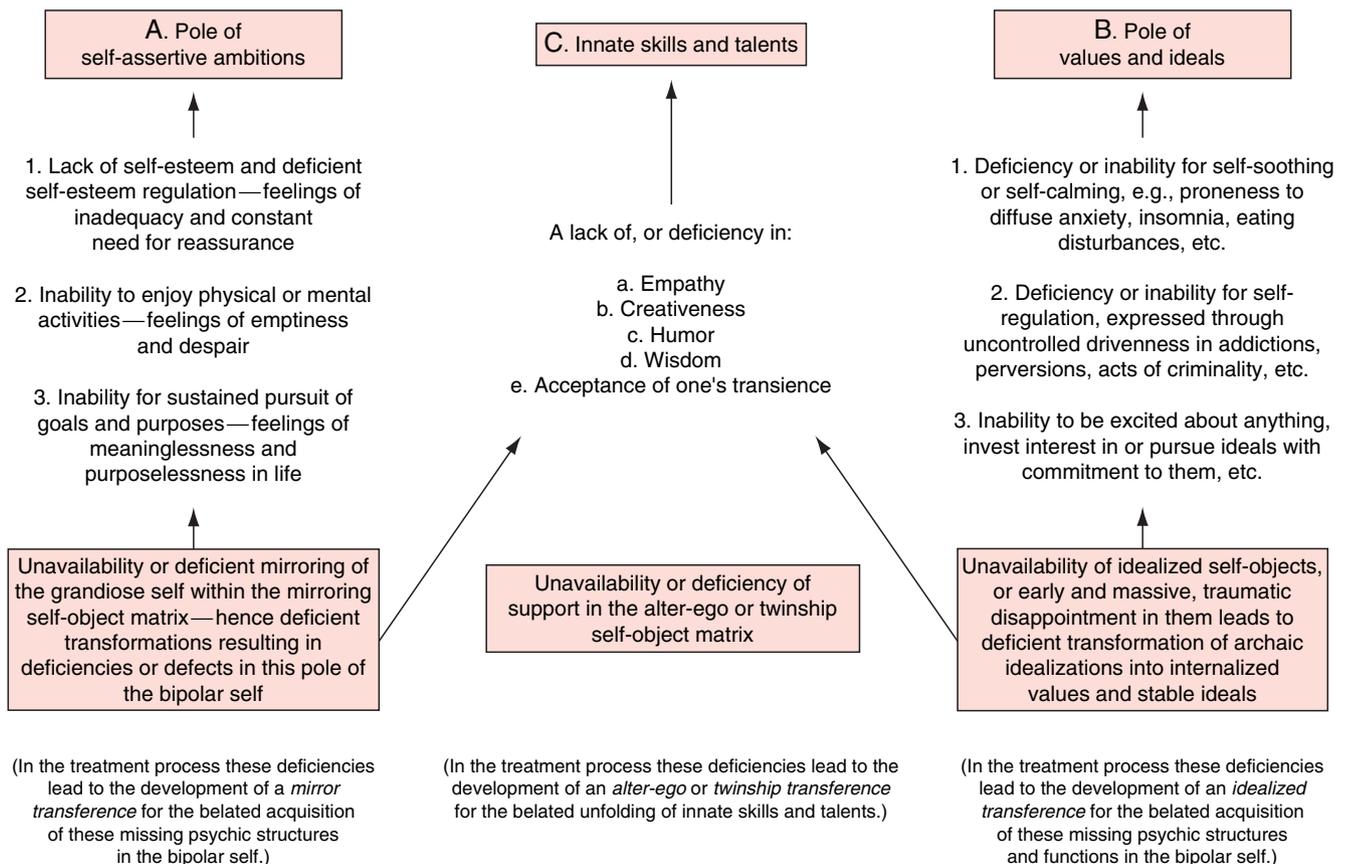

- In **merger**, the self is maintained through the sense that the person and self-object form a unity that is powerful and alive in a way the person could not be by himself or herself. The sense of merger can be found in the feeling that “we” do something. Outside the analytical situation, it is commonly seen in athletic, professional, and military activities.
- **Alter ego (or twinship) self-object** induces a sense of personal coherence by virtue of having a partner who is like oneself.

- The **mirroring self-object proper** supports the sense of personal value and coherence through its accurate, valuing appreciation of the person. The person who feels valuable and whole when a parent's or friend's eyes light up as she or he comes into a room or who feels similarly in response to authentic praise of accomplishment is experiencing such a mirroring self-object.

Self-objects remain essential throughout life. Contrary to psychoanalytic theories that characterize maturity in terms of autonomy, self-psychology views mature people as ordinarily dependent on others for appreciation, comradeship, meaning and solace. The nature of the people and institutions that embody self-objects changes with maturation. They become more numerous and more complex, often serving many psychological functions beyond their self-object function. It refers to the total experience of people and institutions that sustain and support the development of the self.

### Disorders of the Self

The study of self-psychology began with the realization that many symptoms of psychological distress could be understood as arising from disorders of the self. These include symptoms involving direct experiences of an endangered, enfeebled, or fragmented self, and symptoms arising from unsatisfactory attempts to protect an endangered self. In practice, these symptoms may appear in the same patient, but for expository purposes, separating them is useful. Sometimes the symptoms of self-pathology are acute (Figure 18.4), but more often they are chronic states

**Figure 18.4** Structure and functions of the supraordinate bipolar self (deficient or derailed development). (Source: Ornstein P and Kay J [1990] *Developments of psychoanalytic self-psychology: A historical-conceptual overview. Annu Rev Psychiatr* 9, 303–322.)

whose intensity varies as the self is felt to be more or less in danger.

Symptoms that directly express the enfeeblement or fragmentation of the self include certain depressive states, traumatic states, hypochondriasis, some forms of rage, called narcissistic rage, and direct experiences of profound disorganization.

A common response to feeling the self-endangered is rage (Kohut, 1972). Narcissistic rage is a major public health problem. The most common cause of violence and homicide is the rage engendered when people feel “disrespected”. Spousal murders most commonly result when an already demoralized person is confronted by apparently trivial inconsiderate behavior and responds with murderous rage. Communal chronic narcissistic rage may be a major factor in world history when maintaining group dignity or seeking compensation for past inequities may lead to hatred and destructiveness lasting for centuries. Narcissistic rage varies from the momentary fury to lifelong states. Like many activities in the service of the self, narcissistic rage is often rationalized. Perpetrators often describe violence as necessary to achieve a goal but closer examination usually shows that violence does little to effect its supposed aim. Physical child abuse, often a manifestation of narcissistic rage resulting from a sense of inadequacy in caring for children, is commonly rationalized as “educating” the youngster. Narcissistic rage often joins other psychological action designed to invigorate the self.

States involving the direct experience of fragmentation, in which patients cannot organize experience or recognize their coherent wishes, are overwhelmingly distressing. Any solution to this state, including the psychotic reorganization of experience, feels better. Indeed, such states are most commonly seen briefly with the onset of overt psychosis. Patients commonly describe this state as “going crazy” and may attempt desperately to hang on to some organizing principle. These states are psychiatric emergencies because many patients report that death is preferable to the continuation of the intense anxiety they experience. Many other symptoms are understandable as attempts to repair an impaired or endangered self. These include relations with others designed to achieve urgently needed self-object experiences and activities designed to soothe or stimulate the self.

When self-object functions become unavailable to such an extent that the person cannot provide for himself or herself these functions based upon personal abilities and memories already available, a psychological emergency ensues. In this circumstance, the person uses less broadly adaptive means to try to compensate for the missing but needed psychological functions. Pathological functioning is manifested either in direct expression of a distressed self or as problematic compensatory activities.

## Intersubjectivity

Intersubjectivity in psychoanalysis refers to the dynamic interplay between the analyst’s and the patient’s subjective experiences in the clinical situation. To some extent, all schools of psychoanalysis agree on the significance of intersubjectivity in psychoanalytic work. Intersubjectivity embodies the notion that the very formation of the therapeutic process is derived from an inextricably intertwined mixture of the clinical participants’ subjective reactions to one another. Knowledge of the patient’s psychology is considered contextual and idiosyncratic to the particular clinical interaction. This interaction nexus is considered the primary force of the psychoanalytic treatment process.

The intersubjective position is that mental phenomena cannot be sufficiently understood if approached as an entity

that exists within the patient’s mind, conceptually isolated from the social matrix from which it emerges. Intersubjectivists see the analyst and the patient together constructing the clinical data from the interaction of both members’ particular psychic qualities and subjective realities. The analyst’s perceptions of the patient’s psychology are always shaped by the analyst’s subjectivity. Conversely, the patient’s psychology is not conceptualized as something discoverable by the external, unbiased observer (Hoffman, 1991; Ogden 1992a, 1992b, 1994; Spezzano, 1993).

## Glossary of Psychoanalytic Terms

**Abreaction** The discharge of affect associated with a traumatic memory. Abreaction may be brought about by hypnosis or free association.

**Adaptive point of view** A metapsychological framework that considers how the developing mind is influenced by environmental realities. In this model, the ego is thought of as the “organ” of adaptation.

**Aggressive drive** One of the primary instinctual drives, aggression includes the urge to harm or destroy, the urge to dominate or prevail over others, and strivings toward mastery. The aggressive drive is a major source of intrapsychic conflict.

**Anal** Stage of psychosocial development from about 18 months to 3 years during which pleasures and conflicts center on defecation and urination and their symbolic derivatives. In addition, with increased cognitive and motor development, issues of mastery, autonomy, obedience and defiance are observed.

**Cathexis** The attachment of mental energy to a thought or memory, resulting in an increased emotional or motivational intensity associated with the thought or memory.

**Character (personality) disorder** Habitually and generally inflexible patterns of behavior that are ego-syntonic, that is, cause little subjective discomfort and are experienced as appropriate, reasonable, and justified. Such behavior may actually cause problems in adaptive functioning and interpersonal relationships.

**Compromise formation** An activity of the ego that attempts to solve conflicts between opposing forces operating in the mind, in particular the gratification of instinctual wishes that are prohibited by the superego or by reality. Compromises may take many forms including character traits, neurotic symptoms, dreams and fantasies, adaptive behavior and transference.

**Conscious** The portion of mental activity and content that is directly available to immediate perception (as opposed to unconscious or preconscious). Conscious mentation obeys rational, secondary process logic.

**Countertransference** Attitudes and feelings of the psychiatrist toward the patient. As narrowly defined, countertransference comes about as a result of activation of wishes, fantasies, or conflicts from the psychiatrist’s life. More broadly defined, countertransference also includes reactions to the patient’s projections or role enactments. Countertransference responses have the potential to have a negative impact on the therapeutic approach to the patient and also to provide data about unconscious processes occurring in patient and psychiatrist.

**Defense mechanism** Specific unconscious operations used by the ego to protect against the fantasied danger associated with conscious awareness or unconscious wishes. Examples include repression, displacement, reaction formation, projection, isolation and undoing.

**Depressive position** In Kleinian theory, a constellation of internal object relations, defenses and anxieties in which others are viewed ambivalently as containing both goodness and badness (as opposed to the split objects of the paranoid–schizoid position) and in which fear and guilt are felt around the fantasy that one’s aggressive impulses may destroy the needed and loved object.

**Developmental point of view** Metapsychological perspective that emphasizes the progressive unfolding of stages of development and focuses on the contribution of childhood experience to the psychology of the adult.

**Dynamic motivational point of view** Metapsychological perspective that considers the actions of mental forces (wishes or needs inherent in the nature of humans), which may be in opposition to one another, resulting in conflict and compromise.

**Dynamic unconscious** The content and processes of the system unconscious, which are kept outside conscious awareness by repression.

**Ego** In structural model, the mental agency that is positioned between the physiologically based instinctual urges and the outer world. Its functions include mediating between the pressures of the id, superego and reality and the variety of processes of perception, cognition, memory, motor behavior and learning.

**Ego ideal** The portion of superego functions that includes goals, ideals, and standard of thought and behavior. It is involved in the experience of self-esteem, pride and shame.

**Empathy** A mode of knowing or perceiving the emotional or psychological state of another, in which the quality of experience of one person is momentarily shared by another.

**Envy** A primitive emotion of desire, of wanting what the other has, combined with a hostile wish to destroy or spoil the source of that which is desired.

**Fixation** The persistence of modes of gratifying impulses, reacting defensively to perceived danger, and relating to objects that belong to earlier stages of psychosexual development. Points of fixation can be returned to in the process of regression.

**Free association** The basic activity in psychoanalytic treatment in which the patient reports everything that comes to mind without the usual selectiveness used in conventional discourse.

**Id** In the structural model, the collection of unconscious drives and drive derivatives that continually push for gratification.

**Insight** The conscious recognition and comprehension of previously unconscious mental content and conflicts, as occurs during psychoanalytic treatment. Insight is typically accompanied by adaptive behavioral changes.

**Instinctual drives** Innate motivational forces originating within the organism that seek discharge or gratification. In Freud’s theory, drives are characterized by their source, aim and object. The two basic instincts are the sexual and the aggressive.

**Internalization** A process by which aspects and functions of need-gratifying relationships are taken into the self and represented in its psychic structure. Types of internalization include incorporation, introjection and identification.

**Interpretation** The principle type of therapeutic intervention in psychoanalytic treatment that brings to the patient’s attention observations about his or her mental processes and their underlying motives, conflicts, compromises, wishes, needs and patterns of object relations. The expected outcome of interpretation is insight, psychic structural change and symptomatic improvement.

**Latency** Stage of psychosexual development between the approximate ages of 5 and 12 years in which the sexual drives and conflicts are less apparent and the major activities of the child are learning and other socially approved channels of gratification.

**Libido** Term originally used to refer to sexual desire but later used by Freud to describe the metapsychological concept of mental “energy” that could be deployed toward and attached to various mental representations or psychic structures.

**Metapsychology** An abstract conceptual framework used to organize, systematize, and orient clinical observations.

**Narcissism** In its original use, narcissism refers to self-love, but the term was elaborated theoretically by Freud to refer to the libidinal cathexis of the self (or ego). In modern theory, aspects of character organization, self-experience, affect regulation and object relations are discussed along the dimension of normal versus pathological narcissism.

**Neurosis** A set of psychiatric syndromes characterized by abnormalities of emotions, attitudes, behavior and thought and that have in common (in psychoanalytic theory) their origins in unconscious psychic conflict. Classic neuroses include hysteria,

obsessions, phobias and certain types of neurosis are ego-dys-tonic and are recognized by the patient as abnormal and alien to the self.

**Object** As defined by Freud, a person or thing through which instinctual needs can be gratified. The inner mental schemas or constructions that conceptualize other persons are referred to as object representations. The theory of object relations examines the relationship of the self to internal objects and the interpersonal enactments of those mental phenomena.

**Object constancy** A developmental achievement in which mental representations of love objects are experienced as constant and stable, despite their availability or unavailability.

**Oral** The stage of psychosexual development occurring in the first 18 months of life, during which the oral and perioral areas provide the major source of sensual pleasure. Because the infant is extremely dependent during this stage, optimal development requires considerable parental attunement to the needs of the infant; if this is provided satisfactorily, the infant should acquire a sense of trust and a sense that the world is safe and that the infant's needs will be met.

**Paranoid-schizoid position** In Kleinian theory, the earliest and most primitive mental organization, in which there is a predominance of the defenses of projective identification, splitting, primitive denial and idealization. During moments of frustration in this stage, there is the experience of diffuse rage and persecutory anxiety.

**Phallic-oedipal** Stage of psychosexual development for approximately 3 to 6 years of age, during which the genitals become the major source of sensual pleasure. During this stage, the child develops an intense desire to possess exclusively the parent of the opposite sex and to eliminate the other parent who is perceived as a rival. The jealous conflict of this triangular relationship, with accompanying fantasies of retaliation by castration, leads eventually to identification with the parents and the development of the superego.

**Pleasure-unpleasure principle** The tendency of the mental apparatus to seek pleasure and avoid principle unpleasure. According to Freud's libido theory, pleasure is attained through drive discharge, and unpleasure represents the build-up of undischarged mental energy.

**Preconscious** In the topographical theory, mental content and processes that are not conscious but can be readily accessed by the direction of attention.

**Primary process** Type of mentation associated with the unconscious, characterized by irrationality and a predominant emphasis on wish fulfillment and drive discharge. Primary process logic involves many of the mechanisms and qualities seen in dreams including symbolization, displacement, condensation, absence of negatives and timelessness.

**Psychic determinism** A central idea of psychoanalysis, which asserts that all psychological events are influenced and shaped by past experiences that nothing in mental life occurs solely by chance.

**Psychosexual development** The sequence of development of the instinctual drives as theorized by Freud, in which the

expression of drives centers on and is organized around specific erotogenic zones (oral, anal, genital) that shift in emphasis as the infant grows and develops.

**Regression** A shift in the organization of mental functioning to a more developmentally immature level, often occurring defensively in the context of anxiety associated with higher-level functioning but also seen in sleep and dreaming, love and sex, esthetic and religious experiences, and psychoanalytic treatment.

**Repetition compulsion** A controversial concept that descriptively refers to the tendency to repeat certain distressing or painful experiences during the course of life; also referred to as the neurosis of destiny.

**Resistance** The opposition to free association and other aspects of participation in psychoanalytic treatment, activated to prevent the emergence of unconscious wishes and their associated anxieties.

**Secondary process** Rational, logical, linear, controlled thought that characterizes conscious mentation and follows the rules of Aristotelian logic.

**Self** The total person including the body and the psychic organization; the center of subjectivity; the nuclear core of the personality.

**Self-object** In self-psychology as developed by Kohut, objects who provide an interpersonal function that optimally contributes to the maintenance of cohesive self-experience (e.g., mirroring or idealizability).

**Separation-individuation** Developmental process elaborated by Mahler in which the infant progressively emerges from the symbiotic unity with mother and forms a sense of individual selfhood and a sense of differentiation from love objects. The subphases of this process include "hatching" (differentiation), practicing, rapprochement, and "on the way to object constancy".

**Structural model** Also known as the tripartite model, Freud's later model of the mind that divides the mind into three structures: id, ego and superego.

**Superego** Mental structure that includes the functions of moral standards, ideals, prohibitions and conscience, and generates the affects of guilt and shame.

**Therapeutic alliance** The rational, conscious relationship between patient and psychiatrist based on the mutual agreement to work together cooperatively for the patient's benefit.

**Topographical model** Freud's first systematic model of the mind classifying three regions of mental functioning: conscious, preconscious and unconscious.

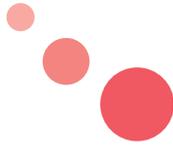

**Transference** The unconscious displacement of feelings, attitudes, and expectations from important persons of childhood onto the person of the analyst or the analytic relationship.

**Unconscious** Set of mental processes and content that operates outside conscious awareness. Unconscious mentation tends to be irrational; obeys primary process logic; and may be revealed through dreams, parapraxes, and free associations.

# Manifestations and Assessments of Psychiatric Illness

---

# Clinical Evaluation and Treatment Planning: A Multimodal Approach

Every psychiatric evaluation must be specific to the context in which it occurs. The evaluation of a patient in the psychiatric emergency room is different from the evaluation of a graduate student applying for psychoanalysis, a member of a couple who seeks consultation for marital distress, or an indicted prisoner who is being evaluated for competence to stand trial. In each case, the evaluation and treatment plan are tailored to the situation.

In this chapter, we present an outline of a comprehensive approach to psychiatric evaluation. The complete psychiatric evaluation consists of the psychiatric interview; physical examination,

including neurological assessment; laboratory testing; and, as appropriate, neuropsychological testing, structured interviews and brain imaging. The results of the evaluation are then used to assess risk, reach tentative and, if possible, definitive diagnoses, and complete initial and comprehensive treatment plans. Clearly, the length, detail and order of the evaluation need to be modified when it is conducted in different settings. The clinician needs to assess the goals of the interview, the patient's tolerance for questioning, and the time available. Table 19.1 shows the variation of the psychiatric evaluation with the type of setting.

**Table 19.1** Psychiatric Evaluation and Treatment Planning

Setting	Psychiatric Interview and Mental Status Examination (MSE)	Physical or Neurological Examination, Laboratory Assessments, Brain Imaging	Treatment Planning
Emergency room	Most often lengthy and extensive, except as limited by patient's ability or willingness to communicate.	Physical examination is often performed; other tests and examinations are ordered as indicated.	Primary focus is on disposition.
Psychiatric inpatient unit	Extensive, but complete information may be obtained in a series of interviews over time.	Physical and neurological examinations and laboratory tests are always performed. Other tests and examinations are ordered as indicated.	Comprehensive and formal plans are developed.
Consultation liaison service	Depth of interview is highly variable depending on reasons for referral and patient's medical condition. An attempt is made to obtain a complete MSE.	Most medical information is obtained from the chart. Psychiatric consultant may request further assessment.	Recommendations focus on reasons for referral and are made to the primary treatment team.
Outpatient office or clinic	Urgency of situation is assessed. In nonurgent situations, the initial interview usually focuses on the chief complaint and MSE.	Medical information is obtained as needed, usually by referral to a general practitioner or specialist.	Planning may be formal or informal, depending on applicable regulatory and reimbursement requirements.
Third-party interviews (e.g., for court, disability determinations)	Interview addresses the reason for referral and may be narrowly focused but contains a complete MSE.	Assessments are ordered according to the purpose of the interview.	Not usually relevant except for recommendations pertaining to the purpose of the interview.

## Psychiatric Interview

Despite the advent of brain imaging tests, standardized diagnostic criteria and structured rating scales, the psychiatric interview (Table 19.2) remains the cornerstone of clinical evaluation in psychiatry. Whether it is conducted in a busy psychiatric emergency room, an inpatient ward, or an outpatient office, the psychiatric interview is essential for establishing rapport with the patient, initiating the therapeutic alliance, eliciting the psychiatric history and performing the Mental Status Examination. When conducted skillfully, the interview may appear to be a relaxed and casual conversation, but it is actually an extremely precise diagnostic tool composed of specific elements: the identifying information, the chief complaint, the history of present illness, the past psychiatric history, the personal history, the family history, the medical history, the substance use history and the Mental Status Examination (MSE). The essential features of the psychiatric interview are highlighted here.

Before beginning, the psychiatrist should introduce himself or herself, explain the purpose of the interview, and try to make the patient as comfortable as possible. The interview gives the most accurate information when the psychiatrist and patient speak in a language in which they are both fluent. When this is not possible, a translator should be used, preferably one with mental health training or experience. Even then, some of the subtleties of the patient's communications are lost.

### Identifying Information

Most interviewers find it helpful to begin with a few questions designed to identify the patient in a general way. Asking the patient's name, age, address, marital status and occupation provides a quick general picture and begins the interview with emotionally neutral material. If the interviewer chooses to begin in this way, it is important to complete this section rapidly and then give the patient a chance to respond to open-ended questions. This allows the interviewer to gain a more accurate sense of the patient's spontaneous speech patterns, thought processes and thought content. If the patient becomes too disorganized in response to this change, the psychiatrist can revert to more focused questions to structure and organize the interview. If it is possible, within the context of the interview, other pieces of identifying information, such as the patient's ethnic group and religious affiliation, should be obtained.

### Chief Complaint

At the start, the interviewer wants to ascertain exactly why the patient is seeking psychiatric help at this time. The interviewer may begin with a fairly general question, such as "What brings you

to treatment at this time?" The patient may have a long history of psychiatric illness, but the chief complaint refers only to the acute problem that necessitates the current intervention. The interviewer should try to help the patient distinguish the chief complaint from any chronic problems, as in the following example:

**Interviewer:** *Can you tell me what brings you to see a psychiatrist at this time?*

**Patient:** *Well, I have had schizophrenia for 25 years.*

**Interviewer:** *I see. But my guess is that something happened recently that has prompted you to come in today, rather than several months ago.*

**Patient:** *Oh, yes. Yesterday my wife kicked me out of the house. I'm homeless.*

Here the patient's chief complaint is homelessness; the schizophrenia is part of his psychiatric history. Although a psychotic patient may offer a chief complaint that seems incoherent or unrealistic, it is important to collect the chief complaint in the patient's words and later look to other sources of information for additional history. Similarly, in response to the question, "What brings you to seek psychotherapy at this time?" a patient may begin to answer by detailing his or her childhood, but the interviewer should help the patient to focus on current issues that precipitated the consultation. Some patients may not be able to cite a chief complaint: "My wife sent me" or "There's no problem. I don't know why the police picked me up". Even these answers give the interviewer information about the patient's current situation, which can be elaborated on by asking the patient for more details.

When the interview is being conducted for a third party – for example to determine whether a patient is eligible for disability – the chief complaint is replaced by the purpose of the interview. The psychiatrist should review such purpose with the patient and discuss the limits of confidentiality.

### History of Present Illness

Having obtained the chief complaint, the interviewer should clarify the nature of the present illness. By definition, the present illness begins with the onset of signs and symptoms that characterize the current episode of illness. For example, the present illness of a manic patient with chronic bipolar disorder who was asymptomatic for the past 3 years would begin with the onset of the current episode of mania. The interviewer should determine the duration of the present illness, as well as precipitating factors such as psychosocial stressors, substance use, discontinuing medication and medical illnesses. The patient should be allowed to tell the story, and the clinician should follow-up with specific diagnostic questions. For example, a patient who tells a story of 6 months of sadness after the death of a relative should then be asked about vegetative symptoms of depression, suicidal ideation and guilty rumination.

### Past Psychiatric History

The interviewer should ask for information regarding any previous episodes of psychiatric illness or treatment, including hospitalization, medications, outpatient therapy, substance use treatment, self-help groups and consultation with culture-specific healers such as shamans. The duration and effectiveness of treatment should be ascertained, as well as the patient's general experience of her or his psychiatric treatment to date.

**Table 19.3** Personal History

Prenatal History
<p>Wanted vs. unwanted pregnancy            History of maternal malnutrition or maternal drug use (including prescription drugs)            Circumstances of birth (vaginal delivery vs. cesarean section)            History of birth trauma            Birth order</p>
Early Childhood (0–3 yr)
<p>Temperament            Major milestones, including speech and motor development            History of toilet training            Early feeding history, including breast-feeding            Early behavioral problems, (e.g., nightmares and night terrors, enuresis and encopresis, aggressive behavior)            Early relationships with parents and siblings            History of significant early illnesses or hospitalizations            History of early separations from caregivers</p>
Middle Childhood – Latency (3–11 yr)
<p>Early school history, including any evidence of cognitive impairment            Relationships with siblings and peers            Early personality development            History of behavioral problems (e.g., separation anxiety, school phobia, aggressive behavior)</p>
Adolescence (12–18 yr)
<p>Psychosexual development, including experience of puberty and menarche, masturbatory history and early sexual behavior            Later school history            Later personality development            History of behavioral or emotional problems (e.g., substance abuse, eating disorders)</p>
Adulthood
<p>Marital history or history of relationships with significant others            History of child-rearing            Sexual history            Occupational and educational history            Religious history            Current living situation</p>

## Personal History

No interview is complete without some understanding of the patient's background and life circumstances (Table 19.3). Within the constraints of the interviewer's time and the patient's tolerance for further questioning, the clinician should inquire about the patient's upbringing, educational and vocational history, interpersonal relations and current social situation. It is important to inquire about the patient's sexual history and to ask about risk factors for human immunodeficiency virus (HIV) infection, such as a history of multiple partners, unprotected vaginal and anal intercourse, and intravenous drug use. This information is relevant not only for the assessment and diagnosis of the present illness but also for treatment planning.

## Family History

The interviewer should ask the patient specifically about any relatives with a history of psychiatric illness or treatment, suicide, or substance use. This information may be of diagnostic importance. For example, a patient who presents with a first

episode of acute psychosis may have any one of a number of disorders, but a family history of affective disorders may lead the interviewer to suspect a diagnosis of bipolar disorder or major depression with psychotic features rather than schizophrenia. This information is also important for treatment planning, particularly if the patient's primary caregivers are also psychiatrically ill or also abuse substances.

## Medical History

A careful review of a patient's medical history is an important part of the psychiatric interview because medical conditions can dramatically affect psychiatric status. Many medical disorders such as endocrinological conditions (thyroid disease, pheochromocytomas, pituitary adenomas), neurological disorders (Parkinson's disease, central nervous system neoplasms, Wilson's disease, stroke syndromes, head trauma) and infectious diseases (HIV infection, meningitis, sepsis) can have manifestations that include psychiatric symptoms (see Chapter 33). When such a disorder is suspected, rigorous inquiry is essential. A review

of all of the patient's medications, including over-the-counter preparations and alternative remedies, is important because many of these substances can produce or exacerbate psychiatric symptoms. For example, propranolol taken for hypertension may produce symptoms of depression, and scopolamine taken for motion sickness may induce delirium. Finally, the toll of chronic, debilitating medical conditions or the acute onset of a catastrophic physical illness may be accompanied by secondary psychiatric symptoms that can be fully understood only in the context of the patient's medical condition.

### Substance Use History

The interviewer should inquire about which substances are used, under what circumstances, and the quantity, variety, and duration of use (Table 19.4). A question such as "Do you drink alcohol?" is likely to be answered with a quick "No". A better question, such as "How much alcohol do you drink?" communicates to the patient that the clinician is not making a value judgment and is more likely to elicit an accurate answer. The interviewer must be sure to ask about past and current drug injection, including the sharing of injection equipment, to assess for HIV risk factors (Table 19.5).

### Mental Status Examination

The MSE is a structured way to assess a patient's mental state at a given time. Unlike the parts of the interview that focus on the history, the MSE provides a descriptive snapshot of the patient at the interview. Much of the information needed for the evaluation of appearance, behavior and speech is gathered without specific questioning during the course of the interview. However, the interviewer generally wants to ask specific questions to assess the patient's mood, thought process and content and cognitive functioning. Bearing in mind the outline of the MSE (Table 19.6) ensures that the interview is comprehensive. The components of the MSE are described in the following paragraphs.

**Table 19.4 Substance Use History**

Survey of drugs that have been used include: Alcohol  
Opioids (heroin, methadone, analgesics)  
Stimulants (cocaine, crack, amphetamines, ecstasy)  
Depressants (benzodiazepines, barbiturates)  
Hallucinogens (cannabis, lysergic acid diethylamide [LSD], mescaline)  
Phencyclidine  
Nicotine  
Caffeine  
Over-the-counter preparations  
Pattern of usage  
Age of first use  
Period of heaviest use  
Pattern or frequency of current use  
Route of administration (injected, intranasal, inhaled, oral)  
Periods of sobriety  
Symptoms of tolerance or dependence.  
Medical history, including HIV status and other substance use-related disorders. Note ongoing substance use despite knowledge that it could worsen medical conditions.  
History of treatment for substance use.  
Legal history. Note relationship to drug use.

**Table 19.5 Human Immunodeficiency Virus Risk Factors**

Parenteral
Use of shared needles or drug works in the course of drug injection or amateur tattooing
Receipt of blood, blood products, or organ transplant in the USA between 1978 and 1985
Maternal–fetal transmission (pediatric cases)
Occupational exposure among health care workers and laboratory technicians through needle-stick injuries and other significant exposures (uncommon)
Unsafe Sexual Activity
Most common for men: unprotected anal intercourse with other men; unprotected vaginal or anal intercourse with women who are known to be HIV-positive, engage in prostitution, or are injection drug users or sexual partners of injection drug users; multiple heterosexual partners
Most common for women: unprotected anal or vaginal intercourse with men who are known to be HIV-positive, are injection drug users, are the sexual partners of injection drug users, are bisexual, or were treated for hemophilia or coagulation disorder when blood products were contaminated; multiple heterosexual partners
Cofactors
Compromise of the skin or mucous membranes, especially through the presence of sexually transmitted diseases, which increases the likelihood of transmission on exposure to HIV-infected body fluids
Use of noninjection drugs, especially alcohol and crack cocaine, through association with high-risk sexual activity
Environmental Context
Risk behavior while living or traveling in geographic areas with high rates of HIV infection, through increased likelihood of exposure to HIV-infected body fluids

### Appearance

The interviewer should note the patient's general appearance, including grooming, level of hygiene and attire.

### Behavior

This includes patient's level of cooperativeness with the interview, motor excitement or retardation, abnormal movements (e.g., tardive dyskinesia, tremors), and maintenance of eye contact with the interviewer.

### Speech

The psychiatrist should carefully assess the patient's speech for rate, fluency, clarity and softness or loudness. The interviewer may want to question the patient directly about his or her speech. For example, the psychiatrist can gain valuable diagnostic information by asking a patient with pressured speech if she or he is able to modulate the rate of the speech or by asking whether a dysarthric patient is aware of not speaking clearly. A bipolar patient who is in the midst of a manic episode is not able to slow down her or his speech; a fast-talking anxious person is able to do so. Similarly,

    - I. Insight
    - J. Judgment

a patient whose dysarthria is secondary to ill-fitting dentures is aware of this problem whereas an intoxicated person is not. It is helpful to clarify whether patients with a speech abnormality feel that this is their normal speech pattern or a new problem.

### Mood and Affect

The interviewer should be aware of the patient's mood and affect. This may be evident from the way in which the patient answers other questions and tells the history, but specific questions are often indicated. The patient's mood is a pervasive affective state, and it is often helpful simply to ask, "What has your mood been like lately?" or "How would you describe your mood?" In contrast, affect is the way in which one modulates and conveys one's feeling state from moment to moment. The clinician judges the congruity between the material the patient is presenting and the accompanying affect, that is, sadness when discussing the death of a loved one or happiness when describing a child's accomplishments. This reveals whether the affect is labile (shifts too rapidly) and whether it is appropriate to the content of the material (see Chapter 17).

### Thought

The clinician should assess the patient's thought process and content. Thought process is the form of the patient's thoughts – are they organized and goal directed or are they tangential, circumstantial, or loosely associated? (See Chapter 45 for definitions and examples.) If the patient's thought processes are difficult to

understand, the clinician can indicate his or her difficulty in following what is being said and then assess the patient's response to this intervention. Some patients – such as patients with stroke who have nonfluent aphasia – may appear to have disorganized speech but are aware that they are not making sense, whereas those with fluent aphasia, psychosis and delirium are not necessarily aware of their impairment. The psychiatrist should ask specifically about the patient's thought content, including delusions (grandiose, persecutory, somatic), hallucinations (auditory, visual, tactile and olfactory), obsessions, phobias, and suicidal and homicidal ideation. Although these questions should be asked with tact and empathy, they should always be asked. Patients are generally relieved that the interviewer has broached the subject of suicide, and simply asking the question does not give patients ideas they have not had before.

### Cognition

Every psychiatric interview should include some assessment of the patient's cognitive functioning (see also Chapter 8). This includes the patient's level of awareness, alertness and orientation (to person, place and time). If there is a question about the patient's memory, formal memory testing may be done to assess short-term, intermediate and long-term memory. A patient who can answer questions for 30 minutes is clearly attentive, but any doubts about the patient's attentiveness should prompt a formal assessment, for example, asking the patient to recite a series of digits forward and backward. Before assessing the patient's calculations and fund of knowledge, it is important to ascertain the patient's level of education. Formal assessment of the patient's ability to abstract may be unnecessary for a patient who has used abstract constructions throughout the interview, but the interviewer may want to ask formally for interpretations of similes and proverbs. It is often helpful to begin with simple constructions, for example, asking the patient the meaning of such phrases as "He has a warm heart" or "Save your money for a rainy day". Patients whose native language is not English may have difficulty in this area that does not reflect a lack of ability to abstract.

The interviewer should gain a full understanding of the patient's insight into the illness by asking why, in the patient's opinion, he/she is currently in need of psychiatric care and what has caused problems. Finally, the interviewer should learn about the patient's judgment. This is best assessed in terms of the circumstances of the patient's life, for example, asking a mother how she would deal with a situation in which she had to leave her children to go to the store or asking a chronically ill person what he does when he sees that he is running out of medicine.

The interviewer may want to use the Mini-Mental State Examination (Mini-MSE) to quantify the degree of cognitive impairment of a patient with obvious cognitive abnormalities. This can be useful as an initial diagnostic tool, as well as a means of assessing changes in cognitive function over time. The Mini-MSE is outlined in Figure 19.1.

### Physical Examination

The physical examination is an important part of the comprehensive psychiatric evaluation for several reasons. First, many patients who present with psychiatric symptoms may have underlying medical problems that are causing or exacerbating the presenting symptoms. For example, an agitated, delirious patient may be septic or a patient being treated for an autoimmune disorder who develops new onset paranoia may have a steroid-induced

<i>Maximum Score</i>	<i>Score</i>	
5	( )	<b>ORIENTATION</b>
5	( )	What is the (year) (season) (date) (day) (month)? Where are we: (state) (county) (town) (hospital) (floor)?
		<b>REGISTRATION</b>
3	( )	Name 3 objects: 1 second to say each. Then ask the patient all 3 after you have said them. Give 1 point for each correct answer. Then repeat them until he learns all 3. Count trials and record. Trials
		<b>ATTENTION AND CALCULATION</b>
5	( )	Serial 7's. 1 point for each correct. Stop after 5 answers. Alternatively spell "world" backwards.
		<b>RECALL</b>
3	( )	Ask for the 3 objects repeated above. Give 1 point for each correct.
		<b>LANGUAGE</b>
9	( )	Name a pencil, and a watch (2 points) Repeat the following "No ifs, ands or buts." (1 point) Follow a 3-stage command: "Take a paper in your right hand, fold it in half, and put it on the floor" (3 points) Ready and obey the following:
		<b>CLOSE YOUR EYES (1 point)</b>
		Write a sentence (1 point) Copy design (1 point)
		Total score
		ASSESS level of consciousness along a continuum
		Alert                      Drowsy                      Stupor                      Coma

**Figure 19.1** Mini-Mental State Examination. (Source: Folstein MF, Folstein SE and McHugh PR [1975] "Mini-mental state". A practical method for grading the cognitive state of patients for the clinician. *J Psychiatr Res* 12, 189–198. Reprinted with permission from Elsevier Science, Pergamon Imprint, Oxford, England.)

psychosis. Secondly, the patient’s physical capacity to tolerate certain psychiatric medications, such as tricyclic antidepressants or lithium, must be assessed. Finally, many patients who present to a psychiatrist have had inadequate medical care and should be routinely examined to assess their general level of physical health. This is especially true for patients with chronic mental illness or substance abuse. In some settings, such as emergency rooms and inpatient wards, the psychiatrist may want to perform the physical examination; in others, it may be more appropriate to refer the patient to a general practitioner for this purpose. Genital, rectal and breast examinations can usually be included even for anxious and paranoid patients, but when they must be postponed, care should be taken to complete them at a later time. A same-sex chaperone is necessary for the security of both the patient and the examiner.

Certain aspects of the information obtained in the psychiatric interview should alert the psychiatrist to the need for a physical examination. Any indication (Table 19.7) from the history that the psychiatric symptoms followed physical trauma, infection, medical illness, or drug ingestion should prompt a full physical examination. Similarly, the acute onset of psychiatric symptoms in a previously psychiatrically healthy individual, as well as symptoms arising at an unusual age, should raise questions about potential medical causes (Table 19.8).

New-onset psychosis or mania in a previously healthy 65-year-old is representative of a case requiring pursuit of a medical condition as the cause because these disorders do not commonly present at this age. Any gross physical abnormalities, such as gait disturbances, skin lesions, eye movement abnormalities, lacerations, flushed skin, or drooling, should raise the interviewer’s

**Table 19.7** Indications for Physical Examination

- History of medical illness
- Current symptoms of medical illness, particularly fever, neurological symptoms, or cardiovascular abnormalities
- Evidence while taking history of altered mental status or cognitive impairment
- History or physical evidence of trauma, particularly head trauma
- Rapid onset of symptoms
- New onset of psychosis, depression, mania, panic attacks
- New onset of visual, tactile, or olfactory hallucinations
- New onset psychiatric symptoms after age 40
- Family history of physical illness that could cause psychiatric illness

**Table 19.8** Physical Illnesses That May Present with Psychiatric Symptoms

Neurological	Metabolic
Amyotrophic lateral sclerosis	Acute intermittent porphyria
Epilepsy – particularly partial complex seizures (e.g., temporal lobe epilepsy)	Electrolyte imbalance
Huntington’s disease	Hepatic encephalopathy
Multi-infarct dementia	Hepatolenticular degeneration (Wilson’s disease)
Normal-pressure hydrocephalus	Hypoxemia
Parkinson’s disease	Uremic encephalopathy
Pick’s disease	
Stroke syndromes (cerebrovascular disease)	Nutritional
	Vitamin B <sub>12</sub> deficiency
Rheumatological (Autoimmune)	Central pontine myelinolysis
Systemic lupus erythematosus	Folate deficiency (megaloblastic anemia)
Temporal arteritis	General malnutrition
	Nicotinic acid deficiency (pellagra)
Infectious	Thiamine deficiency (Wernicke-Korsakoff syndrome)
Acquired immunodeficiency syndrome	Infectious
Brain abscess	
Encephalitis	Traumatic, Particularly Head Trauma Toxic
General infection (e.g., urinary tract)	Environmental toxins
Meningitis	Intoxication with alcohol or other drugs
Syphilis, particularly neurosyphilis	
Tuberculosis	Neoplastic
Viral hepatitis	Carcinoma (general)
	Central nervous system tumors (primary or metastatic)
Endocrine	Endocrine tumors
Adrenal hyperplasia (Cushing’s syndrome)	Pancreatic carcinoma
Diabetes mellitus	
Hypo- or hyperparathyroidism	
Hypo- or hyperthyroidism	
Hypothalamic dysfunction	
Panhypopituitarism	
Pheochromocytoma	

suspicion that there might be an underlying medical condition. Urinary or fecal incontinence is also highly suggestive of a medical etiology. Stigmata of drug or alcohol use or abuse, such as dilated or pinpoint pupils, track marks, evidence of skin popping, or frank evidence of intoxication (e.g., alcohol on the breath) should also signal the need for a more thorough physical examination. Abnormalities of speech, such as impaired fluency or dysarthria, may indicate the presence of an underlying medical disturbance. Many mood problems may be caused by physical disorders, and even apparently healthy patients with dysthymia may have hypothyroidism that can be treated medically. Finally, any cognitive disturbances, such as disorientation, fluctuating level of alertness, inattentiveness, or memory problems are, until proved otherwise, evidence of a physical problem that is causing psychiatric symptoms. In such situations, careful attention should be paid to the patient’s vital signs, neurological examination (See section on Neurological Examination), and any indications of infection. In a hospital setting, a physical examination, including a careful assessment of the patient’s vital signs (including orthostatic measurements), cardiovascular status and pulmonary status precedes the prescription of most psychiatric medications. Psychiatrists should pay particular attention to a patient’s cardiovascular

status (e.g., electrocardiographic abnormalities, orthostatic hypotension, decreased cardiac ejection fraction) before beginning tricyclic antidepressants, which may induce cardiac conduction disturbances and thus must be used with caution for patients with such cardiac abnormalities as arrhythmias or other conduction abnormalities. Patients taking medications such as low-potency neuroleptics, monoamine oxidase inhibitors and tricyclic antidepressants should be assessed for orthostatic hypotension, especially if they are elderly. If beta-blockers such as propranolol are being considered, patients should be evaluated for the presence of asthma, which may be exacerbated by these drugs.

Physical examination may also be warranted during treatment with medication if physical symptoms arise. For example, fever and a change of mental status during a course of neuroleptics require a full physical and neurological examination to rule out neuroleptic malignant syndrome. Urinary retention induced by medications with anticholinergic side effects requires an abdominal examination to assess bladder fullness. Anticholinergic-induced constipation may warrant abdominal or rectal examination to assess for impaction. When patients are seen in office-based practices, the psychiatrist most often obtains a careful medical history and may complete simple procedures such as

blood pressure checks but may refer the patient to another physician for a complete physical examination.

### Neurological Examination

With every patient, the psychiatrist should consider a thorough neurological examination, especially for hospitalized patients. Patients who have a history of neurological disturbances, such as strokes, seizure disorders, central nervous system neoplasms, dementias and movement disorders, should be carefully evaluated, perhaps by a neurologist. The neurological examination should be particularly designed to rule out any lateralizing neurological signs which would point toward the presence of a focal lesion. Unilateral weakness or abnormalities in pupil size or eye movements might suggest a focal neoplasm, infection (such as toxoplasmosis), intracranial bleeding, or a stroke, which may explain such psychiatric symptoms as confusion, sudden onset of speech difficulties, psychosis, or even depression. Stiffness and cogwheel rigidity are classical signs of Parkinson's disease, a disorder which may be associated with such psychiatric symptoms as depression, psychosis and dementia.

Patients with acquired immunodeficiency syndrome should also be carefully evaluated neurologically because many neurological manifestations of advanced HIV-related illness (including HIV-associated dementia and CNS opportunistic infections) and the medicines administered to treat these illnesses may produce psychiatric symptoms, including depression, delirium, mania and psychosis. Gait should be carefully examined in psychiatric patients because certain neurological conditions in which gait disturbances are prominent, such as normal-pressure hydrocephalus, tertiary syphilis (tabes dorsalis) and combined system disease (caused by vitamin B<sub>12</sub> deficiency) may produce a variety of psychiatric symptoms.

### Psychological and Neuropsychological Testing

Psychological and neuropsychological tests are standard instruments used to measure specific aspects of mental functioning. They are usually administered by psychologists or other professionals who have been trained in their use and interpretation. In most cases, several tests, often referred to as a **battery**, are performed together. These test results must then be interpreted in the context of the broad clinical picture of the patient.

Because of the time and expense involved, testing is usually reserved for situations in which there is some uncertainty about a patient's diagnosis, cognitive capacity, or psychological functioning. There are, however, times when psychological testing is essential, for example, IQ testing to establish the severity of mental retardation. In addition, giving simple tests of cognitive functioning, such as asking the patient to copy Bender Gestalt diagrams (Figure 19.2), can be helpful as one aspect of assessing central nervous system impairment caused by a medical condition. Psychological and neuropsychological testing can be particularly useful in the assessment of children with academic or behavioral difficulties in school. Table 19.9 lists some of the most commonly used tests.

### Neuropsychological Examination Compared with Other Examinations

Neuropsychological testing provides information regarding diagnosis; cognitive, perceptual and motor capacities or deficits;

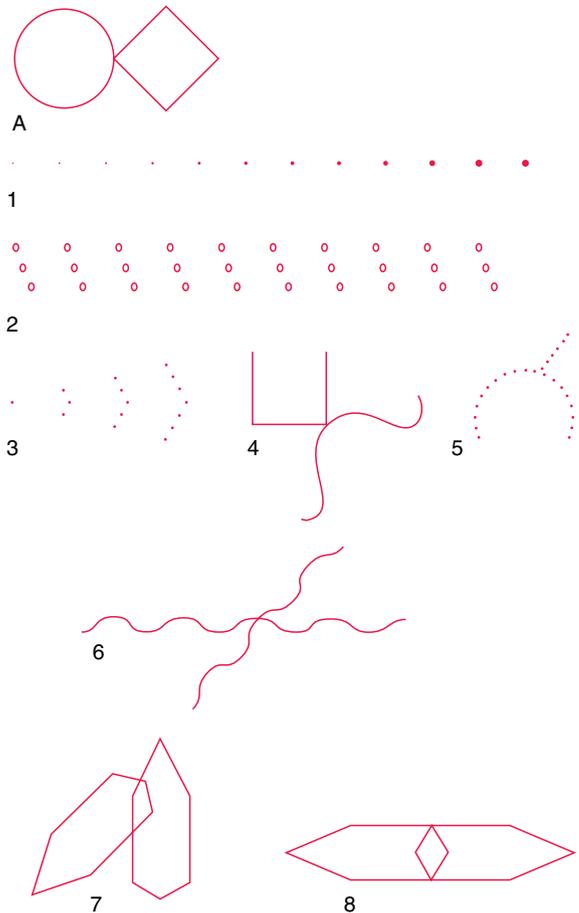

Figure 19.2 Bender Gestalt diagram.

and treatment recommendations (Table 19.10). Experienced clinicians use test data to determine the presence or absence of brain dysfunction, to localize the damage, and to establish the etiology (Milberg *et al.*, 1996). Moreover, a comprehensive functional assessment can lead to neurologically meaningful subgroups of disorders (as in different types of developmental disorders, verbal and nonverbal) that may have relevance to treatment, such as in the application of different strategies of cognitive rehabilitation or school placement (Weinstein and Seidman, 1994).

All neuropsychological approaches assess some aspects of intelligence, reasoning and abstraction, attention (sustained and selective), “executive” and self-control functions (set shifting, planning and organizational capacity), learning and memory (e.g., working memory, declarative), language, perceptual (i.e., auditory and visual) and constructional tasks, and sensory and motor functions. Comprehensive test batteries can be quite lengthy, because the human brain–behavior relationship is quite complex. Test data are interpreted in the context of many factors including the age, sex, education, and handedness of the patient.

### Types of Referral Questions for Neuropsychological Evaluation

The neuropsychological examination has three general aims: 1) identification of neuropsychological dysfunction leading to inferences regarding the presence, type and etiology of brain dysfunction; 2) comprehensive assessment of cognitive, perceptual, and

**Table 19.9** Common Psychological and Neuropsychological Tests

Name of Test	General Purpose
Bender Gestalt Test	Subject's reproduction of geometric designs used to screen for neuropsychiatric impairment
Halstead-Reitan Battery	Complex battery of tests that give a detailed picture of neuropsychiatric functioning
Minnesota Multiphasic Personality Inventory*	Multiple true–false questions designed to assess psychopathology and personality
Rorschach Test	Ten inkblot designs; subject's associations used to assess thinking disturbances and psychological conflicts and defenses
Thematic Apperception Test	Emotionally suggestive pictures portraying one or more people; used to elicit stories that reveal psychological development and motivation
Wechsler Adult Intelligence Scale – Revised	Eleven subscales; used to assess verbal and performance IQ in adults
Wechsler Intelligence Scale for Children – Revised	Twelve subscales; used to assess verbal and performance IQ in children 6 to 16 yr old

motor strengths and weaknesses as a guide for treatment; 3) assessment of the level of performance over a broad range, for both initial evaluation and measurement of change over time.

### Characterization of Adaptive Strengths and Weaknesses and Treatment Planning

Probably the greatest contribution of the neuropsychological examination compared with that of neurological or other neurodiagnostic evaluation is in providing a broad description of the patient's capacities and deficits and the impact of these resources and limitations on the patient's adaptation to the world. This

profile is essential for treatment planning, which may include rehabilitation efforts generally and psychotherapy specifically (Weinstein *et al.*, 1991).

### Assessment of Change of State

Many patients have fluctuating mental states, such as in schizophrenia and affective disorder, medical illness (e.g., renal disease, diabetes), or abuse of drugs or alcohol, or as a result of somatic therapies (medication or electroconvulsive therapy). Repeated testing is often desirable to clarify the patient's cognitive capacities. The effects of a treatment such as electroconvulsive therapy on cognitive function (e.g., verbal memory functions) can persist for months (Squire and Shimamura, 1996). Monitoring cognitive status by repeated testing allows an objective measure of subjective complaints and of recovery of function. Baseline testing early in the course of an illness such as schizophrenia or brain tumor can be compared with later evaluations to clarify the course of the disorder or to assess the impact of various interventions.

Neuropsychological evaluations differ not only in length but also in conceptual focus and in selection of the particular instruments that compose a battery of tests. In general, three batteries are used commonly throughout the USA: the Halstead–Reitan Battery (Reitan and Wolfson, 1993), the Luria–Nebraska Battery (Golden *et al.*, 1980), and a flexible, hypothesis-testing approach typified by the Boston process neuropsychological approach (Goodglass and Kaplan, 1979; Holmes-Bernstein and Waber, 1990; Kaplan, 1990; Milberg *et al.*, 1996). The decision to use one or the other of these approaches depends to some extent on the training of the practitioner, the nature of the referral questions, and a number of other factors discussed in more detail elsewhere (Seidman and Toomey, 1999).

### Limitations of Reliability and Validity

Despite the obvious role of quantification in neuropsychological testing, interpretation of test data ultimately depends on the knowledge base, training and skill of the clinician. Neuropsychological test scores are an indirect measure of the status of the brain, as contrasted with direct measures of structure by

**Table 19.10** Typical Goals of Neuropsychological Testing

Reliably, validly, and as completely as possible, measure the behavioral correlates of brain functions.  
 Differential diagnosis – identify the characteristic profile associated with a neurobehavioral syndrome.  
 Establish possible localization, lateralization and etiology of a brain lesion.  
 Determine whether neuropsychological deficits are present (i.e., cognitive, perceptual, or motor) regardless of diagnosis.  
 Describe neuropsychological strengths, weaknesses, and strategy of problem solving.  
 Assess the patient's feelings about his or her syndrome.  
 Provide treatment recommendations (i.e., to patient, family, school).

#### Indications for Clinical EEG Assessment of Psychiatric Patients

1. Rule out possible organic brain disorders
2. History of head trauma or suspicion of epilepsy
3. Differentiating pseudodementia secondary to depression and true dementia
4. First presentation of psychosis
5. Pre- and post-electroconvulsive therapy
6. Evaluating sleep disorders

magnetic resonance imaging (MRI) or function by positron emission tomography (PET), functional MRI, or EEG. In a psychiatric setting, where problems of motivation, effort, cooperation and stage of the illness are ubiquitous, analysis of neuropsychological data must go beyond the level of performance deficits because many studies have shown performance to be especially affected by functional (emotional) factors. Process analyses oriented to focal syndromes and focused on the relative efficiency of the two sides of the body and hemisphere may enhance predictive validity.

The patient's clinical state may change, and repeated testing when the patient's clinical status is optimal often clarifies the nature of the diagnosis. Selective deficits found in the context of otherwise good performance when patients are tested in their best state can be considered most valid. Neuropsychologists must also take into account the effect of medication on neuropsychological function and distinguish medication effects from the patient's adaptive ability. Different medications are likely to produce different effects. For example, Trimble and Thompson (1986) have demonstrated that, for epileptic patients and normal subjects, anticonvulsants have negative effects on most measures of neuropsychological testing. On the other hand, Cassens and colleagues (1990) have demonstrated that (traditional) antipsychotic medications have negligible or mildly positive effects on most measures of neuropsychological testing in chronic schizophrenia, with the exception of a negative effect on motor performance. Spohn and Strauss (1989) have indicated that typical antipsychotic medications tend to improve attentional performance, such as on versions of the CPT.

### Structured Clinical Instruments and Rating Scales

Structured instruments and rating scales have been developed primarily for research purposes. They allow investigators to compare findings in different studies by ensuring that similar data and criteria have been used to establish diagnoses and to measure the presence and severity of psychiatric symptoms and their response to treatment. Many types of mental health professionals and, in some cases, nonclinicians can be trained to administer these rating scales.

Although most practicing clinicians do not commonly use structured instruments to assess or follow-up patients, a small number of rating scales have come to be used routinely in clinical practice. For example, the Abnormal Involuntary Movement Scale (Figure 19.3) is often used to monitor patients receiving antipsychotic medication for the presence of tardive dyskinesia, and the Global Assessment of Functioning Scale (Figure 19.4), which is a slight modification of the Global Assessment Scale, is now used in Axis V in the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (DSM-IV-TR).

Table 19.11 shows some of the most commonly cited structured instruments and rating scales. Hundreds of other specialized scales are also in use to assess such diverse areas as personality disorder, aggressive behavior, sexual practices, stressful life events and quality of life.

Table 19.12 gives an example of how these different rating scales approach the assessment of two symptoms: guilt, a purely subjective state of mind, and suicide risk, an inclination that is assessed using both subjective and behavioral components.

### Laboratory Assessments

A variety of laboratory tests can aid in the clinical evaluation of the psychiatric patient (Table 19.13). (Council on Scientific Affairs, 1987; Gold and Dackis, 1986).

### Serological Evaluations

Blood tests are particularly helpful in ruling out medical causes of psychiatric symptoms.

### Toxicology

When the clinician suspects that the ingestion of a substance has caused the presenting symptoms, a urine toxicology screen and blood alcohol level determination (Table 19.14) are indicated. (It is important to remember that an alcohol level of zero may indicate that the symptoms are due to a withdrawal syndrome and thus does not rule out alcohol as an inciting factor.) If the patient is known to be taking certain psychiatric medications, such as lithium, tricyclic antidepressants and anticonvulsants, levels of these medications should be tested as toxic levels may cause a variety of psychiatric symptoms.

### Complete Blood Count

The complete blood count is part of the general laboratory evaluation of a new patient. It is used to screen for multiple problems, most commonly infections and anemia. In cases in which alcoholism is suspected or the mean corpuscular volume indicates a macrocytic anemia, vitamin B<sub>12</sub> and folate levels should be tested. Vitamin B<sub>12</sub> deficiency may lead to combined system disease, which can present with psychiatric symptoms such as irritability and forgetfulness in the early stages and dementia or frank psychosis in the later stages. The complete blood count is routinely used to monitor white blood cell counts in patients taking clozapine. Additional emergency complete blood counts may be necessary if such a patient develops fever, malaise, or other symptoms of infection. Certain mood stabilizers, such as carbamazepine and divalproex sodium, can induce a variety of blood dyscrasias.

### Blood Glucose

The blood glucose test is an inexpensive, essential test in the evaluation of patients with a new onset of central nervous system dysfunction, psychosis, affective disorders and anxiety disorders. Hypoglycemia may produce lethargy and vegetative symptoms that may mimic those of depression, and hyperglycemia may produce anxiety and delirium. This test is clearly indicated for known diabetics who present with the first onset of psychiatric symptoms. The atypical antipsychotic olanzapine can elevate blood sugar.

### Kidney Function Tests

The blood urea nitrogen and creatinine levels are important measures of kidney function. Kidney function tests are used to screen for kidney failure and hypovolemic states (in which blood urea nitrogen and creatinine levels increase). It is essential to perform these tests before beginning therapy with lithium, which is cleared by the kidneys.

### Liver Function Tests

These tests, which check for levels of various enzymes in the liver, are indicated when there is some suspicion that liver

INSTRUCTIONS: Complete Examination Procedure before making ratings.

MOVEMENT RATINGS: Rate highest severity observed. Rate movements that occur upon activation one *less* than those observed spontaneously.

Code: 0 = None

1 = Minimal, may be extreme normal

2 = Mild

3 = Moderate

4 = Severe

		(Circle One)				
FACIAL AND ORAL MOVEMENTS:	1. Muscles of facial expression e.g., movements of forehead, eyebrows, periorbital area, cheeks; include frowning, blinking, smiling, grimacing	0	1	2	3	4
	2. Lips and perioral area e.g., puckering, pouting, smacking	0	1	2	3	4
	3. Jaw e.g., biting, clenching, chewing, mouth opening, lateral movement	0	1	2	3	4
	4. Tongue Rate only increase in movement both in and out of mouth, NOT inability to sustain movement	0	1	2	3	4
EXTREMITY MOVEMENTS:	5. Upper ( <i>arms, wrists, hands, fingers</i> ) include choreic movements, (i.e., rapid, objectively purposeless, irregular, spontaneous), athetoid movements (i.e., slow, irregular, complex, serpentine). Do NOT include tremor (i.e., repetitive, regular, rhythmic)	0	1	2	3	4
	6. Lower ( <i>legs, knees, ankles, toes</i> ) e.g., lateral knee movement, foot tapping, heel dropping, foot squirming, inversion and eversion of foot	0	1	2	3	4
TRUNK MOVEMENTS:	7. Neck, shoulders, hips e.g., rocking, twisting, squirming, pelvic gyrations	0	1	2	3	4
GLOBAL JUDGMENTS:	8. Severity of abnormal movements	None, normal	0			
		Minimal	1			
		Mild	2			
		Moderate	3			
		Severe	4			
	9. Incapacitation due to abnormal movements	None, normal	0			
		Minimal	1

		Severe	4			
	10. Patient's awareness of abnormal movements Rate only patient's report	No awareness	0			
		Aware, no distress	1			
		Aware, mild distress	2			
		Aware, moderate distress	3			
		Aware, severe distress	4			

**Figure 19.3** *Abnormal Involuntary Movement Scale.* (Source: Guy W [1976] *ECDEU Assessment Manual for Psychopharmacology*, Rev. National Institute of Mental Health, Rockville, MD. p. 534.)

disease is present. They help the clinician to screen for hepatitis, alcoholism and biliary tract disease. They include creatine kinase, which is often elevated in neuroleptic malignant syndrome as well as in other conditions in which muscle rigidity is prominent. Monitoring of liver function tests is essential with some psychotropic medications such as divalproex sodium and nefazodone.

### Thyroid Function Tests

Both hypothyroidism and hyperthyroidism can mimic the symptoms of psychiatric disorders. Hyperthyroidism may mimic anxiety disorders, psychosis, or mania, and hypothyroidism may

mimic dysthymia and depression. Thyroid function tests are therefore indicated in cases of new onset of a major mental illness. In addition, thyroid function should always be tested when initiating lithium therapy because lithium may cause hypothyroidism.

### Syphilis Screening

These tests should be done for any patient with new-onset psychosis. They have become particularly important with the increasing incidence of syphilitic infection associated with the HIV epidemic. Positive serologic results in the presence of unexplained psychiatric symptoms necessitate a lumbar puncture to test for neurosyphilis.

Consider psychological, social, and occupational functioning on a hypothetical continuum of mental health-illness. Do not include impairment in functioning due to physical (or environmental) limitations.

Code	(Note: Use intermediate codes when appropriate, e.g., 45, 68, 72.)
100	<b>Superior functioning in a wide range of activities, life's problems never seem to get out of hand, is sought out by others because of his or her many positive qualities. No symptoms.</b>
91	
90	<b>Absent or minimal symptoms</b> (e.g., mild anxiety before an exam), <b>good functioning in all areas, interested and involved in a wide range of activities, socially effective, generally satisfied with life, no more than everyday problems or concerns</b> (e.g., an occasional argument with family members).
81	
80	<b>If symptoms are present, they are transient and expectable reactions to psychosocial stressors</b> (e.g., difficulty concentrating after family argument); <b>no more than slight impairment in social, occupational, or school functioning</b> (e.g., temporarily falling behind in schoolwork).
71	
70	<b>Some mild symptoms</b> (e.g., depressed mood and mild insomnia) <b>OR some difficulty in social, occupational, or school functioning</b> (e.g., occasional truancy, or theft within the household), <b>but generally functioning pretty well, has some meaningful interpersonal relationships.</b>
61	
60	<b>Moderate symptoms</b> (e.g., flat affect and circumstantial speech, occasional panic attacks) <b>OR moderate difficulty in social, occupational, or school functioning</b> (e.g., few friends, conflicts with peers or co-workers).
51	
50	<b>Serious symptoms</b> (e.g., suicidal ideation, severe obsessional rituals, frequent shoplifting) <b>OR any serious impairment in social, occupational, or school functioning</b> (e.g., no friends, unable to keep a job).
41	
40	Some impairment in reality testing or communication (e.g., speech is at times illogical, obscure, or irrelevant) <b>OR major impairment in several areas, such as work or school, family relations, judgment, thinking, or mood</b> (e.g., depressed man avoids friends, neglects family, and is unable to work; child frequently beats up younger children, is defiant at home, and is failing at school).
31	
30	<b>Behavior is considerably influenced by delusions or hallucinations OR serious impairment in communication or judgment</b> (e.g., sometimes incoherent, acts grossly inappropriately, suicidal preoccupation) <b>OR inability to function in almost all areas</b> (e.g., stays in bed all day; no job, home, or friends).
21	
20	<b>Some danger of hurting self or others</b> (e.g., suicide attempts without clear expectation of death; frequently violent; manic excitement) <b>OR occasionally fails to maintain minimal personal hygiene</b> (e.g., smears feces) <b>OR gross impairment in communication</b> (e.g., largely incoherent or mute).
11	
10	<b>Persistent danger of severely hurting self or others</b> (e.g., recurrent violence) <b>OR persistent inability to maintain minimal personal hygiene OR serious suicidal act with clear expectation of death.</b>
1	
0	Inadequate information.

**Figure 19.4** *Global Assessment of Functioning Scale.* (Source: American Psychiatric Association [2000] *Diagnostic and Statistical Manual of Mental Disorders, 4th edn, Text Rev. APA, Washington DC, p. 32.*)

**Table 19.11** **Common Structured Instruments and Psychiatric Rating Scales**

Name of Scale	General Purpose
Abnormal Involuntary Movement Scale	Brief structured assessment of abnormal movements; used to rate presence and severity of tardive dyskinesia
Beck Depression Inventory*	Twenty-item rating scale for depression; focuses on mood and cognition
Brief Psychiatric Rating Scale	Eighteen-item scale that rates current severity of psychopathology
Diagnostic Interview Schedule	Diagnostic instrument developed for use by nonclinicians to conduct community surveys
Global Assessment of Functioning Scale	Overall psychosocial functioning rated on a scale from 0 to 100; used as Axis V of DSM-IV
Hamilton Depression Rating Scale	A 17- to 21-item scale that rates the severity of depressive symptoms; strong focus on somatic problems
Nurses' Observation Scale for Inpatient Evaluation	Eighty items used to rate the behavior of hospitalized patients by staff
Overt Aggression Scale	Rates aggression in four categories: verbal, physical against self, physical against objects, physical against other people
Personality Disorder Examination	Items that rate six areas of personality functioning, which are analyzed by computer with a series of algorithms to generate personality disorder diagnoses

**Table 19.11** Common Structured Instruments and Psychiatric Rating Scales *Continued*

Name of Scale	General Purpose
Present State Examination	Continually updated semistructured diagnostic interview used in international research and tied to the manual on the International Classification of Diseases (most recently ICD-10)
Schedule for Affective Disorders and Schizophrenia	Semistructured questions, similar to the Structured Clinic Interview for DSM-IV but more detailed, for establishing diagnoses of affective disorders and schizophrenia
Structured Clinical Interview for DSM-IV-TR	Semistructured questions used to establish DSM-IV-TR Axis I and Axis II diagnoses
Symptom Checklist* (SCL-90)	Ninety-item self-report instrument used to assess psychopathology

\*These instruments are self-administered.

**Table 19.12** Comparison of Rating Scales for Assessing Guilt and Suicide Risk

Rating Scale	Guilt	Suicide Risk
Beck Depression Inventory. Patient picks best answer.	3 = I feel as though I am very bad or worthless. 2 = I feel quite guilty. 1 = I feel bad or unworthy a good part of the time. 0 = I don't feel particularly guilty.	3 = I would kill myself if I had the chance. 2 = I have definite plans about committing suicide. 1 = I feel I would be better off dead. 0 = I don't have any thoughts of harming myself.
Symptom Checklist. Patient rates on 5-point scale from not at all to extremely.	How much were you bothered by: Blaming yourself for things? The idea that you should be punished for your sins? Feelings of guilt?	How much were you bothered by: Thoughts of ending your life? Thoughts of death or dying?
Structured Clinical Interview for DSM-IV. Semistructured interview. Rater selects:  1 = Absent or false 2 = Subthreshold 3 = Threshold or true	<i>Interviewer asks:</i> "How did you feel about yourself? (worthless?)" If no, "What about feeling guilty about things you had done or not done? (nearly every day?)"  <i>Interviewer rates:</i> Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick).	<i>Interviewer asks:</i> Were things so bad that you were thinking a lot about death or that you would be better off dead? What about thinking of hurting yourself?  <i>Interviewer rates:</i> Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or specific plan for committing suicide.
Schedule for Affective Disorders and Schizophrenia. Semistructured interview. Rater selects answers on 6-point scale from not at all to extreme.	<i>Interviewer asks:</i> Do you blame yourself for anything you have done or not done? What about feeling guilty? Do you feel you have done anything wrong? (Do you deserve punishment?) Do you feel you have brought this on yourself?  <i>Interviewer rates:</i> Feelings of self-reproach or excessive or inappropriate guilt for things done or not done, including delusions of guilt.  <i>Further questions:</i> Assess delusions of guilt or sin.	<i>Interviewer asks:</i> When people get upset or depressed or feel hopeless, they may think about dying or even killing themselves. Have you? (Have you thought how you would do it? Have you told anybody about suicidal thoughts? Have you actually done anything?)  <i>Interviewer rates:</i> Suicidal tendencies, including preoccupation with thoughts of death or suicide.  <i>Further questions:</i> Assess gestures, attempts, risk-rescue factors, medical lethality.

*Continues*

**Table 19.12** Comparison of Rating Scales for Assessing Guilt and Suicide Risk *Continued*

Rating Scale	Guilt	Suicide Risk
Hamilton Depression Rating Scale. Rater selects best answer.	0 = Feelings of guilt are absent. 1 = Self-reproach, feelings of having let people down. 2 = Ideas of guilt or rumination over past errors or sinful deeds. 3 = Present illness is a punishment; delusions of guilt. 4 = Hears accusatory or denunciatory voices and/or experiences threatening visual hallucinations.	0 = Thoughts of suicide absent. 1 = Feels life is not worth living. 2 = Wishes he or she were dead or any thoughts of possible death to self. 3 = Suicide ideas or gesture. 4 = Attempts at suicide (any serious attempt rates 4).
Brief Psychiatric Rating Scale. Rater selects answer on 7-point scale where 1 = Not present, 7 = Extremely severe	Overconcern or remorse for past behavior. Rate on the basis of patient's subjective experiences of guilt as evidenced by verbal report with appropriate affect; do not infer guilt feelings from depression, anxiety, or neurotic defenses.	

**Table 19.13** Common Laboratory Tests for Evaluation of Psychiatric Patients

Serologic
Toxicology screen (blood) Complete blood count Blood glucose Kidney function tests Liver function tests Thyroid function tests Syphilis serology HIV antibody test Pregnancy test Blood cultures Vitamin B <sub>12</sub> and folate levels
Urine
Toxicology screen (urine) Dipstick for protein and glucose Pregnancy test
Lumbar Puncture
Electrocardiogram
Chest Radiograph

**Blood Cultures**

Blood cultures are indicated in the evaluation of medically ill patients who develop fever and psychiatric symptoms such as confusion, disorientation and agitation because this delirium may be secondary to sepsis.

**HIV Testing**

Psychiatric patients who present with known risk factors for HIV infection, including injection drug use and unsafe sexual practices (see Table 19.5), should be approached for consent to HIV

testing, especially in geographic areas with high numbers of reported cases of acquired immunodeficiency syndrome. This also applies to patients who present with multiple sexually transmitted diseases or tuberculosis. HIV should always be suspected in cases of unexplained central nervous system dysfunction and when psychiatric illness is accompanied by suggestive medical findings such as thrush or swollen lymph nodes. HIV testing requires consent of the patient and should be preceded and followed by counseling.

**Pregnancy Testing**

The serologic test for the presence of human chorionic gonadotropin b-subunit may assist in ruling out pregnancy before the initiation of therapy with lithium, benzodiazepines, or other medications associated with fetal malformations. It is advisable

**Table 19.14** Toxicology Screens

Drug	Amount per mL	Approximate Duration of Detectability (d)*
Alcohol	300 µg	1
Amphetamines	500 ng	2
Barbiturates	1000 ng	1–3
Benzodiazepines	300 ng	3
Cocaine	150 ng	2–3
Opiates	300 ng	2
Phencyclidine	25 ng	8
Tetrahydrocannabinolcarboxylic acid	<15 ng	3–20

\*May vary widely depending on amount ingested, compound, physical state of subject, and other factors.

**Table 19.15** Indications for Lumbar Puncture (Cerebrospinal Fluid Evaluation) in Psychiatric Patients

Rapid onset of new psychiatric symptoms, including dementia, delirium, psychosis  
 New-onset psychiatric symptoms with fever  
 New-onset neurological symptoms (e.g., seizures, paralysis)  
 Suspected neuroleptic malignant syndrome (e.g., while taking antipsychotics, patient develops fever, tremor, dystonia, autonomic instability, mental status changes)  
 New-onset psychiatric symptoms with a known history of HIV infection or neoplasm (if space-occupying lesion is suspected, brain imaging should precede lumbar puncture)

to perform pregnancy testing for all women of childbearing age before initiating therapy with any psychotropic medication.

### Urine Testing

Urine testing is indicated in two situations. Urine tests for pregnancy are often indicated in the emergency room setting in which an immediate result is required before the initiation of drug therapy. Urinalysis may be indicated for geriatric patients with new onset of central nervous system dysfunction or psychosis because urinary tract infections may manifest themselves in this manner in the elderly.

### Cerebrospinal Fluid Evaluation

Lumbar puncture may be indicated to test for infections, including meningitis, neurosyphilis, toxoplasmosis and cerebrospinal fluid tuberculosis. It is indicated in the evaluation of patients with symptoms such as confusion, disorientation, decreased alertness, or dementia when accompanied by fever (Table 19.15). It is also an important part of the evaluation of patients who have new-onset seizures or who are suspected of having neuroleptic malignant syndrome because these symptoms may be caused by central nervous system infections. In cases in which increased cerebrospinal fluid pressure is suspected, lumbar puncture should be preceded by computed tomographic (CT) scanning to evaluate for mass lesions.

### Electrocardiogram

Because it is important to screen for conduction disturbances and cardiac arrhythmias before beginning therapy with tricyclic antidepressants, an electrocardiogram should precede the initiation of therapy. An electrocardiogram is also indicated before beginning certain other psychotropic medications that may produce electrocardiographic changes (Tables 19.16 and 19.17). An

**Table 19.16** Indications for Electrocardiography

Assessment of cardiac functioning before beginning  
 Tricyclic antidepressants  
 Lithium  
 Thioridazine  
 Ziprasidone  
 $\beta$ -blockers  
 Electroconvulsive therapy  
 Drug overdoses (need varies with substance or substances ingested)

**Table 19.17** Common Electrocardiographic Abnormalities Seen with Psychotropic Medication

Medication	Abnormality
Tricyclic antidepressants	Increased PR, QRS, or QT intervals
Lithium	T wave flattening or inversion Sinoatrial block Sick sinus syndrome
Antipsychotics	Increased QTc interval
Thioridazine	Increased QTc interval
Ziprasidone	Increased QTc interval
Clozapine	Sinus tachycardia

electrocardiographic tracing of a patient who took an overdose of tricyclic antidepressants is shown in Figure 19.5.

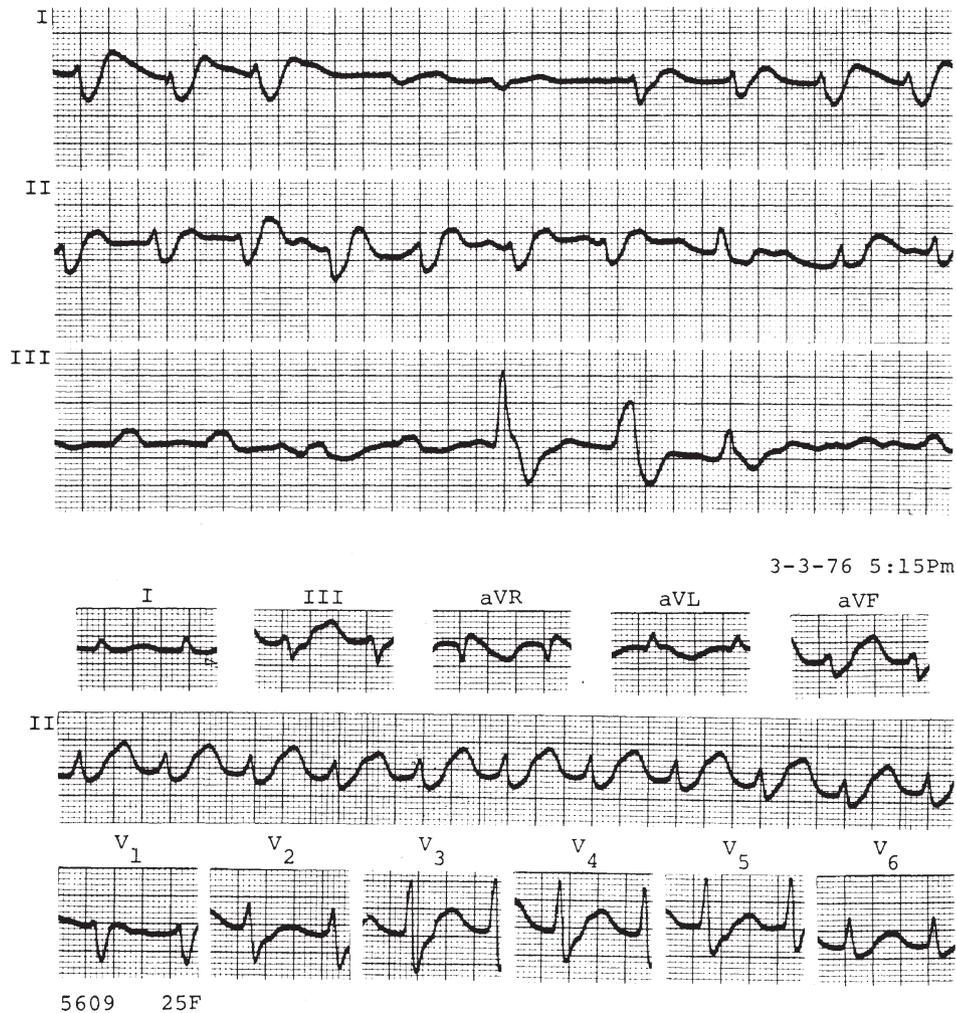

### Electroencephalography

A history of brain injury or head trauma is an indication for an electroencephalogram (EEG) in the work-up of mental status changes or psychiatric symptoms. The patient with new-onset psychosis should also have an EEG because partial complex seizures may produce psychosis. Symptoms suggesting temporal lobe epilepsy (Figure 19.6), such as hyperreligiosity, hyposexuality and hypergraphia, also indicate that an EEG should be obtained, including nasopharyngeal leads, to best evaluate electrical activity in the temporal lobes. EEGs may be useful in the assessment of insomnia and other sleep disturbances.

Abrupt onset of psychiatric symptoms such as psychosis, mania, or personality change, or the presence of visual, olfactory and tactile hallucinations suggest central nervous system dysfunction, which may warrant evaluation by electroencephalography.

### Neurophysiologic Assessment

A variety of techniques are now available that can provide more direct assessments of brain function in psychiatric patients. These include not only neuroimaging techniques (PET scans and functional MRI), but also electrophysiologic measures, such as the EEG and evoked or event-related potentials (ERPs). Electrophysiologic measures have the advantage of being economical and noninvasive, and allow continuous monitoring of brain electrical activity with a temporal resolution that surpasses that of neuroimaging measures. The EEG has traditionally been used in psychiatry to screen for brain disorders. In a conventional clinical EEG, a highly trained reader uses visual inspection of brain waves recorded from scalp electrodes. The presence of epileptiform discharges, spikes, or generalized slowing of brain electrical activity is associated with known central nervous system pathology. In patients who have a history of head trauma or where epilepsy is suspected, a clinical EEG should be done to rule out organic brain disorders (see Table 19.10). When evaluating for epilepsy, several EEGs may be necessary for accurate results because epileptiform activity is not consistently present (Boutros, 1992). The EEG can also play an important role in the diagnosis of dementia, delirium and other cognitive disorders. Generalized EEG slowing in Alzheimer's dementia is correlated with the degree of cognitive impairment and with decreased

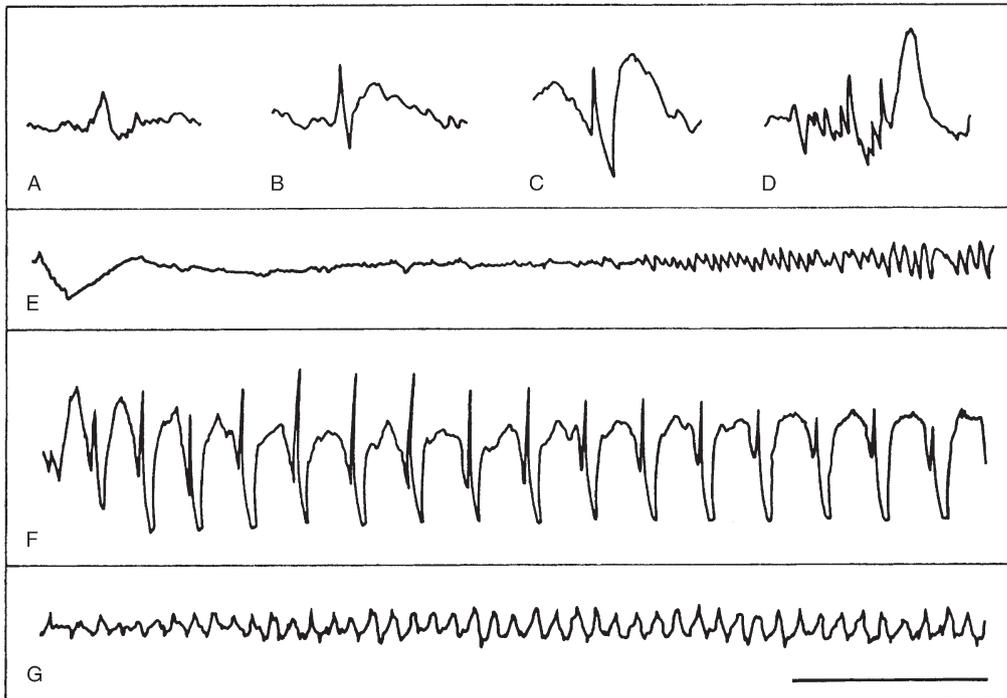

**Figure 19.5** Tricyclic antidepressant overdose. The patient was a 25-year-old woman who took 500 mg of imipramine (Tofranil) 4 hours before the 5 pm tracing was recorded. The three standard limb leads show wide QRS complexes of varying morphology. The exact rhythm cannot be determined. She had severe hypotension at this time. Fifteen minutes later, the tracing shows probable supraventricular rhythm with intraventricular conduction defect. (Source: Chou TC [1991] *Electrocardiography in Clinical Practice*, 3rd edn. WB Saunders, Philadelphia, p. 481.)

regional cerebral blood flow (Hughes and John, 1999). In elderly psychiatric patients, a clinical EEG is of value for distinguishing dementia and pseudodementia associated with depression. This is of importance for treatment selection because EEG abnormality in elderly patients is negatively associated with clinical response to antidepressants (Boutros, 1992).

Patients who experience their first psychotic episode are also candidates for a clinical EEG because brain lesions and seizure disorders, such as temporal lobe epilepsy, can cause psychotic symptoms that are clinically indistinguishable from functional psychoses. EEG recordings before, during and after electroconvulsive therapy (ECT) for depression also have clinical relevance (Hughes, 1996; Small, 1999). Patients with pretreatment EEG abnormalities may respond less well to ECT (Drake and Shy, 1989), and changes in EEG after ECT generally accompany clinical improvement (Sackeim *et al.*, 1996). Reviews of clinical EEG findings in childhood and adult psychiatric disorders show that 30 to 60% of referrals have abnormal EEGs (Hughes, 1996; Small, 1999), which underscores the importance of clinical EEG

evaluations in psychiatry. One of the limitations of routine clinical EEG is that it is dependent on the trained eye of the reader and is therefore subject to human error and may miss subtle abnormalities in the EEG tracing. Brain potentials evoked by auditory or visual stimuli (e.g., clicks or tones) have been used in both clinical and research contexts in psychiatry. Brain stem evoked potentials (BSEPs) refer to seven positive potentials evoked during the first 12 milliseconds after hearing a click. BSEPs have proven useful for assessment of hearing in infants and uncooperative patients, and in the assessment of brainstem lesions and multiple sclerosis (Celesia and Brigell, 1999). A later event-related P3 or P300 potential, typically recorded during an “odd-ball” target detection task with either auditory or visual stimuli, refers to a positive potential that peaks 300 to 500 milliseconds after onset of an infrequent target stimulus. The strongest case for the clinical utility of the P3 potential is in aging and dementia (Polich, 1999). Longer P3 latency distinguishes patients with dementia from those with pseudodementia secondary to depression, and patients with Alzheimer’s disease from healthy subjects

**Figure 19.6** Examples illustrate waveforms of typical interictal EEG transients and ictal EEG discharges. (A) Interictal sharp wave. (B) and (C) Interictal spike-and-wave complexes. (D) Interictal polyspike-and-wave complex. (E) Recruiting rhythm typical of generalized convulsion onsets. (F) Repetitive spike-and-wave discharges typical of absence seizures. (G) Rhythmic pattern seen with temporal lobe seizures. Line at the bottom right of the figure represents 1 second. (Source: Wyngaarden JB, Smith LH, and Bennett JC [1992] Cecil Textbook of Medicine, 19th edn. WB Saunders, Philadelphia, PA. p. 2208.)

(Ford *et al.*, 1997; Frodl *et al.*, 2002; Polich and Herbst, 2000). Although P3 provides a useful index of cognitive efficiency, it has little value for the differential diagnosis of psychiatric disorders such as schizophrenia because it lacks specificity.

## Brain Imaging

Several methods of brain imaging are available to assist in diagnostic assessment. Table 19.17 lists some indications for brain imaging.

Computed tomographic (CT) scans and magnetic resonance imaging (MRI) can be used to assess brain structure and are useful in detecting such abnormalities as mass lesions (central nervous system neoplasms, certain infections and hemorrhage), calcifications, atrophy, or areas of infarction. Mass lesions should be suspected in situations in which focal or lateralizing abnormalities such as focal weakness, unilateral disturbances in reflexes and increased pupillary size are found during the neurological examination. Other situations that call for brain imaging include the work-up of a patient with dementia to look for brain atrophy or lacunar infarctions; the evaluation of new-onset psychosis, acute onset of aphasia or memory loss and neglect syndromes; the evaluation of normal-pressure hydrocephalus (a syndrome characterized by a wide-based gait, dementia and urinary incontinence); and demyelinating conditions.

Whereas CT and MRI provide visualization of brain structure, positron emission tomography (PET), single photon emission computed tomography (SPECT) and regional cerebral blood flow allow investigators to study brain functioning by assessing which areas of the brain are stimulated during various types of mental activity.

## Structural Imaging Modalities

### Computed Tomography

#### Advantages and Limitations

1. CT offers excellent spatial resolution (<1 mm) and is effective at distinguishing tissues with markedly different X-ray attenuation properties (e.g., bone versus soft tissue versus fluid versus gas).
2. CT is useful for the detection of acute bleeding (less than 72 hours) but less helpful in subacute bleeding (more than 72 hours) and in severely anemic patients (hemoglobin below 10 g/dL) (Osborn, 1994). In addition, CT is an excellent modality for imaging bone. CT is the imaging modality of choice for acute trauma or when an acute bleed or ischemia is suspected.
3. CT is not helpful in visualizing subtle white-matter lesions due to CT's poor ability to distinguish between the X-ray attenuation properties of different soft tissue densities.
4. CT uses ionizing radiation and thus is strongly contraindicated in pregnancy. Women of childbearing potential should undergo a pregnancy screen prior to having a CT scan.
5. Patient anxiety is usually less during a CT scan than during an MRI scan because the scanning environment is more open, there is less noise associated with the procedure, and scanning time is relatively brief (~10 minutes for the brain).
6. CT is best for patients with metallic implants (e.g., foreign bodies, some aneurysm clips, pacemakers, etc.) as MRI is contraindicated in this patient population.

## Magnetic Resonance Imaging

### Advantages and Limitations

1. MRI provides excellent spatial resolution and superior soft-tissue contrast in comparison to CT (i.e., more useful for the visualization of white matter and white matter lesions). Also, while CT images are always axial images, MRI data can be resliced in any plane.
2. MRI is superior for surveying the posterior fossa and brain stem.
3. Fresh blood from an acute bleed (less than 48 to 72 hours) is not easily distinguished from gray matter. However, diffusion-weighted MRI may soon change this. Subacute bleeding (greater than 48 to 72 hours) or chronic hematomas are easily identified with MRI.
4. MRI does not use ionizing radiation, and so it is preferable to CT in pregnancy, but still is relatively contraindicated.
5. MRI is contraindicated in patients with metallic implants for the following reasons:
  - Metal can cause artifacts in MR images.
  - Metal can shift position or absorb heat within the magnetic field, causing burn injuries.
  - Mechanical devices such as pacemakers can malfunction within the magnetic field.
6. As many as 10% of patients undergoing MRI scanning experience significant anxiety during the imaging session. This is likely due to a number of factors. MRI scanners are much deeper (often several feet deep) than CT scanners; patients generally perceive the MRI scanner as more tunnel-like and may experience claustrophobia. Pretreatment of potentially anxious patients with benzodiazepines or other sedatives/hypnotics before undergoing MRI may be helpful in these situations. Also, the noise associated with the procedure is much louder than with CT. Lastly, the scanning time required for MRI is longer than that required for CT (20–40 minutes versus ~10 minutes for a study of the brain).

### CT versus MRI

1. CT is the modality of choice for patients with acute bleeds or acute trauma, though diffusion-weighted MRI may soon become the modality of choice for assessing suspected acute brain ischemic events.
2. MRI is superior to CT for the differentiation of white from gray matter and the identification of white matter lesions.
3. MRI is superior to CT for the detection of posterior fossa and brain stem pathology.
4. CT is recommended if MRI is contraindicated (i.e., paramagnetic prostheses; inability to tolerate scanner time, noise, or confinement).
5. MRI is recommended if radiation exposure is contraindicated (i.e., young children or women of childbearing potential).

### Indications for Use of Structural Imaging Modalities in Psychiatric Populations

#### General Guidelines for Structural Neuroimaging

On the basis of existing data, we have suggested criteria for appropriate structural brain imaging:

1. Patients with acute changes in mental status (including changes in affect, behavior, or personality) plus at least one of three additional criteria:
  - Age greater than 50 years;
  - Abnormal neurological exam (especially focal abnormalities);
  - History of significant head trauma (i.e., with extended loss of consciousness, neurological sequelae, or temporally related to mental status change in question).
2. New onset psychosis.
3. New onset delirium or dementia of unknown cause.
4. Possibly for treatment refractory patients.
5. Possibly prior to an initial course of electroconvulsive therapy (may be helpful in identifying lesions that may lead to an adverse outcome such as aneurysms, tumors, arteriovenous malformations, hydrocephalus and basal ganglia infarction).

We estimate that adherence to the criteria listed above should yield positive findings in 10 to 45% of cases. However, only 1 to 5% will produce findings that lead to specific medical intervention. Lastly, if structural neuroimaging is indicated, one should use MRI unless the problem is an acute trauma or an acute bleed is suspected.

## Functional Imaging Modalities

### Positron Emission Tomography

#### Advantages and Limitations

1. PET is the gold standard of functional neuroimaging modalities.
2. Only PET can measure cerebral glucose metabolism.
3. A larger number of radioligands, especially those used for neuroreceptor characterization, are available for PET.
4. PET offers excellent spatial resolution (~4 mm).
5. PET is very expensive and requires relatively rapid access to a cyclotron, which produces the positron-emitting radionuclides. Most PET centers have a cyclotron on the premises. However, because of the high cost of obtaining and maintaining a functional cyclotron, some centers do not have a cyclotron on the premises. <sup>18</sup>F has a longer half-life (110 minutes) than other radionuclides such as <sup>11</sup>C (20 minutes), <sup>13</sup>N (10 minutes) and <sup>15</sup>O (2 minutes), so <sup>18</sup>FDG may be prepared using a cyclotron at one site and then transported to other sites as long as they are within hours (generally ~1–3 half-lives) of the site of synthesis.

### Single Photon Emission Computed Tomography

#### Advantages and Limitations

1. SPECT is more affordable than PET and does not require a cyclotron for production of nuclides.
2. Currently, SPECT provides inferior spatial resolution (~6–8 mm) compared with PET.
3. Typically, SPECT spatial resolution worsens as one attempts to image deeper brain structures, although this is becoming less of an issue with the introduction of newer generation SPECT cameras.

## PET versus SPECT

1. PET provides superior spatial resolution, especially for deeper brain structures.
2. PET offers a broader array of radioligands for use in receptor studies and is the only modality that allows for the measurement of metabolism.
3. SPECT is less expensive than PET and is more widely available.

## Indications for Use of Functional Imaging Modalities in Psychiatric Populations

Although functional neuroimaging modalities include PET, SPECT and functional MRI (to be discussed later), in clinical situations only PET and SPECT are generally used at this time. These modalities are now commonly used as aids for diagnosis and monitoring treatment in cardiology and oncology (including brain tumors). Also, the use of ligands for neuroreceptor characterization is being increasingly used for the diagnosis and assessment of basal ganglia diseases such as Parkinson's disease. Still, most applications of functional neuroimaging in psychiatry occur in the field of research. However, a clinical role for functional neuroimaging in dementia and seizures is evolving and showing promise.

### Dementia

As characteristic functional neuroimaging profiles emerge for various forms of dementia, the role of PET and SPECT in the evaluation of dementia is expanding. For example, Alzheimer's disease is associated with characteristic hypoperfusion in bilateral temporoparietal regions. Some studies have indicated that functional neuroimaging can offer better than 90% sensitivity and specificity in distinguishing Alzheimer's disease from other kinds of dementia (Silverman *et al.*, 2001; Bonte *et al.*, 2001). Since the introduction of cholinesterase inhibitors for treatment of dementia, early diagnosis of Alzheimer's disease may have greater import than in the past. Some PET studies of healthy older subjects with normal cognitive function who are homozygous for the apolipoprotein E epsilon 4 allele (a gene associated with the development of Alzheimer's disease) reveal that these subjects have temporo-parietal hypoperfusion before the onset of disease (Small *et al.*, 1995; Reiman *et al.*, 1996). Initiation of treatment, with cholinesterase inhibitors or other drugs being developed, in these individuals prior to the onset of symptoms of dementia may prove to be of great value.

### Seizures

Some seizures, especially complex partial seizures, are not always detected by electroencephalogram (EEG). EEG measures cortical surface electrical activity but is less efficacious if the seizure focus is deeper in the brain. PET and SPECT images typically demonstrate ictal hypermetabolism and interictal hypometabolism (Krausz *et al.*, 1996, Theodore and Gaillard 2000). This allows for the detection of seizure foci during the predominant interictal period. To evaluate a possible seizure disorder, functional neuroimaging is usually performed in conjunction with EEG. PET is also useful for more precise localization of seizure foci in a patient with a known seizure disorder, if neurosurgical intervention is indicated.

### fMRI

Expanding upon the basic principles underlying standard structural MRI used in clinical situations, functional magnetic

resonance imaging (fMRI) allows investigators to assess brain function. Using either a standard or, preferably, a high-speed MR scanner with specific image-acquisition parameters, indices of cerebral blood flow and blood volume can be measured. While structural MRI studies rely on excitation and relaxation of hydrogen atoms in water, fMRI takes advantage of the paramagnetic properties of hemoglobin to measure blood flow and volume.

fMRI has distinct advantages when compared with PET and SPECT, and these include:

1. fMRI does not expose subjects to radiation and its relative safety has been documented.
2. The spatial resolution of fMRI is at least equal to if not superior to that of PET.
3. The temporal resolution of fMRI is vastly superior to that of PET or SPECT. While the temporal resolution of an <sup>15</sup>O PET study is 1 to 2 min, multiple time points can be assessed per second with fMRI.

The major disadvantage of fMRI when compared with PET or SPECT is that no satisfactory techniques for receptor neuroimaging have yet been developed for fMRI.

While fMRI currently has little utility, it may be useful in clinical situations in the future. One area of research that shows particular promise is the use of intravenous paramagnetic contrast agents with fMRI. This method, termed tracer kinetic technique, produces maps of cerebral blood volume (CBV) (Belliveau *et al.*, 1991). These CBV maps are relatively well matched to PET images of FDG uptake (Gonzalez *et al.*, 1995) and HMPAO SPECT images of cerebral blood flow (Johnson *et al.*, 1995). Because these fMRI CBV maps can be obtained after only 1 to 2 min of imaging without exposure to radiation, this technique may be used instead of PET or SPECT for evaluation of dementia or seizures in the future.

## Special Assessment Techniques

In certain situations, special assessment techniques may be indicated in the psychiatric evaluation of patients who are unable or unwilling to cooperate. These situations include the assessment of patients who are mute, have amnesia, or intentionally provide false information. In general, special techniques are employed only after all conventional ways to obtain the necessary information have been exhausted, including the use of other informants where available and appropriate.

Hypnosis can aid in the recovery of repressed memories. For example, a patient who presents with a conversion symptom may be able to recall the forgotten traumatic events that precipitated it. The usefulness of hypnosis is limited by the patient's susceptibility to the procedure and by concern that the interviewer's suggestions can produce false memories. (See also Chapter 72.)

Another approach available for similar purposes is to use a sedative during the interview to produce disinhibition and allow the patient to speak more freely or access otherwise unavailable memories. Intravenous amobarbital sodium is the best known of the medications used for this purpose. Caution must be exercised to avoid oversedation, to monitor for side effects of the medication, and to ensure that the interviewer does not inappropriately influence the patient's answers.

The assessment of a patient who is suspected of intentionally providing false information or malingering can become

uncomfortable and problematic because it may require techniques that seem at odds with the establishment of the therapeutic alliance. A careful assessment of the patient's motives, confronting the patient with inconsistencies, physical assessment of implausible somatic complaints, and the use of other informants, prior medical records and other documents can all help establish the validity of what the patient is saying. When the case involves the commission of a crime, an assessment of the patient's capacity to understand his or her actions may be important for the disposition plan.

However, because psychiatric evaluation depends on what the patient tells the interviewer and there are few objective means of clarification, it is best for the interviewer not to be overly concerned about the possibility of being intentionally misled. Establishing the truthfulness of the patient's story usually takes place over an extended period.

### Treatment Planning

The psychiatric evaluation is the basis for developing the case formulation, initial treatment plan, initial disposition and comprehensive treatment plan.

### Case Formulation

The case formulation is the summary statement of the immediate problem, the context in which the problem has arisen, the tentative diagnosis and the assessment of risk. The latter two areas are described next in more detail.

### Assessment of Risk

The assessment of risk is the most crucial component of the formulation because the safety of the patient, the clinician and others is the foremost concern in any psychiatric evaluation. Four areas are important: suicide risk, assault risk, life-threatening medical conditions and external threat.

### Suicide Risk

The risk of suicide is the most common life-threatening situation mental health professionals encounter. Its assessment is based on both an understanding of its epidemiology, which alerts the clinician to potential danger, and the individualized assessment of the patient. Suicide is the eighth leading cause of death in the USA. In the past century, the rate of suicide has averaged 12.5 per 100 000 people. Studies of adults and adolescents who commit suicide reveal that more than 90% of them suffered from at least one psychiatric disorder and as many as 80% of them consulted a physician in the months preceding the event. An astute risk assessment therefore provides an opportunity for prevention.

For those who complete suicide, the most common diagnoses are affective disorder (45–70%) and alcoholism (25%). In certain psychiatric disorders, there is a significant lifetime risk for suicide, as listed in Table 19.18. Panic disorder is associated with an elevated rate of suicidal ideation and suicide attempts but estimates of rates of completed suicide are not well established.

Suicide rates increase with age, although rates among young adults have been steadily rising. Women attempt suicide more often than men, but men are three to four times more likely than women to complete suicide. Whites have higher rates of suicide than other groups.

A patient may fit the diagnostic and demographic profile for suicide risk, but even more essential is the individualized

**Table 19.18** Indications for Brain Imaging

History of head trauma
Focal neurological findings on physical examination
New-onset psychosis

Rapid onset of psychiatric symptoms
History of neurological symptoms (including seizures)
Evidence of cognitive impairment
Abnormal electroencephalogram
Abnormal lumbar puncture

assessment developed by integrating information from all parts of the psychiatric evaluation. This includes material from the present illness (e.g., symptoms of depression, paranoid ideation about being harmed), past psychiatric history (e.g., prior attempts at suicide or other violent behavior), personal history (e.g., recent loss), family history (e.g., suicide or violence in close relatives), medical history (e.g., presence of a terminal illness) and the MSE (e.g., helplessness, suicidal ideation).

The most consistent predictor of future suicidal behavior is a prior history of such behavior, which is especially worrisome when previous suicide attempts have involved serious intent or lethal means. Among the factors cited as having an association with risk of suicide are current use of drugs and alcohol; recent loss, such as of a spouse or job; social isolation; conduct disorders and antisocial behavior, especially in young men; the presence of depression, especially when it is accompanied by hopelessness, helplessness, delusions, or agitation; certain psychotic symptoms, such as command hallucinations and frightening paranoid delusions; fantasies of reunion by death; and severe medical illness, especially when it is associated with loss of functioning, intractable pain, or central nervous system dysfunction. Table 19.19 lists risk factors for suicide. It should be noted that assisted suicide is now more openly discussed among people with terminal illnesses and has gained some measure of acceptability. Nonetheless, the vast majority of people who are bereaved or suffer from a serious medical illness do not end their lives by suicide. Adequate end-of-life care should forestall requests for assisted suicide. Although suicidal intent may be lacking, patients who are delirious and confused as a result of a medical illness are also at risk of self-injury.

It is essential to be clear about whether the patient has passive thoughts about suicide or actual intent. Is there a plan? If so, how detailed is it, how lethal, and what are the chances of rescue? The possession of firearms is particularly worrisome, because nearly two-thirds of documented suicides among men and more than a third among women have involved this method.

**Table 19.19** Estimated Lifetime Rates of Completed Suicide by Diagnosis

Major affective disorders: 10–15%
Alcoholism: 10–15% (comorbid depression usually present)
Schizophrenia: 10% (often during a post-psychotic depressive state)
Borderline and antisocial personality disorders: 5–10%

Factors that may protect against suicide include convictions in opposition to suicide; strong attachments to others, including spouse and children; and evidence of good impulse control.

In addition to the assessment of risk factors, it is important to decide whether the possibility of suicide is of immediate concern or represents a long-term ongoing risk.

### Risk of Assault

Unlike those who commit suicide, most people who commit violent acts have not been diagnosed with a mental illness, and data clarifying the relationship between mental illness and violence are limited. The most common psychiatric diagnoses associated with violence are substance-related disorders. Conduct disorder and antisocial personality disorder, by definition, involve aggressive, violent and/or unlawful behavior.

In the absence of comorbid substance-related disorders, most people with such major mental illnesses as affective disorders and schizophrenia are not violent. But data from the National Institute of Mental Health Epidemiological Catchment Area Study suggest that these diagnoses are associated with a higher rate of violence than that found among individuals who have no diagnosable mental illness. The MacArthur Violence Risk Assessment Study found this was only true for psychiatric patients with substance abuse (Steadman *et al.*, 1998).

Table 19.20 lists risk factors for violence. As with suicide, the best predictor of future assault is a history of past assault.

Information from the psychiatric evaluation that helps in this assessment includes the present illness (e.g., preoccupation with vengeance, especially when accompanied by a plan of action), psychiatric history (e.g., childhood conduct disorder), family history (e.g., exposure as a child to violent parental behavior), personal history (e.g., arrest record), and the MSE (e.g., homicidal ideation, severe agitation). Other predictors of violence include possession of weapons and current illegal activities. There is considerable overlap between risk factors for suicide and those for violence.

### Life-threatening Medical Conditions

It is essential to consider life-threatening medical illness as a potential cause of psychiatric disturbance. Clues to this etiology can be found in the present illness (e.g., physical complaints), family history (e.g., causes of death in close family members), medical history (e.g., previous medical conditions and treatments), physical examination (e.g., abnormalities identified) and MSE (e.g., confusion, fluctuation in levels of consciousness). Laboratory assessment, brain imaging and structured tests for neuropsychiatric impairment may also be essential.

Probably the most common life-threatening medical situations that the psychiatrist evaluates are acute central nervous system changes caused by medical conditions and accompanied by mental status alterations. These include increased intracranial pressure or other cerebral abnormalities, severe

**Table 19.20 Risk Factors for Suicide**

Category	Risk Factors for Suicide
Demographic	White Male Older age Divorced, never married, or widowed Unemployed
Historical	Previous suicide attempts, especially with serious intent, lethal means, or disappointment about survival Family history of suicide Victim of physical or sexual abuse
Psychiatric	Diagnosis: affective disorder, alcoholism, panic disorder, psychotic disorders, conduct disorder, severe personality disorder (especially antisocial and borderline) Symptoms: suicidal or homicidal ideation; depression, especially with hopelessness, helplessness, anhedonia, delusions, agitation; mixed mania and depression; psychotic symptoms, including command hallucinations and persecutory delusions Current use of alcohol or illicit drugs Recent psychiatric hospitalization
Environmental	Recent loss such as that of a spouse or job Social isolation Access to guns or other lethal weapons Social acceptance of suicide
Medical	Severe medical illness, especially with loss of functioning or intractable pain Delirium or confusion caused by central nervous system dysfunction
Behavioral	Antisocial acts Poor impulse control, risk taking, and aggressiveness Preparing for death (e.g., making a will, giving away possessions, stockpiling lethal medication) Well-developed, detailed suicide plan Statements of intent to inflict harm on self or others

metabolic alterations, toxic states and alcohol withdrawal. Patients may be at risk of death if these states are not quickly identified.

### External Threat

Some patients who present for psychiatric evaluation are at risk as a result of life-threatening external situations. Such patients can include battered women, abused children and victims of catastrophes who lack proper food or shelter. Information about these conditions is usually obtained from the present illness, the personal history, the medical history and physical examination.

### Differential Diagnosis

The differential diagnosis is best approached by organizing the information obtained in the psychiatric evaluation into five domains of mental functioning according to the disturbances revealed by the evaluation (see Table 19.21 and the subsequent chapters in this section for more detail). After organizing the information into these five domains, the psychiatrist looks for the psychopathological syndromes and potential diagnoses that best account for the disturbances described. A complete diagnostic evaluation includes assessments on each of the five axes of DSM-IV-TR (Table 19.22).

Disturbances of consciousness, orientation and memory are most typically associated with delirium related to a general medical condition or a substance use disorder. Memory impairment and other cognitive disturbances are the hallmarks of dementia. Results of the history, physical examination, laboratory testing and brain imaging often help in defining the specific

etiology. It is important to elicit risk factors for HIV infection and, when they are present, to encourage voluntary HIV antibody testing. Neuropsychological testing is particularly useful in the diagnosis of subcortical dementia, such as that caused by Huntington's disease and HIV infection. Dissociative disorders and severe psychotic states may also present with disturbances in this domain without evidence of any medical etiology. Cognitive impairment caused by mental retardation is established by intelligence testing.

Disturbances of speech, thinking, perception and self-experience are common in psychotic states that can be seen in patients with such diagnoses as schizophrenia and mania, as well as in central nervous system dysfunction caused by substance use or a medical condition. Disturbances in self-experience are also common in dissociative disorders and certain anxiety, somatoform and eating disorders. Cluster A personality disorders may be associated with milder forms of disturbances in this domain (American Psychiatric Association, 2000).

Disturbances of emotion are most typical of affective and anxiety disorders. These disturbances may also be caused by substance use disorders and general medical conditions. Mood and affect disturbances accompany many personality disorders and may be especially pronounced in borderline personality disorder.

Physical signs and symptoms and any associated abnormalities revealed by diagnostic medical tests and past medical history are used to establish the presence of general medical conditions, which are coded on Axis III. When a medical disorder is causally related to a psychiatric disorder, a statement of this relationship should appear on Axis I. Physical signs and symptoms

**Table 19.21 Risk Factors for Violence**

Category	Risk Factors
Demographic	Young Male Limited education Unemployed
Historical	Previous history of violence to self or others, especially with high degree of lethality History of animal torture Past antisocial or criminal behavior Violence within family of origin Victim of physical or sexual abuse
Psychiatric	Diagnosis: substance-related disorders, antisocial personality disorder; conduct disorder; intermittent explosive disorder; pathological alcohol intoxication; psychoses (e.g., paranoid, toxic) Symptoms: physical agitation; intent to kill or take revenge; identification of specific victim(s); psychotic symptoms, especially command hallucinations to commit violence and persecutory delusions Current use of alcohol or other drugs
Environmental	Access to guns or other lethal weapons Living under circumstances of violence Membership in violent group
Medical	Delirium or confusion caused by central nervous system dysfunction Disinhibition caused by traumatic brain injuries and other central nervous system dysfunctions Toxic states related to metabolic disorders (e.g., hyperthyroidism)
Behavioral	Antisocial acts Agitation, anger Poor impulse control; risk taking or reckless behavior Statements of intent to inflict harm

**Table 19.22** Categorizing Features of Mental Disturbance

Area of Mental Functioning	Examples of Relevant Evidence of Disturbance
Consciousness, orientation, and memory	Abnormalities on interview or MSE, especially impairments in awareness; alertness; orientation to person, place, time; immediate, short-term or long-term memory; attention; calculations; fund of knowledge; abstractions Past history of foregoing Positive substance use history Risk factors for HIV; positive HIV antibody result Focal neurological findings on physical examination Laboratory and brain imaging abnormalities Impairments on neuropsychological testing
Speech, thinking, perception, and self-experience	Abnormalities on interview or MSE, especially disturbances of speech, thinking, reality testing, and presence of hallucinations, delusions Past history of foregoing
Emotions	Abnormalities on interview or MSE, especially labile, depressed, expansive, elevated, irritable mood, and inappropriate affect, anger, or anxiety Past history of foregoing Positive scores for mood disturbance on structured interviews
Physical signs and symptoms; physiological disturbances	Physical or neurological findings indicative of medical or mental disorder Laboratory abnormalities Past medical illnesses Positive substance use history
Behavior and adaptive functioning	Personality dysfunction Impaired social or occupational functioning Impaired activities of daily living Impulsive, compulsive, or avoidant behaviors History of behavioral or functional disturbances Personal history (highest levels of achievement)

may also suggest diagnoses of mood or anxiety disorders or states of substance intoxication or withdrawal. Physical symptoms for which no medical etiology can be demonstrated after thorough assessment suggest somatoform or factitious disorders or malingering, although the possibility of an as-yet-undiagnosed medical condition should still be kept in mind.

Information about behavior and adaptive functioning is useful for diagnosing personality disorders, documenting psychosocial and environmental problems on Axis IV, and assessing global functioning on Axis V. This information is also useful for diagnosing most psychiatric disorders, which typically include criteria related to abnormal behaviors and functional impairment.

When all information has been gathered and organized, it may be possible to reach definitive diagnoses, but sometimes this must await further evaluation and the development of the comprehensive treatment plan.

### Initial Treatment Plan

The initial treatment plan follows the case formulation, which has already established the nature of the current problem and a tentative diagnosis. The plan distinguishes between what must be accomplished now and what is postponed for the future. Treatment planning works best when it follows the biopsychosocial model.

### Biological Intervention

This includes an immediate response to any life-threatening medical conditions and a plan for the treatment of other less acute

physical disorders, including those that may contribute to an altered mental status. Prescription of psychotropic medications in accordance with the tentative diagnosis is the most common biological intervention.

### Psychosocial Intervention

This includes immediate plans to prevent violent or suicidal behavior and address adverse external circumstances. An overall strategy must be developed that is both realistic and responsive to the patient's situation. Developing this strategy requires an awareness of the social support systems available to the patient; the financial resources of the patient; the availability of services in the area; the need to contact other agencies, such as child welfare or the police; and the need to ensure child care for dependent children.

### Initial Disposition

The primary task of the initial disposition is to select the most appropriate level of care after completion of the psychiatric evaluation. Disposition is primarily focused on immediate goals. After referral, the patient and the treatment team develop longer term goals.

### Hospitalization

The first decision in any disposition plan is whether hospitalization is required to ensure safety. There are times when a patient presents with such severe risk of harm to self or others that hospitalization seems essential. In other cases, the patient could be

managed outside the hospital, depending on the availability of other supports. This might include a family who can stay with the patient or a crisis team in the community able to treat the patient at home. The more comprehensive the system of services, the easier it is to avoid hospitalization. Because hospitalization is associated with extreme disruption of usual life activities and in and of itself can have many adverse consequences, plans to avoid hospitalization are usually appropriate as long as they do not compromise safety.

### Day Programs, Crisis Residences and Supervised Housing

These interventions provide ongoing supervision but at a lower level than that available within the hospital. They are most often used to treat patients with alcohol and substance use disorders or severe mental illness. Crisis housing can be useful when a patient cannot safely return home, when caregivers need respite, and when the patient is homeless. Other forms of supervised housing usually have a waiting period and may not be immediately available.

There are many different types of and names for day-long programming, including partial hospitalization, day treatment, psychiatric rehabilitation and psychosocial clubs. Depending on the nature of the program, it may provide stabilization, daily medication, training in social and vocational skills, and treatment of alcohol and substance use problems. Long-term day programs should generally be avoided if a patient is functioning successfully in a daytime role, such as in a job or as a homemaker. In these instances, referral to a day program may promote a lower level of functioning than the patient is capable of.

### Outpatient Medication and Psychotherapy

The most common referral after psychiatric evaluation is to psychotherapy and/or medication management. In office-based settings, the psychiatrist decides whether she or he has the time and expertise to treat the patient and makes referrals to other practitioners as appropriate. Hospital staff usually have a broad overview of community resources and refer accordingly. There are high rates of dropout when patients are sent from one setting to another. These can be reduced by providing introductions to the treatment setting and/or conducting follow-up to ensure that the referral has been successful.

### Comprehensive Treatment Planning

The psychiatric evaluation usually continues beyond the initial disposition. The providers assuming responsibility for the patient, who may be inpatient staff, outpatient staff, or private practitioners, complete the evaluation and take responsibility for developing the comprehensive treatment plan. This plan covers the entire array of concerns that affect the course of the patient's psychiatric problems. In hospital settings, the initial treatment plan is usually completed within 24 to 72 hours after admission, followed by comprehensive treatment plan after more extensive evaluation.

The comprehensive treatment plan usually includes more definitive diagnoses and a well-formulated management plan with central goals and objectives. For severely ill or hospitalized patients, every area is usually covered (Table 19.23 and 19.24). It is best for the patient and, as appropriate, the family, to have input into the plan. The comprehensive treatment plan guides and coordinates the direction of all treatment for an extended time, usually

**Table 19.23 DSM-IV-TR Multiaxial System**

Axis I	Clinical disorders Other conditions that may be a focus of clinical attention
Axis II	Personality disorders Mental retardation
Axis III	General medical conditions
Axis IV	Psychosocial and environmental problems
Axis V	Global assessment of functioning

months, and is periodically reviewed and updated. For more focal psychiatric problems (e.g., phobias, sexual dysfunctions) and more limited interventions (e.g., brief interpersonal, cognitive, and behavioral therapies in office-based practices), the comprehensive treatment plan may focus on only several of the possible areas.

### Conclusion

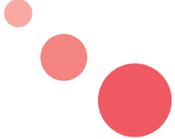

The psychiatric evaluation is a method of collecting present and past psychological, biological, social and environmental data for the purpose of establishing a comprehensive picture of the patient's strengths and problems, including the psychiatric diagnoses, and developing treatment plans. It is the essential beginning of every course of psychiatric treatment and, when carried out successfully, integrates a multimodal approach to understanding mental illness and providing clinical care.

**Table 19.24 Areas Covered by Comprehensive Treatment Plan**

Mental health	Diagnoses on five axes Psychiatric management, including medications
Physical health	Medical diagnoses Medical management, including medications
Personal strengths and assets	
Rehabilitation needs	Educational Occupational Social Activities of daily living skills Use of leisure time
Living arrangements	
Social supports and family involvement	
Finances	Personal finances Insurance coverage Eligibility for social service benefits
Legal or forensic issues	
Central goals and objectives	
Listing of treatment team members	
Evidence of participation by patient and, as appropriate, family members and others	
Criteria for discharge from treatment

# Behavior and Adaptive Functioning

---

To function adaptively means to behave in such a way that one's attitudes and actions are well matched to the demands and constraints of the external environment and that one's sense of internal discomfort or distress is minimized. Therefore, by definition, the ability to adapt depends both on the individual's behavioral repertoire and on the external environment. A person's capacity for adaptive functioning is so crucial that it has been studied in situations ranging from adaptation to long-term missions in outer space (Eksuzian, 1999) to the self-management of life-threatening illnesses such as chronic heart failure (Buetow *et al.*, 2001). This chapter focuses on the ingredients that shape personality and the ways in which personality in turn affects behavior. In addition, the domains in which individuals are typically expected to function are reviewed, with particular attention to the ways in which various personality styles affect functioning in each domain. Patterns of behavior that are frequently pathological in nature, such as impulsive, compulsive and avoidant behaviors, are examined. Finally, approaches to the assessment of behavior and adaptive functioning in the psychiatric interview are reviewed.

---

### Clinical Vignette 1

Mr C, a young schizophrenic man, attempted to avoid hospitalization by beginning to shave more regularly and cutting his fingernails. However, he remained unwilling and unable to have his hair cut, attempting to disguise its length by wearing it up under a baseball cap when going outside.

---

### Clinical Vignette 2

Ms D, a middle-aged woman, came to the emergency department claiming that she had run out of Valium and that her prescribing physician was out of town. Her story was convincing and the resident physician was about to give her a prescription when he noted on close examination that she had a dirty hem on both her pants and her jacket sleeves, which seemed inconsistent with her presentation of herself as an executive secretary. After pressing her for more details of her story and consulting with another emergency department, he determined that the patient was actually a homeless woman who got prescriptions from hospitals and then sold them on the street.

### Personality Style

An individual's personality style has a great influence on his or her behavior and adaptive functioning. Personality is shaped from a blend of inborn temperament, genetic strengths and vulnerabilities, and the impact of positive and negative life experiences. Psychiatry is moving toward an improved understanding of human behavior that focuses on the ways that these factors interact with one another.

There is evidence of striking variation among neonates in their capacity to tolerate frustration, which reflects their inborn temperaments (Thomas *et al.*, 1963). Such individual differences in temperament form the biological substrate that interacts with early development. Temperament affects the degree to which different infants are susceptible to distress as well as their variations in attachment style (Rothbart and Ahadi, 1994).

Genetic factors of various types also play a role in development, particularly when they interact with environmental factors. In general, genetic factors account for between 30 and 60% of the variance in adult personality traits (Carey and DiLalla, 1994).

Life experiences also have an impact on an individual and affect her or his behavior for better or worse. Considering whether particular experiences are the result of fate in contrast to whether they are partially brought about by the person's own actions can be important in thinking about their impact and meaning.

While psychiatrists have long suspected links between early life experiences, especially traumatic ones, and adult psychopathology, these connections are just now being clearly, empirically demonstrated. For example, in one recent study, childhood verbal abuse conferred an increased likelihood of borderline, narcissistic, paranoid, schizoid and schizotypal personality disorder during adolescence which was independent of other facts like temperament, physical and sexual abuse, use of corporal punishment, parental psychopathology and cooccurring psychiatric disorders (Johnson *et al.*, 2001). Further, as the relationships between genetic propensities expressed as temperament or personality factors and environmental influences have been explicated, some fascinating interactions have emerged. For example, one recent study suggested that high levels of the personality trait of sensation seeking, which appears to be genetically mediated, might result in a high incidence of adverse life events that would in turn help to precipitate depression (Farmer *et al.*, 2001). Further, exploration of patterns of disease and personality factors is beginning to shape genetic investigations by serving as guides for genetic linkage studies (Nigg and Goldsmith, 1998). For instance, in one study, twins and siblings who were highly

concordant and discordant for neuroticism, a personality factor, were examined for evidence of anxiety and depression. Tissue samples were collected to look for areas of genetic overlap and thus to identify potential foci on chromosomes that warranted further exploration (Kirk *et al.*, 2000).

Personality styles have been described in a variety of ways with use of different models of normal personality variation. These models are either categorical or dimensional in nature. In a categorical model, a person is described as meeting or not meeting the criteria for various diagnostic categories. In a dimensional model of personality, a person is evaluated in terms of the blend of various traits or factors he or she possesses, measured on a continuum. In general, as a person moves toward the extreme end of a given continuum in the dimensional model, she or he becomes more likely to meet the criteria for a categorical diagnosis. Some dimensional models set a threshold beyond which a given characteristic is likely to be a problem or pathological.

The categorical model is a more common approach to diagnosis within clinical psychiatry and within medicine in general. It now seems clear that useful information is gained from both categorical and dimensional approaches to examining personality. Thus, although personality disorders as outlined in the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (DSM-IV-TR) (American Psychiatric Association, 1994) are currently cast in categorical terms, Oldham and Skodol (2000), among others, have suggested that elements of both categorical and dimensional systems be included when revisions are made in DSM-V. Others have proposed a prototype-matching approach to diagnosing personality disorders in which models of various personality styles are constructed and psychiatrists make diagnosis by matching their patient to the best available prototype (Westen and Shedler, 2000).

Oldham and Morris (1995) translated each of the personality disorders of the DSM-IV-TR system into a less pathological collection of categories that describe normal personality styles. In their system, a cross between a categorical and a dimensional model, conscientiousness is the positive personality trait that in excess becomes obsessive–compulsive personality disorder. Table 20.1 summarizes the personality style–personality disorder continuum described by Oldham and Morris.

A continuum model such as this one acknowledges that whereas too much of a good thing may constitute a disorder, everyone’s personality consists of traits that can be adaptive or maladaptive. The quantity rather than the quality of a given trait

is often what makes it a problem or adaptive. Similarly, flexibility and variability are important determinants of a person’s adaptive capacity.

Examples of dimensional models of personality include the five-factor model (Widiger *et al.*, 1994), Cloninger’s seven-factor model (Cloninger, 1987; Cloninger *et al.*, 1993), and the biogenic spectrum model of Siever and Davis (1991). The five-factor model of personality was first suggested by McDougall (1932) and was elaborated and updated by Digman (1990) and McCrae and Costa (1987) among others. In the five-factor model, personality traits are described in terms of a taxonomy of five dimensions. These include neuroticism, extraversion, openness to experience, agreeableness and conscientiousness. Table 20.2 summarizes the factors of the five-factor model and their relationship to DSM-IV-TR categories.

A second dimensional model of personality is Cloninger’s seven-factor model of temperament and character (Cloninger, 1987; Cloninger *et al.*, 1993) (Table 20.3). In this model, a patient’s behavior is evaluated on seven separate dimensions. Four of the seven dimensions are related to temperament and have been shown to be independently heritable, manifested early in life, and involved in early perceptual memory and habit formation.

**Table 20.1 Oldham and Morris’ Personality Style–Personality Disorder Continuum**

Style	DSM-IV Disorder
Vigilant	Paranoid
Solitary	Schizoid
Idiosyncratic	Schizotypal
Adventurous	Antisocial
Mercurial	Borderline
Dramatic	Histrionic
Self-confident	Narcissistic
Sensitive	Avoidant
Devoted	Dependent
Conscientious	Obsessive–compulsive

**Table 20.2 The Five-Factor Model**

Factor	Traits	DSM-IV Example
Neuroticism	Anxiety	High in borderline Low in schizoid
	Hostility	
	Depression	
	Self-consciousness	
	Impulsiveness Vulnerability	
Extraversion	Warmth	High in histrionic Low in avoidant
	Gregariousness	
	Assertiveness	
	Activity	
	Excitement seeking Positive emotions	
Openness	Fantasy	High in schizotypal
	Esthetics	
	Feelings	Low in paranoid
	Actions	
	Ideas Values	
Agreeableness	Trust	High in dependent Low in narcissistic
	Straightforwardness	
	Altruism	
	Compliance	
	Modesty Tendermindedness	
Conscientiousness	Competence Order	High in obsessive– compulsive
	Dutifulness	
	Achievement	Low in antisocial
	striving	
	Self-discipline Deliberation	

**Table 20.3** Cloninger's Seven-Factor Model of Temperament and Character

Temperament Factor	Behavioral Effect
Harm avoidance	Behavioral inhibition
Reward dependence	Motivation for behavior
Novelty seeking	Initiation of exploration
Persistence	Maintenance of behavior
Character Factor	Self-Concept Effect
Self-directedness	Sense of self as autonomous
Cooperativeness	Sense of self as part of community
Self-transcendence	Sense of self in the universe

These four dimensions include novelty seeking, harm avoidance, reward dependence and persistence. Figure 20.1 is a schematic representation of Cloninger's model.

Cloninger also describes three dimensions of character, namely, self-directedness, cooperativeness, and self-transcendence. The blend of these three characteristics that an individual possesses helps to determine self-concept, such as whether the individual identifies himself or herself as an autonomous individual, as an integral part of humanity, and as a part of the universe as a whole. Those with low degrees of self-directedness and low degrees of cooperativeness are more likely to have personality disorders (Svrakic *et al.*, 1993).

A third dimensional model of personality is the biogenic spectrum model of Siever and Davis (1991). This model proposes that certain personality styles and disorders are associated with and are characterological variants of various Axis I disorders. Thus, personality disorders are not extreme variants of normal but are characterological variants of Axis I disorders. The biogenic spectrum model may be useful in guiding treatment, such as using anxiolytics to treat avoidant personality disorder because it is considered to be on a spectrum with Axis I anxiety disorders. There is growing evidence that the biogenic spectrum model is useful for at least some Axis I/Axis II disorders. One example is the link between schizophrenia and schizotypal personality disorder in which those with the Axis II disorder demonstrate a better capacity for buffering in certain frontal brain regions as shown by functional imaging as compared with those with the full-blown Axis I disorder (Kiran and Siever, 2000). Table 20.4 presents details of the biogenic model.

## Domains of Functioning

Each person's unique personality style is reflected in the various domains in which the person functions. DSM-IV's Axis V, the

**Table 20.4** The Biogenic Model and DSM-IV-TR

Axis I Disorder	Example of Axis II Variant
Mood	Borderline
Anxiety	Avoidant
Impulse control	Antisocial
Psychotic	Schizoid

Global Assessment of Functioning, provides a 100-point scale with which to rate a person's overall level of adaptation. It provides a useful global rating of adaptive function that assesses the degree of symptoms and the capacity to function in social and occupational spheres (American Psychiatric Association, 1994). These domains are somewhat overlapping. Oldham and Morris' model of normal personality derived from the DSM categories provides a framework for thinking about how different personality styles predispose people to emphasize or minimize the importance they assign each domain and to function more or less effectively in each area (Oldham and Morris, 1995).

## Social and Interpersonal Functioning

Interpersonal styles greatly affect social functioning, which in turn has a large impact on both work- and leisure-time functioning. Distinctive individual personality styles affect a person's perception of the importance of relationships with others as well as the quality and depth of the bonds they can form. Those with solitary traits are unlikely to crave and seek close relationships, whereas those with a devoted style become uneasy and feel incomplete if they are not with others. Vigilant people are cautious of the attentions of others, whereas dramatic types thrive on the admiration of their peers. Those who are mercurial often run "hot" and "cold" in their relationships with others, sometimes expressing their feelings in ways that offend others; sensitive types are easily affected by the perspectives and behavior of others but tend to keep their feelings to themselves.

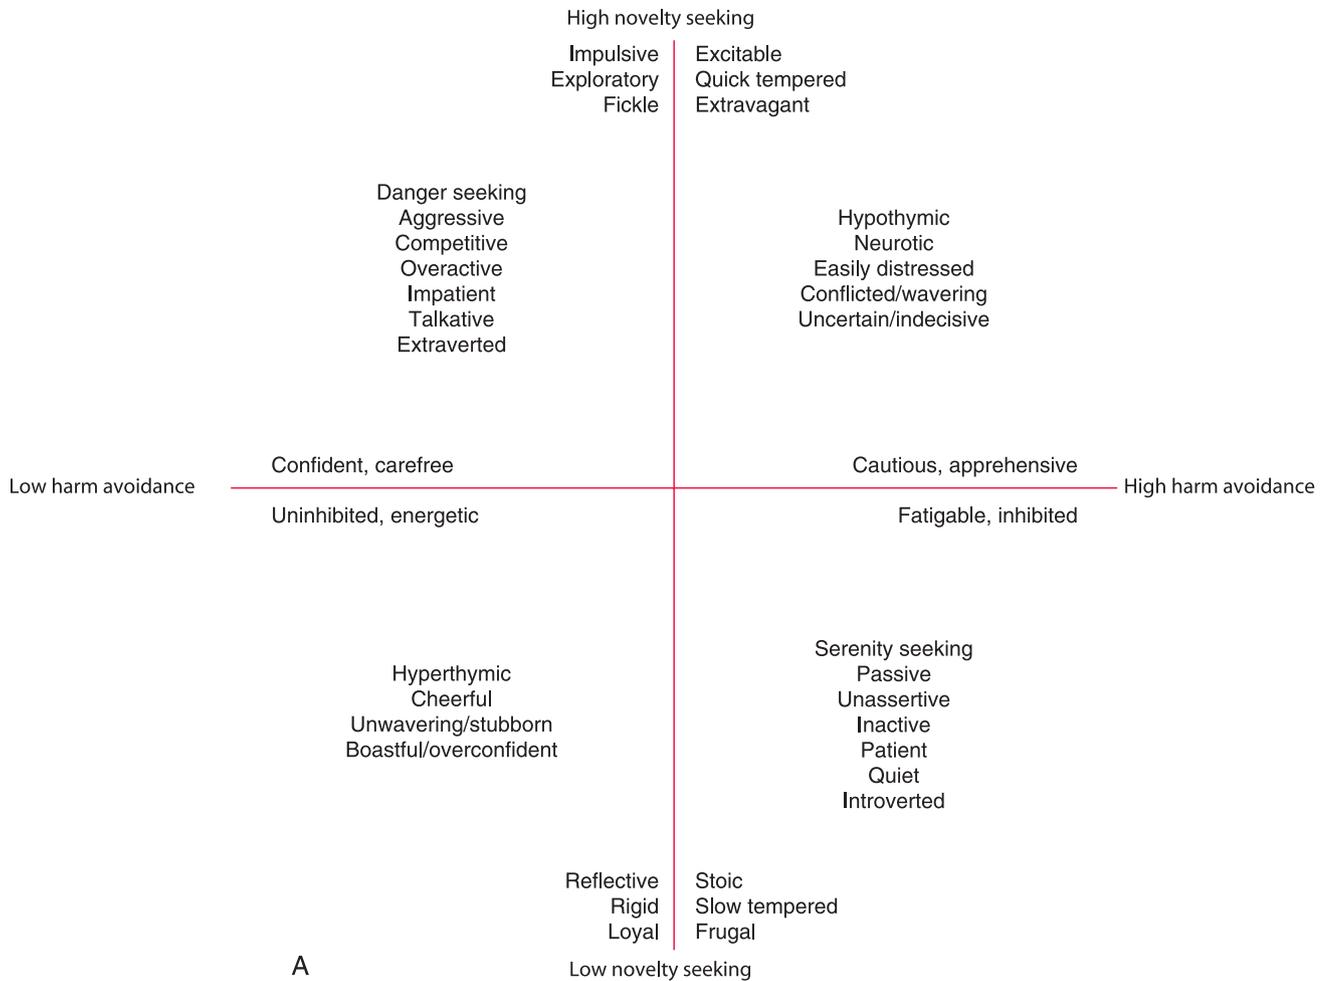

The Social Adjustment Scale (Weissman *et al.*, 1974, 2001) provides a quantitative way to investigate several types of interpersonal functioning (Table 20.5) including a person's relationships with family of origin, spouse or partner, children, work colleagues, and friends and acquaintances. Inherent in these assessments of functioning is an assumption that to be successful, relationships should be interpersonally relatively free of friction and arguments, reciprocal and supportive. In addition, each person's experience of the relationship should be comfortable and relatively conflict free.

Benjamin's Structural Analysis of Social Behavior (Figure 20.2) provides another means of assessing recurrent patterns in a person's interactions with others (Benjamin, 1986b). It has three dimensions: 1) the focus of the interaction; 2) the tone of the interaction (loving versus hating); and 3) whether the interaction is characterized by interdependence or independence. The focus in the Structural Analysis of Social Behavior can be on another person, on oneself in relation to another person, or on inward, internal aspects of the self. The Structural Analysis of Social Behavior is widely used in research settings to describe and quantify a person's mode of interpersonal functioning in various relationships.

## Occupational Functioning

Assessing adaptive occupational functioning requires examining the ways in which an individual completes tasks, takes and gives orders, delegates responsibilities and cooperates with others. Job situations also require an ability to balance demands, obey regulations and make decisions. Clearly, success in these tasks in part depends on one's capacity for interpersonal functioning.

Weissman's Social Adjustment Scale (Weissman *et al.*, 2001) provides a means of evaluating a person's occupational functioning. The scale focuses on both externally observable

**Figure 20.1** Cloninger's model: harm avoidance, reward dependence, and novelty seeking. (Reprinted with permission from Cloninger CR [1987] *A systematic method for clinical description and classification of personality variants: A proposal*. Arch Gen Psychiatr 44, 573–588. Copyright 1987, American Medical Association.)

behaviors, such as number of days lost in a month and the degree of impairment of performance at work, as well as internal states, such as feeling inadequate, angry and distressed at work. In addition, whether a person is distressed, disinterested and bored by work is also assessed. These questions begin to suggest what adaptive occupational functioning comprises, namely, that it consists of being engaged and feeling satisfied about and competent at work. In addition, the Social Adjustment Scale assesses whether these positive internal states are reflected in work performance and relationships with superiors and subordinates.

## Leisure

The capacity to enjoy leisure depends in part on other external demands and responsibilities as well as financial and other resources. Leisure is more than time left over from work and family. The gusto with which leisure activities are pursued and the types of activities that are chosen are affected by a person's characteristic style. In contrast to the work domain, those with a leisurely style are likely to enjoy their free time and to have myriad hobbies and interests; those with conscientious styles may approach leisure as another job, by working hard at trying to have fun. Those with aggressive styles may choose competitive leisure pursuits, such as

sports, in which they can pit their prowess against others; solitary types may prefer solo leisure pursuits that do not involve others.

The Social Adjustment Scale may be used to evaluate how well developed and specific a patient's interests are as well as the frequency with which such activities are pursued. It can be helpful in assessing whether a person's leisure-time contacts with others are diminished. The Social Adjustment Scale quantifies aspects of leisure, such as how many social events one has attended in the last month. The experience of loneliness or boredom during free time as well as the person's ability to compensate for these painful states yields a measure of leisure-time adaptation.

## Assessing Behavior and Adaptive Functioning in the Clinical Interview

Finding out about a patient's personality style, level of adaptive functioning and usual patterns of behavior is one of the major tasks of the psychiatric interview. A psychiatrist gains important information from what a patient and those people close to the patient say about her or his behavior. However, a psychiatrist also gains invaluable information by closely observing the person during the interview itself. Whether the psychiatrist is quickly sizing up an agitated patient during a psychiatric emergency or carefully

**Table 20.5 The Social Adjustment Scale**

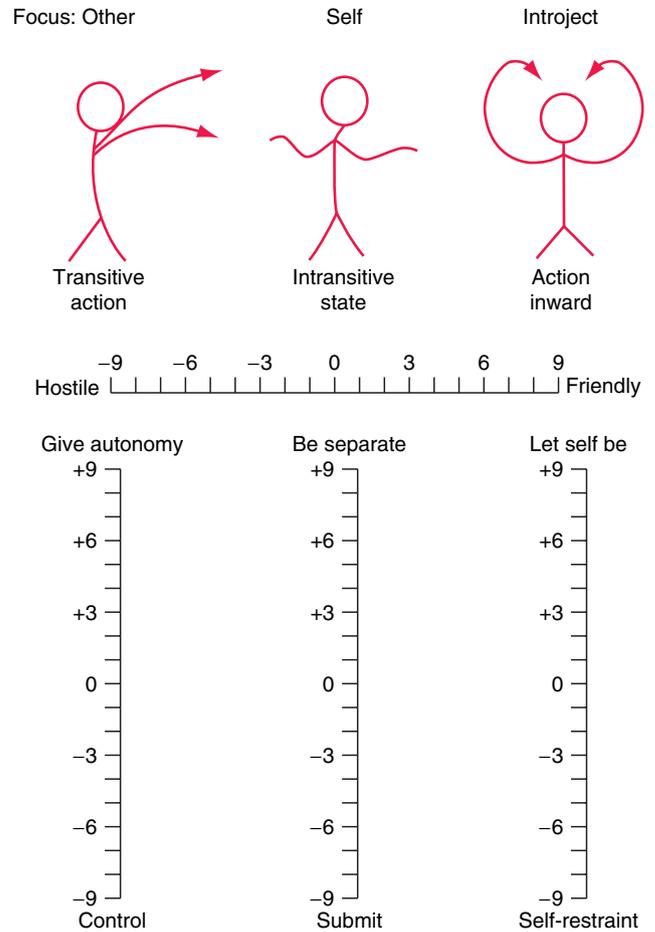

Domain*	Assessment Questions
Work	Time lost?
Outside home	Impaired performance?
At home	Feelings of inadequacy?
At school	Friction with coworkers?
	Distress about work?
	Disinterest in work?
Social	Impaired leisure activities?
	Diminished contacts with others?
	Diminished social interactions?
	Reticence to have social contacts?
	Friction within social contacts?
	Hypersensitivity?
	Social discomfort?
	Loneliness?
	Boredom?
	Diminished dating?
	Disinterest in dating?
Interpersonal	Friction?
Extended family	Reticence?
Spouse or partner	Withdrawn?
Parental functioning	Dependency?
Family unit	Rebellion?
	Worry?
	Guilt?
	Resentment?
	Submissiveness?
	Domineering behavior?
	Lack of affection?
	Sexual interest, frequency, problems with partner?
	Lack of involvement?
	Impaired communication?

\*Each domain is scored on a 5-point scale ranging from 1 (not a problem) to 5 (an extreme problem). In addition, a global score in each domain is assigned by use of this same scale.

noticing how a patient shifts in the chair during a psychotherapy session, the ability to observe a patient’s behavior is one of a psychiatrist’s most important tools. A patient’s appearance, attitude and motor behaviors during an interaction with the psychiatrist provide important clues to personality, capacity for interpersonal interactions and potentially problematic behavior patterns.

**Appearance**

Observing a patient’s appearance includes making a judgment about the overall physical impression of the person reflected by grooming, clothing, poise and posture. The ability to appear well-kempt is impaired in many psychiatric disorders, ranging from the psychotic patient who appears disheveled after being up for several nights to the depressed patient dressed in dark, somber tones and slumped in the chair. Clothing often reveals aspects

**Figure 20.2** The three dimensions of the Structural Analysis of Social Behavior model. Therapy content and process expressed in interactional terms can be coded in terms of the three dimensions: focus, love versus hate, and interdependence. Viewing all relationships in terms of these dimensions makes parallels among early and current relationships more apparent. (Source: Benjamin LS [1986a] *Adding social and intrapsychic description to Axis I of DSM-III*, in *Contemporary Directions in Psychopathology: Toward the DSM-IV* [eds Million T and Klerman GL]. Guilford Press, New York, p. 608.)

of personality; patients with extroverted, histrionic, or dramatic personalities often wear brightly colored, unusual clothes and are often garishly made up. Problems with appearance can suggest the possibility of other functional impairments as well. The motivation and degree of volitional control over appearance must usually be inferred. At times, appearance may provide an important clue of an inconsistency in a patient’s verbal presentation and suggest a serious behavior problem.

**Clinical Vignette 3**

Ms G, a 21-year-old woman with borderline personality disorder, carved the word “monster” on her arm. Of this act she said, “I was feeling so tense and angry, like there was a tornado inside of me. As I focused on the small red lines I made with the razor, I began to feel better. The physical pain let me center my attention on my body, and my angry feelings seemed to fade away”.

---

### Clinical Vignette 4

Mr H, a 23-year-old college senior, sought help for his paraphilia, namely, exhibitionism. He would resist the urge to exhibit his genitals to a woman for weeks but would eventually feel that the desire was irresistible. As he noted the look of shock or surprise on the woman's face when he exhibited his penis, he would often ejaculate. However, after this, he would feel ashamed, remorseful, afraid that the woman would recognize him on the street, and convinced that she would notify the police and he would be arrested.

### Attitude and Cooperation

The interviewer can also detect a patient's attitude and willingness to cooperate during an examination. Attitude and cooperation are related but not identical concepts; a paranoid patient may have a suspicious attitude but may cooperate by answering the interviewer's questions nonetheless. Often, however, a person's attitude and ability to cooperate are both affected by psychiatric illness. Patients may be friendly or hostile, seductive, defensive, or apathetic. During the psychiatric interview, they may seem attentive or disinterested and be frank or evasive and guarded. Again, each of these attitudes and the degree of cooperation a patient exhibits can depend on the underlying psychiatric state or can reflect a conscious manipulation on the part of the patient for the sake of achieving a desired goal. Attitude and degree of cooperativeness with an interviewer yield data about a patient's capacity to establish rapport and relate to others, thereby suggesting the person's general level of interpersonal functioning.

### Motor Behavior

The astute examiner can also observe motor behaviors that provide clues to a patient's internal state. First, the overall level of activity should be noted. Behavioral activity is often quantitatively increased in patients with mania or anxiety disorders, whereas it may be decreased in those with depression or intoxication. In addition, impulsivity can sometimes be revealed by motor behaviors, as when a person pounds on a wall or hurls an object. Motor behavior can also provide clues to personality; the dramatic patient often gesticulates freely during conversation, whereas the obsessive patient often conveys a sense of constricted facial movements and gestures. The types of behaviors associated with overactivity may include restlessness, pacing, handwringing, or other forms of agitation. In contrast, psychomotor retardation is a slowing of the usual body movements. A depressed patient with psychomotor slowing may be observed sitting perfectly still, staring into space. Similarly, patients with underlying neurological disorders such as Parkinson's disease or those who are taking medicines that produce parkinsonism may exhibit motor slowing in the form of lack of facial expressiveness and loss of the body movements and gestures that often accompany speech.

Another clinically relevant way of approaching the task of assessing a patient's behavior was suggested by Halleck (1994). He suggested that in addition to focusing on appearance, attitude and cooperation in the clinical evaluation, the interviewer can assess 1) the patient's physical and emotional attractiveness; 2) his or her means of seeking control and whether control is a central issue; and 3) the degree to which the patient is dependent,

passive, aggressive, attention seeking, private, or exploitative in his or her behaviors. Although patients with different styles have different motives for and various ways of expressing these types of behaviors, examining their behavior in each of these categories is likely to provide a productive additional approach to evaluating behavior and adaptive functioning.

### Problematic Patterns of Behavior

Problematic patterns of behavior, such as impulsivity, compulsivity and avoidance, cut across diagnostic groups; looking for these patterns can be a fruitful way of characterizing aspects of maladaptive functioning. Each of these three patterns can arise from a wide array of psychiatric problems. For example, intoxicated people are often disinhibited and impulsive, acting in ways that they would not act if they were sober. However, a manic patient may also be impulsive, often spending money freely or engaging in sexual activity without considering the consequences of these actions. Labeling each of these patterns of behavior impulsive is an important first step in reaching a diagnosis. In addition, finding one type of impulsive behavior should prompt the psychiatrist to look for others and to predict that the patient may act impulsively in the future.

### Impulsive Behaviors

---

#### Clinical Vignette 5

Ms I, a 50-year-old financially comfortable housewife, came for treatment after being arrested for shoplifting (kleptomania). She was puzzled by her urges, stating, "I feel compelled to steal things even though I don't need them and could easily buy them. Half the time I throw them away afterward". Although she felt that she could resist these urges if a security guard was in plain view, she recognized that the threat of being arrested did not deter her at the moment of the theft.

---

#### Clinical Vignette 6

Mr J, a 43-year-old married executive, engaged in cross-dressing (transvestic fetishism). He frequently masturbated to orgasm while wearing his wife's lingerie, paying little attention to whether his wife would suspect him when she discovered the soiled undergarments.

Impulsive behaviors are actions that arise without much delay between the formation of an idea or desire and its gratification in action. Not all impulsive behavior is pathological; in a muted and well-modulated form, impulsivity is closer to spontaneity. Certain personality styles, such as dramatic characters, are more likely to be spontaneous or impulsive than others. In contrast, a person with a conscientious style might decide to think about the purchase for a few days, then return to buy the necklace only to find it gone.

However, in its more extreme forms, impulsivity is often pathological. A number of behaviors that seem dissimilar may have impulsivity as the common and uniting thread. Another advantage of thinking about impulsivity as a distinct pattern of

**Table 20.6 Impulsive, Compulsive and Avoidant Patterns of Behavior**

Pattern	Examples
Impulsive	Self-mutilation Suicide Substance abuse Pathological gambling Binging and purging Hair pulling Kleptomania Pyromania Paraphilias
Compulsive	Handwashing, checking Sexual compulsions Food restriction
Avoidant	Agoraphobia Simple phobias (e.g., acrophobia) Social phobia

problem behavior is that impulsivity in one sphere is often accompanied by impulsive behaviors in other arenas.

Behaviors that are frequently impulsive in nature include self-mutilation and suicide, substance abuse, pathological gambling, binging and purging eating behaviors, and hair pulling. In addition, urges to steal (kleptomania), to set fires (pyromania), or to engage in sexually perverse or unusual behaviors (paraphilias) also result in impulsive behaviors (Table 20.6).

Different types of impulsive behaviors are often experienced in similar ways by patients. One hallmark of impulsive acts is that they are often preceded by a growing internal sense of tension and discomfort that is reduced by the impulsive act itself. Whether the act is hair pulling (trichotillomania) that results in baldness, or pathological gambling that has severe financial consequences, the person is likely to feel that she or he can no longer tolerate the internal tension and that giving in to the impulse will provide relief to an uncomfortable internal state.

#### Clinical Vignette 7

Mr K, a 35-year-old construction worker, experienced irresistible urges to set fires (pyromania). He often did so in a hasty and unpremeditated fashion at construction sites where he worked. Because his actions were poorly planned and executed, he was at risk of being seen setting the fires. Firefighters rapidly concluded that the fires were the result of arson. In addition, Mr K tended to feel compelled to stay and watch the consequences of his actions, enjoying the sight of the fire itself as well as the various equipment used to extinguish it. This meant he was remaining at the scene of his crime for an extended time.

A second characteristic of impulsive acts is that they are often frankly pleasurable at the moment of action even if the person is extremely remorseful afterward.

#### Clinical Vignette 8

Ms N is a 34-year-old woman with obsessive–compulsive disorder who has recurrent, intrusive thoughts about having been contaminated with germs by objects she has touched. These thoughts are pervasive and extremely anxiety producing. She attempts to neutralize them by compulsively cleaning her house and washing her hands. When treated by use of a technique called flooding in which she was not permitted to wash her hands despite her obsessional thought, she became overwhelmingly anxious and panicky.

A third hallmark of impulsive behaviors is that patients are often relatively impervious to the consequences of their actions at the time and tend to underestimate their chances of being caught.

#### Clinical Vignette 9

Mr O is a 38-year-old man who is distressed by the compulsion to masturbate that he feels nearly every morning on awakening with an erection. He describes the activity in detached terms, stating, “I think it’s a waste of time. I don’t enjoy it. I’m often making a mental list of things I have to do at work or even watching morning television programs while I’m masturbating. But I feel nervous for the rest of the day if I don’t do it”.

Patients with impulsive patterns of behavior also tend to underestimate the chances of being caught by a spouse or friend. In addition, the impulsive nature of the action itself may increase the odds of apprehension and punishment.

#### Clinical Vignette 10

Mr R is a 26-year-old man who had his first panic attack while attending church. Because he was sitting in the middle of a pew, he was forced to climb over several people to flee during the attack. He felt this was both scary and embarrassing. Since this initial attack, he has avoided sitting anywhere other than in the back row at the end of the pew while attending services. He feels relatively comfortable sitting in this location because he can escape quickly if another attack occurs. He is not bothered by sitting in the middle of a row at the movies or in a theater.

#### Clinical Vignette 11

Mr S is a 38-year-old man who began having panic attacks in his early twenties. After one unexpected attack while he was on the subway, he began to ride the bus instead. Before long, he had another panic attack on the bus, and began walking to work. Walking took about 1 hour, but he persisted until he had a panic attack in the street. After this attack, Mr S avoided leaving his house unless accompanied by another person, often his brother who lives nearby. His agoraphobia forced him to quit work and apply for disability compensation.

Another feature common to impulsive behaviors is that they often involve a binge, an episode of engaging in a behavior that seems out of control and cannot be terminated by the patient. Often, the binge ends only when an external constraint forces the patient to abandon the action. An eating binge and the relapse of an alcoholic person are often similarly described: “Once I started eating (drinking) I couldn’t stop. I just kept on stuffing myself (ordering drinks) until I was too exhausted and sick (drunk and broke) to continue”.

It is noteworthy that impulsively bingeing on a substance such as alcohol sets the stage for further impulsive behaviors secondary to intoxication.

## Compulsive Behaviors

### Clinical Vignette 12

Ms T, a 24-year-old student, recognized that she was mildly afraid of heights. However, she wished to climb the Mayan temple at Chichén Itzá during her vacation in Mexico. As she started the steep climb to the top, she began to feel anxious and to anticipate arriving at the top and being unable to descend from the monument. Pausing to try to calm down, she turned to look at the ground and began to feel overwhelmingly anxious and afraid of falling. She decided to descend at once but found that her legs felt shaky and weak, making the climb especially frightening. On making it down from the stairs, she vowed never to climb such a monument again.

### Clinical Vignette 13

Mr. M is a 48-year-old executive who suffers from obsessive–compulsive disorder. Despite treatment with a variety of medications including fluoxetine and clomipramine, he has been unable to rid himself of the idea that he has accidentally hit someone while driving to work. Any bump in the road that he notices sets off this obsessive worry, and he feels compelled to circle back to the scene to double-check that he is not guilty of a hit-and-run accident. Sometimes he is not reassured by this initial check and continues to circle the area until “something clicks” and he feels certain that he has not hit anyone. This behavior makes Mr. M as much as 2 hours late for work.

In its muted form, compulsivity can be seen as carefulness or attention to detail. It is easy to see how such attention to detail is helpful in a variety of settings in daily life. Many jobs depend on thoroughness and a willingness to keep working until the books are balanced to the last penny. However, compulsive behaviors become a problem when they begin to consume much more time than necessary and when they are a response to nonsensical thoughts (obsessions).

At first glance, compulsive patterns seem to be the opposite of impulsive patterns of behavior. In compulsive behaviors, a person repetitively behaves in a stereotyped way. Yet repeated impulsive behaviors can become difficult to distinguish from compulsive ones. Is a young female patient who repeatedly gives in to the urge to pull her hair out impulsive or compulsive or both?

In fact, there is evidence that impulsive and compulsive behaviors tend to cooccur in the same individual. In one study, impulsive aggression was found to be common in patients with obsessive–compulsive disorder (Stein and Hollander, 1993). The authors theorized that obsessive–compulsive disorder and impulsivity may both arise from a similar problem in the self-regulation of behavior due to a neuroanatomical lesion in the serotonergic system. They found that treating the obsessive–compulsive disorder with serotonin reuptake inhibitors also decreased these patients’ impulsive aggression.

The compulsions of obsessive–compulsive disorder, food-restricting behaviors such as those found in anorexia nervosa, and compulsive sexual behavior are common types of compulsivity (see Table 20.6). Like impulsive behaviors, compulsions share common features and are experienced in similar ways by patients. However, the driving force behind compulsive behaviors is not the gratification of impulses, but rather the prevention or reduction of anxiety and distress.

### Clinical Vignette 14

Ms. N is a 34-year-old woman with obsessive–compulsive disorder who has recurrent, intrusive thoughts about having been contaminated with germs by objects she has touched. These thoughts are pervasive and extremely anxiety producing. She attempts to neutralize them by compulsively cleaning her house and washing her hands. When treated by use of a technique called flooding in which she was not permitted to wash her hands despite her obsessional thought, she became overwhelmingly anxious and panicky.

The concept that compulsive behavior is an attempt to reduce anxiety is easy to understand when the behavior is a response to an obsessive thought. However, even when the compulsive behavior is sexual in nature, it is driven by the need for anxiety reduction rather than by sexual desire (Coleman, 1992).

### Clinical Vignette 15

Mr. O is a 38-year-old man who is distressed by the compulsion to masturbate that he feels nearly every morning on awakening with an erection. He describes the activity in detached terms, stating, “I think it’s a waste of time. I don’t enjoy it. I’m often making a mental list of things I have to do at work or even watching morning television programs while I’m masturbating. But I feel nervous for the rest of the day if I don’t do it.”

## Avoidant Behaviors

### Clinical Vignette 16

Mr. P is a 55-year-old man who was robbed at gunpoint 1 year ago after visiting an automated teller machine to withdraw money. Since the robbery, he has felt somewhat afraid when using the automated teller machine in the daytime, although this fear has diminished over time. He has avoided needing to use the automated teller machine at night by carefully planning his finances since the robbery.

**Clinical Vignette 17**

Ms. Q is a 40-year-old woman who works in a university library. She has gradually become more accustomed to dealing with patrons at the reference desk but continues to prefer the solitary task of looking for books that are misshelved. Despite her boss's encouragement, she has decided not to apply for a higher level job that would involve teaching groups of new employees about the library computer system. She realizes that she is passing up a good career opportunity, but she also recognizes that the public speaking and writing on the board that this new position would entail are terrifying to her. She worries that she will stammer and blush and make a fool of herself in front of the group. Even now, she feels uncomfortable on her lunch break because she is reluctant to join other employees in the cafeteria.

As with impulsivity and compulsivity, avoidance in its modulated form can be positive; learning from past negative experiences and avoiding prior mistakes are important capacities.

Avoidant behaviors usually arise from a patient's history of being fearful or concerned that he or she will become fearful in a given situation. Because of the past history or the perceived threat, the anxiety-provoking situation is avoided. Avoiding the situation means avoiding the fear and anxiety the situation threatens to produce.

**Clinical Vignette 18**

Mr. R is a 26-year-old man who had his first panic attack while attending church. Because he was sitting in the middle of a pew, he was forced to climb over several people to flee during the attack. He felt this was both scary and embarrassing. Since this initial attack, he has avoided sitting anywhere other than in the back row at the end of the pew while attending services. He feels relatively comfortable sitting in this location because he can escape quickly if another attack occurs. He is not bothered by sitting in the middle of a row at the movies or in a theater.

One study showed that fear and avoidance ratings were highly correlated both at baseline level and after behavior therapy for agoraphobia (Cox *et al.*, 1993). In another study, panic disorder patients with agoraphobia were differentiated from panic disorder patients without agoraphobia by increased rates of anxiety-relevant cognitions in the agoraphobic group (Ganellen *et al.*, 1986).

Another feature common to avoidant behaviors is that they become self-reinforcing and tend to worsen in severity over time if left untreated.

**Clinical Vignette 19**

Mr. S is a 38-year-old man who began having panic attacks in his early twenties. After one unexpected attack while he was on the subway, he began to ride the bus instead. Before long, he had another panic attack on the bus, and

began walking to work. Walking took about 1 hour, but he persisted until he had a panic attack in the street. After this attack, Mr. S avoided leaving his house unless accompanied by another person, often his brother who lives nearby. His agoraphobia forced him to quit work and apply for disability compensation.

**Clinical Vignette 20**

Ms. T, a 24-year-old student, recognized that she was mildly afraid of heights. However, she wished to climb the Mayan temple at Chichén Itzá during her vacation in Mexico. As she started the steep climb to the top, she began to feel anxious and to anticipate arriving at the top and being unable to descend from the monument. Pausing to try to calm down, she turned to look at the ground and began to feel overwhelmingly anxious and afraid of falling. She decided to descend at once but found that her legs felt shaky and weak, making the climb especially frightening. On making it down from the stairs, she vowed never to climb such a monument again.

A further common feature of avoidant behaviors is their tendency to heighten anticipatory anxiety and precipitate the very reactions that a person fears.

**Conclusion**

In evaluating the adaptiveness of a person's behavior, an understanding of the strengths and weaknesses of various character styles and the constraints and demands of the external environment is essential. Behavior is the final common pathway for the expression of genetics, temperament, personality traits and psychiatric symptoms. Behavior is an observable entity in a field where many important aspects of a patient's internal life must be inferred by the psychiatrist. Although some behaviors are clearly more adaptive than others, emphasizing the strengths of a person's capacities is important. Even pathological behaviors often represent a person's best attempt at adaptation; a paranoid patient who installs extra locks on the door may be doing the best she or he can in the face of illness to survive, to cope and to adapt to the environment the patient perceives around her or him.

# Cultural Aspects of Psychiatric Disorders

---

## Introduction

From the outset, psychopathological research has usually assumed that mental disorders exist as “objective” states and can be evaluated with universal and standardized criteria, forgetting, in part, the impact of social, economic, cultural, and political factors in the explanation of psychopathological disorders. This oversight is all the more critical when comparing culturally distinct groups. However, in the last 30 years this oversight has been mitigated by significant contributions in cross-cultural research, whose objective has been to understand the cultural component of psychopathology.

This research, which has increased dramatically since the 1970s and 1980s, was consolidated via the creation of a group working on cross-cultural studies for the preparation of the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (DSM-IV-TR) (American Psychiatric Association, 1994; Mezzich *et al.*, 1993). The Manual contains three kinds of information relating to cultural factors: 1) in the clinical presentation of disorders, a discussion of cultural variants of each disorder, called symptoms dependent on culture and gender; 2) guidelines for a “cultural formulation” of the clinical presentation to help clinicians perform a culturally sensitive diagnosis; and 3) a description of “culture-bound” syndromes, including the name of the disorder, the cultures in which it has been diagnosed, and a brief description of the psychopathology associated with each clinical presentation (the last two sections are included in Appendix I of the DSM-IV-TR). The ICD-10 has also been revised and updated to account for cultural factors, as evidenced by the emergence of new diagnostic systems such as the *Chinese Classification of Mental Disorders* and the *Latin American Guide for Psychiatric Diagnosis* (Berganza *et al.*, 2001; Mezzich *et al.*, 2001). While both of these culturally sensitive diagnostic manuals recognize the value of local cultural requirements to enhance the validity of psychiatric diagnosis, they also illustrate the complementary need to integrate such systems of diagnosis into a global and reliable diagnostic language (Lee, 1993; Berganza *et al.*, 2001).

The existence of a rich modern tradition of cross-cultural research and debate led directly to the increased attention to cultural factors in DSM-IV-TR. In turn, the publication of the manual stimulated continued research on the influence of cultural factors on the etiology, symptomatology, course and treatment outcome of psychopathological disorders. In this chapter, we will focus on cultural considerations pertinent to the use of diagnostic criteria in ethnically and culturally diverse populations. We will also comment briefly on related culture-bound syndromes.

## Specific Cultural Considerations

### Cognitive Disorders

Less attention has been paid to cultural variants of the cognitive disorders than to other psychopathological forms, probably because of the widespread assumption that this group of disorders is influenced exclusively by biological factors. Nevertheless, these disorders show several kinds of social, cultural and ethnic influences. Given the etiologically based subtyping of the cognitive disorders, these influences are exerted, first, by effects on the nature and rates of the diseases that are the causative agents of these disorders (Lin and Fábrega, 1997).

Socioeconomic factors influence the prevalence rates of diseases affecting the brain. Low industrialization of a country or the poverty of a particular social group tends to increase the rates of infectious diseases, nutritional disorders, toxic exposures (e.g., lead), head injuries, endocrinological abnormalities and seizure disorders among others (Cruickshank and Beevers, 1989). This, in turn, may result in differences in the rates of the subtypes of dementia, of delirium, and of other specific cognitive syndromes (Spector, 1979; Westermeyer and Canino, 1997).

Cultural factors, such as prohibitions against substance use and variations in sexual mores, also affect the rates of alcohol- and drug-related syndromes as well as of acquired immunodeficiency syndrome (AIDS) related organic mental disorders (Agarwal and Goedde, 1990; Kaslow and Francis, 1989). Ethnic determinants are also important. Hypertension and strokes have been suggested to be more prevalent among the African-Americans and some Asian groups; this may result in different rates of multi-infarct dementia (de la Monte *et al.*, 1989). In addition, research on Alzheimer's dementia is currently evaluating reports of lower rates among the Chinese and the Chinese-Americans as well as the African-Americans (de la Monte *et al.*, 1989; Zhang *et al.*, 1990). The detection and assessment of the cognitive disorders are also influenced by social and cultural factors. Social groups that tolerate and even expect substantial decreases in decision-making and self-care among older persons may not be regarded as pathological milder degrees of disorientation among the elderly (Ikels, 1991). Educational level and cultural differences appear to exert separate but intermingled effects on the inappropriately high identification of cognitive impairment with the Mini-Mental State Examination (MMSE) among several ethnic groups, including the Hispanic, Taiwanese, Chinese, Southeast Asian (Williams, 1987), and Afro-Caribbean populations (Richards *et al.*, 2000). Based on a review of the literature and consultations with members of the aboriginal community,

Cattarinich and colleagues (2001) note that differing degrees of acculturation within and between aboriginal groups create problems for cognitive evaluations. On the basis of these and other findings, some researchers have begun to question the adequacy of the MMSE and other cognitive assessment instruments, and as a consequence some practitioners have begun modifying their methods.

## Substance Use Disorders

Sociocultural factors exert considerable influence over some aspects of substance use disorders and not others. The prevalence rates of alcohol and drug abuse and dependence vary significantly across cultures. Lifetime rates for alcoholism, for example, range from 23% among the American Indians to 0.45% among the population of Shanghai (Helzer and Canino, 1992). Specific local factors that affect degree of risk for substance-related disorders include patterns of use, attitudes toward substance consumption, accessibility of the drug, physiological reactions to the same drug, and family norms and patterns (Westermeyer and Canino, 1997) (Table 21.1). Recent studies of teenagers find that different ethnic groups in the US experience different rates of substance abuse (Turner and Gill, 2002). Of even greater concern is the epidemiological finding that rates of alcohol and other substance abuse are higher among the US-born Mexican-Americans than among Mexico-born migrants, and increase with length of stay in the USA, indicating either a pathogenic impact of the US residence, a loss of protective social factors with migration, or both. These findings suggest that interventions should be tailored to the needs of different minority and immigrant populations, particularly as substance abuse has been related to other psychological disorders (Vega *et al.*, 1998; Lee, 2001; Griffin *et al.*, 2000). In part, these differences may be influenced by the way the local culture influences the definition of pathological substance use through differences in the perception of the impairment caused by high consumption and frequent intoxication (Osterberg, 1986). Particular cultural views toward drinking in children, the value of moderation, the tolerance for intoxication, and the association of drinking with family activities and special social occasions appear to influence the degree of risk for alcoholism (Valliant, 1986). The availability of a substance also increases its rates of abuse and dependence (Helzer and Canino, 1992). Sociocultural factors such as religious proscriptions may exert their influence in this fashion. Heath (2001) has remarked on the long tradition of drug inhalation, from tobacco to hallucinogens, in tropical South America, which contradicts the perception in North America

of drug inhalation as a novel, and therefore aberrant, trend (Kirmayer and Groleau, 2001).

Several aspects of substance use disorders appear to be less affected by cultural factors. Such aspects include the comorbidity patterns, the nature of dependence syndromes, the age at onset, and the results of laboratory tests and physical examinations (Westermeyer, 1989). For example, alcoholism is associated in many societies with abuse of other substances, mania and antisocial personality as well as with depression and anxiety (Anthony and Helzer, 1991). Alcoholism and drug abuse are reliably more common among men, although the sex ratio can vary from 2:1 to 4:1 (Helzer and Canino, 1992; Robins *et al.*, 1981). Drug abuse is also more prevalent among urban populations, the less educated, and the young (Anthony and Helzer, 1991). The physical symptoms as well as the temporal relationship between onset of use and dependence are substance-specific and also fairly similar across cultures (Berger and Westermeyer, 1977).

## Schizophrenia and Related Psychotic Disorders

The cross-cultural presentation and course of schizophrenia are among the best-studied aspects of cultural psychiatry. Research has revealed both cross-cultural similarities and differences, both of which are important for elucidating the biological and environmental bases of the disease. A “spectrum” of schizophrenic syndromes – consisting of a combination of certain positive and negative psychotic symptoms – has been found nearly everywhere, although the specific content of hallucinations and delusions as well as the prevalence of visual and other nonauditory hallucinations varies (Krassoievitch *et al.*, 1982; Ndeti and Vagher, 1984). Significant cross-cultural variation has been found, however, in several features of the syndrome. Its distribution is not uniform, ranging from 1 in a 1000 in the nonWestern societies to more than 1% in the West; its highest prevalence is displayed in economically and technologically advanced, urbanized and bureaucratized societies (Kleinman, 1988; Warner, 1985). Its phenomenology varies with cultural setting, with much higher rates of catatonia in India and of hebephrenia in Japan than in the West. Most important, the course and outcome of schizophrenia are markedly better in nonindustrialized countries, even when cultural differences in outcome assessment and in acuteness of presentation are taken into account (Sartorius *et al.*, 1986; Lin and Kleinman, 1988; Kulhara and Chakrabarti, 2001). Variations in outcome are thought to be related in part to different attitudes toward persons with the disorder, a set of culturally patterned interactions studied under the rubric of expressed emotion (Jenkins and Karno, 1992) (Table 21.2). Other cross-cultural variations with regard to schizophrenia include higher misdiagnosis among patients from devalued and ethnic minority groups (Good, 1992/93), differences in cultural and gender-related conceptions

**Table 21.1** Sociocultural Factors Related to Substance Use Disorders

- Attitudes toward substance consumption
- Accessibility of drugs
- Local patterns of drug use
- Ethnic-specific physiological reactions to various drugs
- Immigrant status (protective in some cases)
- Religious proscriptions
- Male gender
- Urban life
- Lower education

**Table 21.2** Sociocultural Factors Associated with Better Outcome in Persons Experiencing Schizophrenia

- Residence in nonindustrialized society
- Social attitudes toward persons experiencing the disorder
- Culturally patterned interactions
- Well-knit support systems

regarding the expression of emotion that complicate the assessment of flat affect (Karno and Jenkins, 1997), and culturally syntonetic experiences that may be mistaken for schizophrenic symptoms. The latter include the accepted appearance of hallucinations among the bereaved Native Americans (Hultkrantz, 1979) or reports of perceptual alterations among the distressed Puerto Ricans (Guarnaccia *et al.*, 1992).

Cross-cultural differences have also been detected in emotional processing among the German, American and Indian subjects with schizophrenia. Face discrimination performance was most impaired in the Indian subgroup (Habel *et al.*, 2000). Another study comparing the German natives and the Turkish immigrants with schizophrenia also found cross-cultural differences, this time in higher indices of hostile excitement and depression among the immigrant group (Haasen *et al.*, 2001).

### Mood Disorders

Contemporary cross-cultural research on mood disorders has focused on unipolar depression syndromes, revealing extensive cultural patterning as well as significant similarities. For example, the World Health Organization Collaborative Study on Depression found a core depressive syndrome in the five countries studied, but it also revealed substantial cross-cultural differences in symptom presentation, affect conceptualization, level of severity, and influence of acculturation, despite a methodology that tended to accentuate similarities at the expense of local differences (Marsella *et al.*, 1985).

Culture and other social factors, such as class and gender, influence the interpretation of and exposure to stressors that predispose to depression (Brown and Harris, 1978). The specific characteristics of the dysphoria of depressive illness also vary cross-culturally. For example, among the Hopi in North America, feelings of guilt, shame and sinfulness are separate experiences displaying distinct relationships to subtypes of depression (Manson *et al.*, 1985). Whereas reports of irritability, rage and “nervousness” are prominent descriptors of depressive affect among the Puerto Ricans and other Latinos (Lewis-Fernández, 2002). The frequent combination of depression and anxiety noted around the world, particularly in primary care settings, has fueled the DSM-IV-TR proposal for a mixed anxiety–depression disorder (Katon and Roy-Byrne, 1991).

In addition, most cross-cultural studies have found a significantly higher rate of somatic complaints associated with depression (and anxiety) among the nonWestern groups than in the Western settings, including the presence of unique symptoms (e.g., “heat or water in the head” and “crawling sensation of worms and ants” in the Nigerian cultures) (Marsella *et al.*, 1985; Ebigbo, 1982). Emotional complaints are often present as well but may not be considered the source of distress or impairment. The mix of emotional and somatic symptoms has also been found to vary by sex in some studies (Clark *et al.*, 1981; Guarnaccia *et al.*, 1989). For example, a study comparing the Puerto Ricans, Mexican-Americans and Cuban-Americans on the Center for Epidemiologic Studies Depression Scale of depressive symptoms found that the women in all three groups tended to endorse depressive and somatic scale items together as a single factor. This happened significantly more often amongst women than men (Guarnaccia *et al.*, 1989).

Finally, the threshold at which dysphoria becomes disorder is affected by cultural factors. The two-week duration criterion for major depression, an important proxy for pathological

intensity, may vary among some nonWestern groups. Manson and colleagues (1985) found that the Hopi identify five distinct indigenous syndromes related to depression, only one of which shares significant parameters with Western depressive disorder. This folk syndrome, however, differed from major depression in its average duration of 1 week, not 2, although still causing comparable morbidity. On the basis of this, duration criterion for major depressive disorder when it is used with the Hopi patients should be shortened (Manson *et al.*, 1985). Conversely, in a study of the Bambui community in Brazil, researchers were surprised to find depressive episodes averaging 1 month, higher than that observed in similar studies in many other societies (Vorcaro *et al.*, 2001).

The substantial overlap of depression with anxiety, somatoform and dissociative disorders implies a higher probability of under-recognition or misidentification of affective disorders in many ethnocultural groups (Kirmayer and Groleau, 2001). These findings raise serious issues about the universality of the prototypical representation of depression in the North American psychiatry and the operational criteria of the depressive disorders, and tend to support the phenomenological expansion of the depression categories (Manson and Good, in press; Kirmayer and Groleau, 2001).

### Anxiety Disorders

The effect of culture on anxiety is similar to that on depression, especially since cross-cultural studies have shown a marked tendency for anxiety and depression to overlap (American Psychiatric Association, 1994). Cultural factors affect the precipitants, symptom presentations, pathological thresholds and specific syndrome criteria of the anxiety disorders (Good and Kleinman, 1985). For example, the cross-cultural validity of criterion A for the *Diagnostic and Statistical Manual of Mental Disorders*, Third Edition, Revised (DSM-III-R) generalized anxiety disorder (GAD) has been challenged because it restricts the diagnosis of chronic pathological anxiety to a disturbance stemming from undue worry in the absence of actual stressors or excessive worry after minor stress. This leaves out the much larger group of patients in developing societies and devalued minorities in the West who experience chronic pathological anxiety as a result of recurrent stress (Lewis-Fernández and Kleinman, 1995).

Cultural and ethnic elements have been invoked to explain local differences in anxiety disorder prevalence that persist after controlling for other social factors. For example, the higher rate of simple phobia social phobia and agoraphobia among the African-Americans, as compared with whites (Neal and Turner, 1991), has been attributed to the stress resulting from racial discrimination (Brown *et al.*, 1990). In fact, the cross-cultural epidemiological literature reveals a complex pattern of similarities and differences with regard to the anxiety disorders, and opinions differ as to the role of culture in this process (Guarnaccia and Kirmayer, in press). For example, it is presently unclear why the Mexicans born in Mexico, when compared with those born in the USA, show a markedly lower rate of anxiety and other disorders. Suggested explanations include selective migrations, different thresholds for perceiving and reporting a disorder stemming from distinct cultural interpretations of what constitutes a “hard life” and acceptable suffering, and a combination of both explanations (Shrout *et al.*, 1992).

Multiple cross-cultural studies point to the coappearance of anxiety, depression, somatoform complaints and dissociative

symptoms among the nonWestern groups. A markedly somatic idiom predominates, often in the form of culturally specific symptoms (Ebigbo, 1982). These often coalesce distinctively as culture-bound syndromes characterized also by specific etiological factors, demographics, patterns of impairment and help-seeking choices (Hughes *et al.*, in press). It is far from clear that this represents the comorbidity of the Western disorders rather than a different organization of pathological experience (Maser and Dinges, 1992). Examples include *ataque de nervios* among the Latinos, *koro* in the Asian communities and *taijin kyofusho* among the Japanese (Guarnaccia and Kirmayer, in press). Each of these disorders exhibits significant differences that prevent simple one-to-one correlations with the established Western categories (Weiss, 1996).

### Somatoform Disorders

In a survey of international use of DSM-III and DSM-III-R, somatoform disorders were among the more problematic diagnoses (Maser *et al.*, 1991), probably because of their cross-cultural limitations (Kirmayer and Weiss, 1997). First, many nosologies around the world do not distinguish between mood, anxiety, somatoform disorders and dissociative disorders, because sufferers report single syndromes that run across boundaries of the diagnostic categories (Lewis-Fernández, 1992). This is similar to the situation with depression, where a single description of the disorder has led to under-recognition and misidentification of depressive syndromes in many ethnocultural groups (Kirmayer and Groleau, 2001). Demarcating somatoform conditions in these settings may create artificial distinctions that confound accurate diagnosis. Examples include neurasthenia in China and other Asian settings, and *nervios* in Latin America (Lin, 1989; Angel and Guarnaccia, 1989).

Secondly, the idioms of distress of many societies rely on somatic complaints for the expression of nonpathological, personal and social predicaments. Interpretations of these communication mechanisms as a somatoform disorder may result in overpathologization (Kirmayer and Robbins, 1991). In addition, the use of somatic idioms varies according to intracultural factors, such as gender and class, which in turn may determine who receives a somatoform diagnosis. For example, conversion symptoms appear to be more common in the rural and less educated sector of nonWestern societies, and particularly in family or social structures that allow few opportunities for protest (Kirmayer and Weiss, 1997; Nichter, 1981).

Thirdly, the symptom lists of DSM-III-R and DSM-IV-TR do not canvas the rich variety of somatic symptoms reported in other parts of the world, such as the complaints of worms and ants in the head described earlier (Ebigbo, 1982). Examples of other common somatic symptoms include chronic fatigue; heat in the feet, chest, or head; painful “gas” that moves from the abdomen around the flank to the back; “brainache”; and feeling presences when alone or among others.

Fourthly, in most of the world, the degree to which symptoms are medically unexplained is difficult to ascertain owing to the marked limitation of diagnostic tests and medical personnel. Moreover, the high prevalence of endemic disease in the underdeveloped countries, often with protean and inchoate manifestations, may also confound the assessment of the somatoform disorders. This may result in overdiagnosis if organic causes are not identified, or underdiagnosis if organic explanations are uncritically accepted for systemic illness (Kirmayer and Weiss, 1997).

### Dissociative Disorders

Syndromes characterized by pathological dissociation are common worldwide, but the current concepts of dissociative disorders do not appear to account for their phenomenological variety (Lewis-Fernández, 1992; González *et al.*, 1997). For example, a study performed in an outpatient psychiatric clinic in India found that more than 90% of dissociative disorder cases did not fulfill criteria for the specified categories, ironically receiving instead a DSM-III diagnosis of atypical dissociative disorder. Distressing trance states and possession trance episodes constituted most of these cases (Saxena and Prasad, 1989). These instances of misdiagnosis again call to question the usefulness of some of the standard diagnostic categories of North American psychiatry (Kirmayer and Groleau, 2001). Many indigenous illness syndromes around the world display salient features of pathological dissociation. Some of these syndromes are characterized by involuntary possession trance – dissociative alterations in identity attributed to the invasion by external spirits or agents – distinguished from dissociative identity disorder by their episodic and remitting course, the nature and number of their alternative identities and their gradual response to treatment. These syndromes have been identified in India, western Africa, China, Malaysia, Brazil and the Caribbean, among many other settings (Lewis-Fernández, 1994; Ward, 1989; Spiegel and Cardeña, 1991).

Other dissociative syndromes are characterized by alterations of consciousness and memory, during which the person runs around in an agitated state (Arctic *pibloktoq*); attacks others indiscriminately (Malayo-Indonesian *amok*); undergoes convulsive movements, screaming fits and aggressive acts toward self or others (Caribbean *ataque de nervios*); or lies as if dead, suffering from specific perceptual alterations; hears and understands what is happening but cannot see or move (“falling out” among the African-Americans in southern USA, Bahamian “blacking out”, and Haitian *indisposition*) (González *et al.*, 1997; Cardeña *et al.*, 2002; Weidman, 1979). In a recent study, Lewis-Fernández and colleagues (1997) confirmed the association between *ataque de nervios* and dissociation. Among the female Puerto Rican psychiatric outpatients, *ataque* frequency was directly related to self- and clinician-ratings of dissociative symptoms and disorders. Of note, patients with and without *ataque* did not differ on measures of childhood trauma, which was uniformly high among subjects (Lewis-Fernández *et al.*, 1997). The proposed dissociative trance disorder category in DSM-IV-TR would provide a Western nosological niche for these disorders, although not without the risk of overpathologizing some culturally accepted instances of these behaviors (Lewis-Fernández, 1992).

In fact, extensive cross-cultural research reveals that most dissociative experiences around the world are completely normal, usually forming part of religious and ritual events (Lewis-Fernández, 1994). The Western emphasis on pathological experiences of dissociation that result from overwhelming trauma probably stems from the relative absence of normal dissociation among the dominant Western groups and from the acknowledgment by mental health professionals of the sequelae of physical and sexual abuse (Ross, 1991; Martínez-Taboas, 1991). Depersonalization, considered one of the most common psychiatric symptoms in the West (Steinberg, 1991), is a greatly desired goal for Hindu yogis, revealing the substantial cultural patterning of dissociative experience (Castillo, 1991).

## Sexual Disorders

Research on cross-cultural influences on sexual disorders is limited, owing to the lack of uniform descriptive methodology and to the fact that the major ethnic minorities in the USA do not seek medical treatment for this class of complaints (Davis and Herdt, 1997). Some cross-cultural studies have concluded that the paraphilias as currently characterized in the DSM-IV-TR are determined by specific features of the Western society, such as demographical size and complexity (whereby individuals may escape social sanction through anonymity), the nonavailability of partners, and the primacy of masturbatory activities as sexual outlets (Rooth, 1973; Gebhard, 1971). Despite a few small clinical studies that found similar rates of sexual dysfunctions among African-American populations (Fisher, 1980; Finkle and Finkle, 1978), most cross-cultural research suggests that sexual response is influenced by cultural and ethnic considerations. Racist stereotypes, machismo, anxiety about infertility, and the tendency toward somatization of mood disorders as impotence have been cited as etiological factors of sexual dysfunction in African-American and Latino populations (Wyatt, 1982; Espin, 1984). In addition, the ethnographical literature shows that standards for sexual competence differ across the cultural spectrum and that many societies display a more flexible approach to issues of sexual orientation than is assumed by the diagnostic categories (Davis and Whitten, 1987; Herdt, 1990).

This cross-cultural diversity complicates the assessment of the sexual disorders. At present, it is unclear whether certain culture-bound syndromes involving sexual organs, such as *koro* among the Asians (characterized by the fear of genital retraction) or *dhat* in India (involving obsession or anxiety about semen loss), should be categorized among the sexual or the somatoform disorders (Davis and Herdt, 1997).

## Eating Disorders

Research has disclosed a significant cultural effect on the patterning and distribution of the eating disorders. An important determinant appears to be the Western premium on thinness as an esthetic and moral value (Ritenbaugh, 1982; Nichter and Nichter, 1991; Banks, 1992). Cases of eating disorder have been found in many nonWestern societies and several ethnic minorities in the USA, but their presenting features often differ somewhat from the DSM-IV-TR criteria for anorexia nervosa and bulimia nervosa (Shisslak *et al.*, 1989).

Groups at high risk include those experiencing rapid acculturation to the Western society, such as immigrants or those living in areas undergoing accelerated industrialization (Ritenbaugh *et al.*, 1997). For example, one study found a 12% prevalence of DSM-III eating disorders among the Egyptian female college students in London and no evidence of these conditions among a similar sample in Cairo (Nasser, 1986). Although it is as yet unclear exactly how acculturation predisposes the nonCaucasians to eating disorders, as a rule these conditions are more prevalent among the Caucasians than persons of other ethnic backgrounds (Wildes *et al.*, 2001). Bulimia nervosa appears more common than anorexia nervosa among the US minorities and is often associated with higher than average weight, female sex and sometimes older age, for example, among the American Indian groups (Rosen *et al.*, 1988). Anorexia nervosa has been found among lower socioeconomic class samples in several cultures but often characterized by atypical features, such as the absence of distorted body image or of the fear of gaining weight (Suematsu

*et al.*, 1985; Lee *et al.*, 1989). Cross-cultural studies have proposed more flexible diagnostic criteria for anorexia nervosa so that abdominal fullness, epigastric pain, or distaste for food may be accepted instead of intense fear of weight gain to account for the severe restriction of food intake or other weight-losing behavior (Lee, 1991).

## Adjustment Disorders

The effect of culture on the adjustment disorders is pervasive. Culturally based interpretations are essential to the appraisal of the repertoire of behavioral and emotional responses that pattern both normal and disordered reactions to stress (Jenkins and Kinzie, 1997). Whereas some experiences are uniformly stressful (e.g., natural disaster), others may make sense only within particular cultural contexts (e.g., facing deadlines, witchcraft accusations) (Fábrega and Mezzich, 1987). In addition, the judgment of what constitutes a maladaptive response to a stressor must be made in relation to what exceeds cultural norms (Kleinman, 1988). Diagnosis of an adjustment disorder may be a particular problem among refugee populations. These groups have undergone distressing experiences, but their intensively challenged coping styles may be unknown to caregivers in the host country (Beiser, 1996).

## Personality Disorders

The current configuration of the personality disorders has received substantial cross-cultural challenge. Even the basic concept of personality as a set of individual internal traits is considered inseparable from the Western cultural assumptions on individuality by many authors (Lewis-Fernández and Kleinman, 1993). Difficulties in the reliable assessment of these disorders within the Western cultures may be due to the degree to which these conditions are determined by social and contextual factors. These factors include adaptational strategies toward adverse communal environments (including the relative value of aggression or avoidance), family-based customs and traditions, occupational and educational options and cultural methods of child-rearing (Alarcón and Foulks, 1997). It is striking, for example, that the antisocial personality disorder is nearly absent among the Hutu-terites, an ethnoreligious enclave living for more than a century in the USA and Canada (Favazza, 1985). Intracultural diversity may be more important in this respect than cross-cultural difference. For example, in his studies of affective and personality disturbances among the Inuit and the Yoruba, Leighton (1981) was unable to disentangle cultural influences from “the much more powerful effects” of gender, age and class.

Epidemiological assessment of DSM-III antisocial personality disorder has been performed as part of the Epidemiological Catchment Area study using a clearly operationalized survey instrument, the Diagnostic Interview Schedule (Robins *et al.*, 1984). This yielded similar prevalence rates in the USA and Puerto Rico (Canino *et al.*, 1987). However, low reliability rates for the diagnosis of personality disorders across standardized instruments raise serious doubts about the validity of this aspect of the Epidemiological Catchment Area study data (Perry, 1992). One World Health Organization study was able to identify cases of most of the *International Classification of Diseases* personality disorders in 15 urban clinic samples in Africa, Asia, North America and Europe (Paris, 1991), but the cross-cultural validity of the definitions of these categories had been criticized earlier by Shepherd and Sartorius (1974).

## The Case of Culture-bound Syndromes and Idioms of Distress

Investigation of so-called culture-bound syndromes was geared for decades toward incorporation of these “exotic” categories into the Western nosologies (Simons and Hughes 1985). The term “culture-bound” (Table 21.3) was used to describe a certain number of psychiatric disorders whose phenomenologies made them distinct from the Western categories and that theoretically could be singled out as unique to a particular cultural setting (Hughes *et al.*, 1997). The clear implication was that the Western categories were not culture-bound but rather universal, and that proper characterization would disclose a translation key for specific nonWestern syndromes. However, these conditions have been studied more critically to understand instead the culture-bound nature of the Western classification schemes themselves and to enable the appropriate treatment of patients whose understandings and presentation of illness conform to these indigenous categories (Good, 1994; Good and Delvecchio Good, 1982).

Contemporary cultural psychiatry recognizes that all classification schemes are inherently cultural and subjects Western nosologies to the same kind of social analysis that it continues to apply to the indigenous nosologies (Lewis-Fernández and Kleinman, 1995). In this modern sense, “cultural-bound syndrome” is an inherited and controversial term that is used in practice to describe psychiatric categories, whether they are part of the Western or nonWestern nosologies, on whose emergence, manifestation, or course culture is thought to exert a particularly strong influence (Hahn, 1985; Guarnaccia, 1993). The term continues to refer to relatively consistent illness categories with characteristic courses (“syndromes”) and specific labels, some of

which are discussed in this chapter (e.g., *amok*, *taijin kyofusho*, *anorexia nervosa*). The organizing principle that unifies a syndrome conceptually can be 1) a collection of symptoms, which can follow diverse classificatory schemes (descriptive); 2) a cause, including an immediate precipitating context (etiological); or 3) a response to treatment (Good and Delvecchio Good, 1982).

“Idiom of distress” is a newer term, which was coined to refer to a more general level of analysis (Nichter, 1981). Rather than denoting specific syndromes, the term refers to the more general illness “languages” of social groups, the culturally preferred ways of expressing distress, such as by somatic complaints, psychologizing explanations, possession or witchcraft terminology, oppositional or violent behavior illnesses due to “nerves”, or attributions of inexplicable misfortune. In this sense, a given idiom of distress, such as somatization, can be expressed as multiple culture-bound syndromes such as *ataques de nervios*, *neurasthenia*, “brain fog”, and so on. DSM-IV-TR presented a substantial list of culture-bound syndromes and idioms of distress in one of its appendices.

Contemporary use of this terminology allows us to understand certain difficulties in the integration of the Western and nonWestern categories of psychiatric illness (Lewis-Fernández, 1992; Wig, 1983). First, the Western nosologies are based at present nearly exclusively on descriptive parameters. Wary of “theoretical” causes, our current diagnostic system privileges a formal definition of psychopathological processes. Most indigenous nosologies, on the other hand, distinguish illness from normality at least as much on the basis of contextual characteristics as on descriptive ones. These include assessments regarding appropriateness of the symptom in the particular setting at the specific time in question, the relative sufficiency of precipitating stressors, and the nature and quality of the human relationships of the sufferer. These discrepancies between the organizing principles of the Western and nonWestern nosologies prevent an easy consolidation of psychopathological criteria across cultures.

Secondly, nosologies also differ in the configurations of their phenomenologies (Kleinman, 1988; Weiss, 1996; Good and Delvecchio Good, 1982). The symptoms of many culture-bound syndromes, such as *amok* in Malaysia, or *ataque de nervios* in Puerto Rico, are composed of a variety of behavioral and experiential elements that are considered by the Western nosologists to belong to separate diagnostic categories. The characteristic presentations of these conditions exhibit diverse combinations of dissociative, psychotic, anxiety, depressive, characterological and somatic symptoms (Lewis-Fernández, 1992). Significant phenomenological variation occurs among individual cases, which are nevertheless unifying under a single nosological label.

These differences in definitions of illness and phenomenological organization between the Western and nonWestern categories ensure that the two nosologies are overlapping as global systems. From the psychiatric perspective, a cohort of individuals identified by a cohort indigenous label will prove to be diagnostically heterogeneous or even nonpathological. The obverse is that almost homogeneous psychiatric cohorts will appear locally verse. A nomographical, one-to-one relationship between the Western and nonWestern nosologies appears thus unattainable (Weiss, 1996). What is achievable is the systematic characterization of individual cases of persons suffering from culture-bound syndromes in terms of the Western categories of psychiatric illness, retaining at the same time an account of their distinct definitions of illness, idioms of distress, unique symptoms and other associated factors in the form of a cultural formulation

**Table 21.3** Culture-bound Syndromes and Idioms of Distress Listed in DSM-IV

- *amok*
- *ataques de nervios*
- bilis and colera
- *boufée delirante*
- brain fog
- *dhat*
- falling out or blacking out
- ghost sickness
- *hwa-byung*
- *koro*
- *latah*
- *locura*
- *mal de ojo*
- *nervios*
- *pibloktoq*
- *qi-gong* psychotic reaction
- rootwork
- *sangue dormido*
- *shenjing shuairuo*
- *shen-k'uei*; *shenkui*
- *shin-byung*
- spell
- *susto*
- *taijin kyofusho*
- zar

**Table 21.4 Components of the DSM-IV Outline for a Cultural Formulation**

- Cultural identity of the individual
- Cultural explanations of the individual's illness
- Cultural factors related to psychosocial environment and levels of functioning
- Cultural elements of the relationship between the individual and the clinician
- Overall cultural assessment for diagnosis and care

(Mezzich and Good, 1997) (Table 21.4). This iterative process of translation will result eventually in a comprehensive cultural psychiatry that integrates diverse local and professional classifications of psychiatric illness with the goal of more effective communication and care of patients.

In spite of the importance of including culture-bound syndromes in the DSM-IV-TR, Guarnaccia and Rogler (1999) warn that important methodological issues remain unaddressed, since DSM-IV-TR does not include a system of norms to delimit the range of psychiatric disorders that relate to particular culture-bound syndromes, nor include these cultural conditions within the established disorder categories.

## Conclusion

The importance of culture in the understanding of psychopathology is revealed by the literature summarized in this chapter. However, future studies must evolve to include psychological and psychiatric measures that are relevant and appropriate for distinct cultural groups, since many cross-cultural studies utilize the Western concepts to explain the modes of expression of psychopathological manifestations (Kirmayer and Groleau, 2001), ways of seeking aid, use of mental health services, or treatment outcome, without taking into account their close relationship with cultural factors (Aneshensel and Phelan, 1999). At the same time, new possibilities are emerging for the application of cultural information to diagnostic systems and the diagnostic process. This chapter has focused on some of the most conspicuous contributions aimed at enhancing the cultural suitability of DSM-IV-TR, and thus on the use of diagnostic categories and criteria in multicultural settings. Other contributions, such as the glossary of culture-bound syndromes and idioms of distress and the guidelines for a cultural formulation, have been referred to succinctly. Cultural developments are also being worked into the family of classifications of the *International Classification of Diseases and Related Health Problems*, 10th Revision (Mezzich, 1995). All these efforts promise to increase the applicability and usefulness of the new diagnostic systems for our multicultural world. Further, they may encourage psychiatrists and the field as a whole to stay focused on the person of the patient and his or her context to augment the validity of diagnosis and the effectiveness of clinical care.

PART

Five Disorders

---

## Introduction

There is a natural human predilection to categorize and classify for simplifying and organizing the wide range of observable phenomena and experiences that one is confronted with, thus facilitating both their understanding and their predictability. The current system for the diagnosis of mental disorders, the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (DSM-IV) (American Psychiatric Association, 1994), is just the latest example from the long and colorful history of psychiatric classification. Although there was a more recent text revision, DSM-IV-TR (American Psychiatric Association, 2000), we will refer to DSM-IV as the “current” version since DSM-IV-TR primarily differs with respect to the textual descriptions of the disorders. The classification, diagnostic terms and virtually all of the diagnostic criteria are identical (First and Pincus, 2002).

## Goals of a Classification System

Perhaps the most important goal of a psychiatric classification is to allow mental health practitioners and researchers to communicate more effectively with each other by establishing a convenient shorthand for describing the mental disorders that they see (First, 1992). For example, saying to a colleague that a patient has major depressive disorder can convey a great deal of information in only a few words. First of all, it indicates that depressed mood or loss of interest is a central aspect of the presenting problem and that the depression is not the kind of “normal” mood fluctuation that lasts for only a few days but rather that it persists every day for an extended period of time, for at least 2 weeks. Furthermore, one can expect to find a number of additional symptoms occurring at the same time, like suicidal ideation and changes in appetite, sleep, energy and psychomotor activity. Finally, information is also communicated about what is not to be found in this patient – specifically, that the depression is not caused by the direct physiological effects of alcohol, other drugs, medications, or a general medical condition; that substance use and general medical conditions have been ruled out as etiological factors; and that there is no history of schizophrenia or manic or hypomanic episodes.

DSM-IV also facilitates the identification and management of mental disorders in both clinical and research settings. Most of the DSM-IV diagnostic labels provide considerable and important predictive power. For example, making a diagnosis of bipolar disorder suggests the choice of treatment options (e.g., mood stabilizers), that a certain course may be likely (e.g., recurrent and episodic), and that there is an increased prevalence of this disorder in family members. By defining more or less homogeneous groups of individuals for study, DSM-IV can also further efforts to understand the

etiology of mental disorders. The classifications of the manual have been a reflection of, and a major contribution to, the development of an empirical science of psychiatry. DSM-IV also plays an important role in education. In its organization of disorders into major classes, the system offers a structure for teaching phenomenology and differential diagnosis. DSM-IV is also useful in psychoeducation by showing patients that their pattern of symptoms is not mysterious and unique but rather has been identified and studied in others.

## Approaches to Classification

### Etiological Versus Descriptive

Historically, there have been two fundamental approaches to formulating systems of psychiatric classification: etiological and descriptive. Etiology-based classification systems organize categories around pathogenetic processes so that disorders corresponding to a particular category share the same underlying cause. Because the etiological basis for most psychiatric conditions remains elusive, etiological classification systems tend to be based instead on a particular conceptualization of the process of mental disorders. Although such classifications may be heuristically useful to proponents of the particular conceptualization that forms the basis of the system, they are often considerably less useful for proponents of different etiological principles, which greatly limits their utility. For this reason, a descriptive approach to classification has proved to be of greater utility given our current understanding. The descriptive approach aims to eschew particular etiological theories and instead relies on clinical descriptions of presenting symptoms. This approach, advanced by the work of the 19th century psychiatrist Emil Kraepelin, formed the basis for the system of classification of the *Diagnostic and Statistical Manual of Mental Disorders*, Third Edition (DSM-III) introduced in 1980. As a result, DSM-III and its successors, the *Diagnostic and Statistical Manual of Mental Disorders*, Third Edition, Revised (DSM-III-R) and DSM-IV, have proved to be useful in a variety of different settings and by psychiatrists of widely different backgrounds and conceptual orientations.

### Syndrome Versus Symptom

Given that the manual lacks a specific etiological conceptualization, what is its organizing principle? The fundamental element is the syndrome, that is, a group or pattern of symptoms that appear together temporally in many individuals. It is assumed that these symptoms cluster together because they are associated in some clinically meaningful way, which perhaps may reflect a common etiological process, course, or treatment response.

**Table 22.1 Example of DSM-IV Multiaxial Evaluation\***

Axis I	296.23 Major depressive disorder, single episode, severe but without psychotic features, with postpartum onset 307.51 Bulimia nervosa
Axis II	301.6 Dependent personality disorder Frequent use of denial
Axis III	Rheumatoid arthritis
Axis IV	Partner relational problem
Axis V	GAF = 35 (current)

\*GAF, Global Assessment of Functioning Scale score.

Although it was hoped that the syndromes identified in the DSM represented relatively homogeneous subpopulations of patients, over the past 20 years since the publication of these definitions in DSM-III, the goal of discovering common etiologies for each of the DSM-defined syndromes has remained elusive. Epidemiologic and clinical studies have shown extremely high rates of comorbidities among the disorders, undermining the hypothesis that the syndromes represent distinct etiologies. Furthermore, epidemiologic studies have shown a high degree of short-term diagnostic instability for many disorders. With regard to treatment, lack of specificity in treatment response is the rule rather than the exception. The efficacy of many psychotropic medications cuts across the DSM-defined categories. For example, the selective serotonin reuptake inhibitors (SSRIs) have been demonstrated to be efficacious in a wide variety of disorders from many different sections of the DSM, including major depressive disorder, panic disorder, obsessive-compulsive disorder, dysthymic disorder, bulimia nervosa, social anxiety disorder, post traumatic stress disorder generalized anxiety disorder, hypochondriasis, body dysmorphic disorder and borderline personality disorder. Results of twin studies have also contradicted the DSM assumption that separate syndromes have a different underlying genetic basis. For example, twin studies have shown that generalized anxiety disorder and major depressive disorder may share the same genetic risk factors (Kendler, 1996), and evidence from molecular genetics research (Berrettini, 2000) indicates that three of the putative susceptibility loci associated with DSM-defined bipolar disorder also contribute to the risk of DSM-defined schizophrenia.

Given these clear limitations in the syndromal approach, it is important that users of the DSM resist the temptation to reify the DSM diagnostic categories as if they were actual diseases. They are best viewed as clinically useful constructs that are helpful in facilitating communication and record keeping and in selecting treatment. As more information about the causes of mental disorders become evident over the next decades, it is more than likely that the syndromal approach will be replaced by a classification system that is more reflective of the underlying etiology and pathophysiology.

### Categorical Versus Dimensional

The diagnoses included in DSM-IV are defined categorically, that is, diagnostic criteria are provided that indicate whether an individual's clinical presentation either meets or does not meet the diagnostic criteria for a particular disorder. This method of

classification is similar to what is used in other fields in medicine, namely that a patient either has or does not have a particular diagnosis, like pneumonia, colon cancer, multiple sclerosis, and so on. This tendency to define illness in terms of categories is undoubtedly due to the fact that it is reflective of basic human thought processes, embodied by the use of nouns in everyday speech to indicate categories of "things" (e.g., chairs, tables, dogs, cats).

In principle, however, variation in the symptomatology can be represented by a set of dimensions rather than by multiple categories. An example of this in medicine is blood pressure, which is measured along a continuum from low to high. (It only becomes categorical when we apply the label "hypertension" to indicate that a patient has a significant elevated level of blood pressure that puts him or her at risk for developing serious illness.) While a categorical approach to classification has important heuristic appeal, it may not represent the true state of things. Implicit in the categorical approach is an assumption that mental disorders are discrete entities, separated from one another and from normality, either by recognizably distinct combinations of symptoms or by demonstrably distinct etiologies. While this has been shown to be the case for a small number of conditions (e.g., Down syndrome, fragile X syndrome, phenylketonuria, Alzheimer's disease, Huntington's disease and Creutzfeldt-Jakob disease), there is little evidence supporting the applicability of this model for most other psychiatric symptoms. Indeed, in the last 20 years, the categorical approach has been increasingly questioned as evidence has accumulated that the so-called categorical disorders like major depressive disorder and anxiety disorders, and schizophrenia and bipolar disorder seem to merge imperceptibly both into one another and into normality (Kendler and Gardner, 1998) with no demonstrable natural boundaries.

Dimensional approaches do have some clear advantages. First of all, the commonly observed phenomena of excessive comorbidity (i.e., an individual receiving multiple, simultaneous DSM diagnoses) is arguably a direct result of having a categorical system with more than 250 categories. A dimensional approach, which would characterize an individual's psychopathology by indicating the extent of his or her psychiatric symptomatology across a number of dimensions, virtually eliminates apparent comorbidity. For example, consider an individual who presents with depression, anxiety and social avoidance. Using the DSM-IV categorical system, criteria might be met for three diagnoses (i.e., major depressive disorder, social phobia and generalized anxiety disorder), thus warranting a diagnosis of all three disorders on Axis I. A dimensional approach may simply indicate that the person has "high scores" on the depression, anxiety and social avoidance dimensions. Another advantage of the dimensional approach is that it avoids setting particular thresholds for distinguishing between pathology and normality. Rather than categorically saying that an individual has major depressive disorder, a dimensional approach might say that the person is high on the depression dimension.

There are a number of practical problems that potentially limit the utility of adopting a dimensional approach. First of all, clinicians are accustomed to thinking in terms of diagnostic categories, and the existing knowledge base about the presentation, etiology, epidemiology, course, prognosis and treatment is based on these categories. Furthermore, decisions about the

management of individual patients (e.g., whether to treat and with what type of treatment) are also much easier to make if the patient is thought of as having a particular disorder (with its associated prognostic and treatment implications) rather than as a profile of scores across a series of dimensions. It should be noted that, at least for personality disorders, current dissatisfaction with the categorical approach has led to proposals for research that might allow for the adoption of a dimensional approach to classifying personality functioning in DSM-V (First *et al.*, 2002).

## DSM-IV OVERVIEW

The remainder of this chapter provides an overview of the DSM-IV multiaxial system, as well as a presentation of some of the organizational principles of the various diagnostic groupings included in the DSM-IV classification. The succeeding chapters are organized according to the presentation of disorders in the DSM-IV classification and provide detailed information regarding the diagnosis, etiology and pathophysiology, epidemiology, course and treatment of these DSM-IV disorders.

## DSM-IV Multiaxial System

The multiaxial system was first introduced by DSM-III in order to encourage the clinician to focus his or her attention during the evaluation process on issues above and beyond the psychiatric diagnosis. Use of the multiaxial system requires that information be noted on each of the five different axes, each axis devoted to a different aspect of the evaluation process. Axes I, II and III are the diagnostic axes that divide up the diagnostic pie into three separate domains. Axis I is for “clinical syndromes and disorders”, an admittedly confusing name since Axis II and Axis III are also diagnostic axes. The most accurate name for Axis I is “diagnoses not coded on Axis II and Axis III”, since Axis II and Axis III were carved out of Axis I specifically to draw attention to certain disorders that clinicians were more likely to overlook.

That said, Axis II is designated for coding personality disorders and mental retardation. There have been many recent criticisms of the coding of personality disorders on Axis II. Critics correctly point out that there is no firm conceptual basis for this division. Although disorders on Axis II tend to be lifelong and pervasive, a number of disorders on Axis I (e.g., schizophrenia, autistic disorder, dysthymic disorder) fit this description as well. Others have made the incorrect assumption that categories on Axis II are unresponsive to medication treatment, which is at odds with more recent evidence that medications are often helpful in the treatment of personality disorders. The fact is that the Axis I/Axis II division was made strictly pragmatic. It was introduced in DSM-III as a way of drawing attention to a set of disorders that were thought not to be given adequate attention by mental health professionals. First introduced in DSM-III, Axis II was designed to draw attention to certain disorders that were thought to be overshadowed in the face of the more florid Axis I presentations. Certainly the placement of personality disorders on a separate axis has increased both their clinical visibility and their importance as a subject for research studies. Whether the Axis I/Axis II division has finally outlived its usefulness remains a topic of heated debate, and will be revisited during the DSM-V deliberations.

**Figure 22.1** *DSM-IV-TR Axis IV: Psychosocial and Environmental Checklist.* (Source: Modified from American Psychiatric Association [2000] *Diagnostic and Statistical Manual of Mental Disorders, 4th edn., Text Rev. APA, Washington DC, p. 36.*)

Axis III, like Axis II, is intended to encourage clinicians to pay special attention to conditions that they tend to overlook; in this case, clinically relevant general medical conditions. The concept of “clinically relevant” is intended to be broad. For example, it would be appropriate to list hypertension on Axis III even if its only relationship to an Axis I disorder is its impact on the options for the choice of antidepressant medication.

Psychosocial stressors are well known to play an important role in the etiology, maintenance and management of a number of mental disorders. Axis IV provides the psychiatrist with the opportunity to list clinically relevant psychosocial and environmental problems (e.g., homelessness, poverty, divorce). To facilitate a comprehensive evaluation of such problems, DSM-IV includes a psychosocial and environmental checklist that allows the psychiatrist to indicate which types of problems are present and relevant (Figure 22.1).

Mental disorders differentially impact on individual’s level of functioning. For example, one patient with schizophrenia may function quite well-being able to live in the community, marry and have a family, and maintain a steady job whereas another patient with schizophrenia may function quite poorly, requiring chronic institutionalization. Since both of these patients have symptoms that meet the diagnostic criteria for schizophrenia, their important differences in functioning are not captured by the clinical diagnosis alone. Some of the differences in functioning may be due to different symptom profiles or symptom severities. Other differences may be related to resilience factors or different levels of psychosocial support. Whatever the reason, the DSM-IV multiaxial system provides the clinician with the ability to indicate the patient’s overall level of functioning in addition to the diagnosis on Axis V, using the Global Assessment of Functioning (GAF) Scale (Figure 22.2). This GAF Scale has been criticized because

Consider psychological, social, and occupational functioning on a hypothetical continuum of mental health-illness. Do not include impairment in functioning due to physical (or environmental) limitations.

	(Note: Use intermediate codes when appropriate, e.g., 45,68,72.)
100	Superior functioning in a wide range of activities, life's problems never seem to get out of hand, is sought out by others because of many positive qualities. No symptoms.
91	
90	Absent or minimal symptoms (e.g., mild anxiety before an examination), good functioning in all areas, interested and involved in a wide range of activities, socially effective, generally satisfied with life, no more than everyday problems or concerns (e.g., an occasional argument with family members).
81	
80	If symptoms are present, they are transient and expectable reactions to psychosocial stressors (e.g., difficulty concentrating after family argument); no more than slight impairment in social, occupational, or school functioning (e.g., temporarily falling behind in school work).
71	
70	Some mild symptoms (e.g., depressed mood and mild insomnia) OR some difficulty in social, occupational, or school functioning (e.g., occasional truancy, or theft within the household), but generally functioning pretty well, has some meaningful interpersonal relationships.
61	
60	Moderate symptoms (e.g., flat affect and circumstantial speech, occasional panic attacks) OR moderate difficulty in social, occupational, or school functioning (e.g., few friends, conflicts with peers or coworkers).
51	
50	Serious symptoms (e.g., suicidal ideation, severe obsessional rituals, frequent shoplifting) OR any serious impairment in social, occupational, or school functioning (e.g., no friends, unable to keep a job).
41	
40	Some impairment in reality testing or communication (e.g., speech is at times illogical, obscure, or irrelevant) OR major impairment in several areas, such as work or school, family relations, judgment, thinking, or mood (e.g., depressed man avoids friends, neglects family, and is unable to work; child frequently beats up younger children, is defiant at home, and is failing at school).
31	
30	Behavior is considerably influenced by delusions or hallucinations OR serious impairment in communication or judgment (e.g., sometimes incoherent, acts grossly inappropriately, suicidal preoccupation) OR inability to function in almost all areas (e.g., stays in bed all day; no job, home or friends).
21	
20	Some danger of hurting self or others (e.g., suicide attempts without clear expectation of death, frequently violent, manic excitement) OR occasionally fails to maintain minimal personal hygiene (e.g., smears feces) OR gross impairment in communication (e.g., largely incoherent or mute).
11	
10	Persistent danger of severely hurting self or others (e.g., recurrent violence) OR persistent inability to maintain minimal personal hygiene OR serious suicidal act with clear expectation of death.
1	
0	Inadequate information

**Figure 22.2** *DSM-IV-TR Axis V: Global Assessment of Functioning Scale.* (Source: American Psychiatric Association [2000] *Diagnostic and Statistical Manual of Mental Disorders, 4th ed., Text Rev. APA, Washington DC, p. 34.*)

it is not actually a “pure” measure of an individual’s ability to function, since it incorporates symptom severity into the scale, for example, level 41 to 50 is for serious symptoms (e.g., suicidal ideation, severe obsessional rituals, frequent shoplifting) or any serious impairment in social, occupational, or school functioning (e.g., no friends, unable to keep a job). For this reason, the DSM-IV includes a scale (the Social and Occupational Functioning Scale [SOFAS]) that relies exclusively on functioning in its appendix of Criteria Sets and Axes Provided for Further Study (American Psychiatric Association, 2000, pp. 817–818).

## DSM-IV-TR Classification and Diagnostic Codes

The “DSM-IV-TR Classification of Mental Disorders” refers to the comprehensive listing of the official diagnostic codes, categories, subtypes and specifiers (see below). It is divided into various “diagnostic classes” which group disorders together based on common presenting symptoms (e.g., mood disorders, anxiety disorders), typical age-at-onset (e.g., disorders usually first diagnosed in infancy, childhood and adolescence), and etiology (e.g., substance-related disorders, mental disorders due to a general medical condition).

**DSM-IV-TR CLASSIFICATION**

NOS = Not Otherwise Specified.

An x appearing in a diagnostic code indicates that a specific code number is required.

An ellipsis (...) is used in the names of certain disorders to indicate that the name of a specific mental disorder or general medical condition should be inserted when recording the name (e.g., 293.0 Delirium Due to Hypothyroidism).

If criteria are currently met, one of the following severity specifiers may be noted after the diagnosis:

Mild  
Moderate  
Severe

If criteria are no longer met, one of the following specifiers may be noted:

In Partial Remission  
In Full Remission  
Prior History

**Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence****MENTAL RETARDATION**

Note: *These are coded on Axis II.*

317 Mild Mental Retardation  
318.0 Moderate Mental Retardation  
318.1 Severe Mental Retardation  
318.2 Profound Mental Retardation  
319 Mental Retardation, Severity Unspecified

**LEARNING DISORDERS**

315.00 Reading Disorder  
315.1 Mathematics Disorder  
315.2 Disorder of Written Expression  
315.9 Learning Disorder NOS

**MOTOR SKILLS DISORDER**

315.4 Developmental Coordination Disorder

**COMMUNICATION DISORDERS**

315.31 Expressive Language Disorder  
315.32 Mixed Receptive–Expressive Language Disorder  
315.39 Phonological Disorder  
307.0 Stuttering  
307.9 Communication Disorder NOS

**PERVASIVE DEVELOPMENTAL DISORDERS**

299.00 Autistic Disorder  
299.80 Rett's Disorder  
299.10 Childhood Disintegrative Disorder  
299.80 Asperger's Disorder  
299.80 Pervasive Developmental Disorder NOS

**ATTENTION-DEFICIT AND DISRUPTIVE BEHAVIOR DISORDERS**

314.xx Attention-Deficit/Hyperactivity Disorder  
.01 Combined Type  
.00 Predominantly Inattentive Type

.01 Predominantly Hyperactive-Impulsive Type  
314.9 Attention-Deficit/Hyperactivity Disorder NOS  
312.xx Conduct Disorder  
.81 Childhood-onset Type  
.82 Adolescent-onset Type  
.89 Unspecified Onset  
313.81 Oppositional Defiant Disorder  
312.9 Disruptive Behavior Disorder NOS

**FEEDING AND EATING DISORDERS OF INFANCY OR EARLY CHILDHOOD**

307.52 Pica  
307.53 Rumination Disorder  
307.59 Feeding Disorder of Infancy or Early Childhood

**TIC DISORDERS**

307.23 Tourette's Disorder  
307.22 Chronic Motor or Vocal Tic Disorder  
307.21 Transient Tic Disorder  
*Specify if:* Single Episode/Recurrent  
307.20 Tic Disorder NOS

**ELIMINATION DISORDERS**

—.— Encopresis  
787.6 With Constipation and Overflow Incontinence  
307.7 Without Constipation and Overflow Incontinence  
307.6 Enuresis (Not Due to a General Medical Condition)  
*Specify type:* Nocturnal Only/Diurnal Only/Nocturnal and Diurnal

**OTHER DISORDERS OF INFANCY, CHILDHOOD, OR ADOLESCENCE**

309.21 Separation Anxiety Disorder  
*Specify if:* Early Onset  
313.23 Selective Mutism  
313.89 Reactive Attachment Disorder of Infancy or Early Childhood  
*Specify type:* Inhibited Type/Disinhibited Type  
307.3 Stereotypic Movement Disorder  
*Specify if:* With Self-Injurious Behavior  
313.9 Disorder of Infancy, Childhood, or Adolescence NOS

**Delirium, Dementia and Amnestic and Other Cognitive Disorders****DELIRIUM**

293.0 Delirium Due to ... [*Indicate the General Medical Condition*]  
—.— Substance Intoxication Delirium (*refer to Substance-Related Disorders for substance-specific codes*)  
—.— Substance Withdrawal Delirium (*refer to Substance-Related Disorders for substance-specific codes*)

V61.9	Relational Problem Related to a Mental Disorder or General Medical Condition
V61.20	Parent–Child Relational Problem
V61.10	Partner Relational Problem
V61.8	Sibling Relational Problem
V62.81	Relational Problem NOS

#### PROBLEMS RELATED TO ABUSE OR NEGLECT

V61.21	Physical Abuse of Child ( <i>code 995.54 if focus of attention is on victim</i> )
V61.21	Sexual Abuse of Child ( <i>code 995.53 if focus of attention is on victim</i> )
V61.21	Neglect of Child ( <i>code 995.52 if focus of attention is on victim</i> )
—.	Physical Abuse of Adult (if by partner)
V61.12	(if by person other than partner) ( <i>code 995.83 if focus of attention is on victim</i> )
V62.83	(if by person other than partner) ( <i>code 995.83 if focus of attention is on victim</i> )
—.	Sexual Abuse of Adult (if by partner)
V61.12	(if by person other than partner) ( <i>code 995.83 if focus of attention is on victim</i> )
V62.83	(if by person other than partner) ( <i>code 995.83 if focus of attention is on victim</i> )

#### ADDITIONAL CONDITIONS THAT MAY BE A FOCUS OF CLINICAL ATTENTION

V15.81	Noncompliance With Treatment
V65.2	Malingering
V71.01	Adult Antisocial Behavior
V71.02	Child or Adolescent Antisocial Behavior
V62.89	Borderline Intellectual Functioning

Note: *This is coded on Axis II*

780.9	Age-Related Cognitive Decline
V62.82	Bereavement
V62.3	Academic Problem
V62.2	Occupational Problem
313.82	Identity Problem
V62.89	Religious or Spiritual Problem
V62.4	Acculturation Problem
V62.89	Phase of Life Problem

#### ADDITIONAL CODES

300.9	Unspecified Mental Disorder (nonpsychotic)
V71.09	No Diagnosis or Condition on Axis I
799.9	Diagnosis or Condition Deferred on Axis I
V71.09	No Diagnosis on Axis II
799.9	Diagnosis Deferred on Axis II

## Multiaxial System

Axis I	Clinical Disorders Other Conditions That May Be a Focus of Clinical Attention
Axis II	Personality Disorders Mental Retardation
Axis III	General Medical Conditions
Axis IV	Psychosocial and Environmental Problems
Axis V	Global Assessment of Functioning

The diagnostic codes listed in the DSM-IV are derived from the *International Classification of Diseases*, Ninth Revision, Clinical Modification (ICD-9-CM), the official coding system for reporting morbidity and mortality in the USA. That is the reason why the codes go from 290.00 to 319.00; they are actually derived from the mental disorders section of a much larger coding system for all medical disorders that extends from 001 to 999. Clinicians working in the USA are required to use ICD-9-CM in order to receive reimbursement from both government agencies (e.g., Medicare and Medicaid) and private insurers.

## Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence

The classification begins with disorders usually first diagnosed in infancy, childhood, or adolescence. The provision for a separate section for so-called childhood disorders is only for convenience. Although most individuals with these disorders present for clinical attention during childhood or adolescence, it is not uncommon for some of these conditions to be diagnosed for the first time in adulthood (e.g., attention-deficit/hyperactivity disorder). Moreover, many disorders included in other sections of the DSM-IV have an onset during childhood (e.g., major depressive disorder). Thus, a clinician evaluating a child or adolescent should not only focus on those disorders listed in this section but also consider disorders from throughout the DSM-IV. Similarly, when evaluating an adult, the clinician should also consider the disorders in this section since many of them persist into adulthood (e.g., stuttering, learning disorders, tic disorders).

The first set of disorders included in this diagnostic class (mental retardation, learning and motor skills disorders, and communication disorders). While they are not, strictly speaking, regarded as mental disorders, they are included in the DSM-IV-TR to facilitate differential diagnosis and to increase recognition of these conditions among mental health professionals. Autism and other pervasive developmental disorders are characterized by gross qualitative impairment in social relatedness, in language, and in repertoire of interests and activities. Disorders covered include autistic disorder, Asperger's disorder, Rett's disorder and childhood disintegrative disorder. Attention-deficit/hyperactivity disorder and other disruptive behavior disorders are grouped together because they are all characterized (at least in their childhood presentations) by disruptive behavior. The chapter on feeding disorders includes both the DSM-IV-TR categories of pica, rumination disorder and feeding disorder of infancy and early childhood (also known as "failure to thrive"), as well as several disorders that have been identified by researchers but are not currently included in the DSM-IV-TR (i.e., feeding disorder of state regulation, feeding

disorder of reciprocity, infantile anorexia, sensory food aversions and post traumatic feeding disorder). Tic disorders and elimination and other disorders of infancy and early childhood conclude the childhood disorders.

## Delirium, Dementia, Amnestic Disorder and Other Cognitive Disorders

In the previous DSM-III-R, delirium, dementia, amnestic disorder and other cognitive disorders were included in a section called "organic mental disorders", which contained disorders that were due to either a general medical condition or substance use. In DSM-IV-TR, the term **organic** was eliminated because of the implication that disorders not included in that section (e.g., schizophrenia, bipolar disorder) did not have an organic component (Spitzer *et al.*, 1992). In fact, virtually all mental disorders have both psychological and biological components, and to designate some disorders as organic and the remaining disorders as nonorganic reflected a reductionistic mind-body dualism that is at odds with our understanding of the multifactorial nature of the etiological underpinnings of disorders.

DSM-IV-TR replaced each unitary organic mental disorder (e.g., organic mood disorder) with its two component parts: mood disorder due to a general medical condition and substance-induced mood disorder. Because of their central roles in the differential diagnosis of cognitive impairment, delirium, dementia and amnestic disorder are contained within the same diagnostic class in DSM-IV-TR.

Whereas both delirium and dementia are characterized by multiple cognitive impairments, delirium is distinguished by the presence of clouding of consciousness, which is manifested by an inability appropriately to maintain or shift attention. DSM-IV-TR includes three types of delirium: delirium due to a general medical condition, substance-induced delirium and delirium due to multiple etiologies.

Dementia is characterized by clinically significant cognitive impairment in memory that is accompanied by impairment in one or more other areas of cognitive functioning (e.g., language, executive functioning). DSM-IV-TR includes several types of dementia based on etiology, including dementia of the Alzheimer's type, vascular dementia, a variety of dementia due to general medical and neurological conditions (e.g., human immunodeficiency virus infection, Parkinson's disease), substance-induced persisting dementia and dementia due to multiple etiologies.

In contrast to dementia, amnestic disorder is characterized by clinically significant memory impairment occurring in the absence of other significant impairments in cognitive functioning. DSM-IV-TR includes amnestic disorder due to a general medical condition and substance-induced persisting amnestic disease.

## Mental Disorders Due to a General Medical Condition Not Elsewhere Classified

This diagnostic class includes all of the specific mental disorders due to a general medical condition. In DSM-IV-TR, most of the mental disorders due to a general medical condition have been distributed throughout the various diagnostic classes alongside their "nonorganic" counterparts in the classification. For example, mood disorder due to a general medical condition and substance-induced mood disorder are included in the mood disorders section of DSM-IV-TR. Two specific types of mental disorder

due to a general medical condition (i.e., catatonic disorder due to a general medical condition and personality change due to a general medical condition) are physically included in this diagnostic class.

### Substance-related Disorders

The term **substance** in DSM-IV has a broader meaning than merely a drug of abuse. It also includes medication side effects and the consequences of toxin exposure. Two types of substance-related disorders are included in DSM-IV-TR: substance use disorders (dependence and abuse), which describe the maladaptive nature of the pattern of substance use; and substance-induced disorders, which cover psychopathological processes caused by the direct effects of substances on the central nervous system. Criteria sets for substance dependence, substance abuse, substance intoxication and substance withdrawal that apply across all drug classes are included before the substance-specific sections of DSM-IV.

### Schizophrenia and Other Psychotic Disorders

The title of this diagnostic class is potentially misleading for two reasons: 1) there are other disorders that have psychotic features that are not included in this diagnostic class (e.g., mood disorders with psychotic features, delirium) and 2) it may incorrectly imply that the other psychotic disorders included in this section are related in some way to schizophrenia (which is only true for schizophreniform disorder and possibly schizoaffective disorder). Instead, what ties together all of the disorders in this diagnostic class is the presence of prominent psychotic symptoms. Included here are schizophrenia, schizophreniform disorder, schizoaffective disorder, delusional disorder, shared psychotic disorder and brief psychotic disorder.

It should be noted that the definition of the term **psychosis** has been used in different ways historically and is not even used consistently across the various categories in the DSM-IV-TR. The most restrictive definition of psychosis (used in substance-induced psychotic disorder) requires a break in reality testing such that the person has delusions or hallucinations with no insight into the fact that the delusions or hallucinations are caused by taking drugs.

### Mood Disorders

This diagnostic class includes disorders in which the predominant disturbance is in the individual's mood. Although the term **mood** is broadly defined to include depression, euphoria, anger and anxiety, the DSM-IV-TR generally restricts mood disturbances to depressed, elevated, or irritable mood.

The mood disorders section begins with the criteria for mood episodes (major depressive episode, manic episode, hypomanic episode, mixed episode), which are the building blocks for the episodic mood disorders. The codable mood disorders come next and are divided into the depressive disorders (i.e., major depressive disorder and dysthymic disorder, and the bipolar disorders (i.e., bipolar I disorder, bipolar II disorder and cyclothymic disorder). Finally, the many specifiers that provide important treatment-relevant information close this section. Several so-called "subthreshold mood disorders" (i.e., they are characterized by depression but fall short of meeting the diagnostic criteria for either major depressive disorder or dysthymic

disorder) are included in DSM-IV-TR appendix B, for Criteria Sets and Axes Provided for Further Study. These include minor depressive disorder, brief recurrent depressive disorder, mixed anxiety depressive disorder, postpsychotic depressive disorder of schizophrenia and premenstrual dysphoric disorder.

### Anxiety Disorders

The common element joining these disparate categories together is the fact that the anxiety is a prominent part of their clinical presentation. This grouping has been criticized because of evidence suggesting that at least some of the disorders are likely to be etiologically distinct from the others. Most particularly, obsessive-compulsive disorder and post traumatic stress disorder seem to share little in common with the other anxiety disorders. In fact, separate diagnostic classes for stress-related disorders (that would also include adjustment disorders and perhaps dissociative disorders) and for obsessive-compulsive spectrum disorders (which might also include trichotillomania, tic disorders, hypochondriasis, body dysmorphic disorder and other disorders characterized by compulsive behavior) have been proposed.

### Somatoform Disorders

This diagnostic class includes disorders in which the defining feature is a physical complaint or bodily concern that is not better accounted for by a general medical condition or another mental disorder. These disorders can be divided into three groups based on the focus of the individual's concerns: 1) focus on the physical symptoms themselves (somatization disorder, undifferentiated somatoform disorder, pain disorder and conversion disorder); 2) focus on the belief that one has a serious physical illness (hypochondriasis); and 3) focus on the belief that one has a defect in physical appearance (body dysmorphic disorder).

### Factitious Disorders

This diagnostic class contains only one disorder: factitious disorder, which describes presentations in which the individual intentionally produces or feigns physical or psychological symptoms in order to fulfill a psychological need to assume the sick role. Factitious disorder should always be distinguished from malingering, in which the individual similarly pretends to have physical or psychological symptoms. The difference is that in malingering, the person's motivation is to achieve some external gain (e.g., disability benefits, lessening of criminal responsibility, shelter for the night). For this reason, unlike factitious disorder, malingering is not considered a mental disorder.

### Dissociative Disorders

The common element to this group of disorders is the symptom of dissociation, which is defined as a disruption in the usually integrated functions of consciousness, memory, identity and perception. Four specific disorders are included: dissociative amnesia, dissociative fugue, dissociative identity disorder and depersonalization disorder.

### Sexual and Gender Identity Disorders

This diagnostic class contains three relatively disparate types of disorders, linked together only by virtue of their involvement in human sexuality. Sexual dysfunctions refer to disturbances in sexual desire or functioning, paraphilias refer to unusual sexual preferences that interfere with functioning (or in the case of preferences that involve harm to others like pedophilia, merely

acting on those preferences), and gender identity disorder refers to a serious conflict between one's internal identity of maleness and femaleness (gender identity) and one's anatomical sexual characteristics.

### Eating Disorders

Although the name of this diagnostic class focuses on the fact that the disorders in this section are characterized by abnormal eating behavior (refusal to maintain adequate body weight in the case of anorexia nervosa and discrete episodes of uncontrolled eating of excessively large amounts of food in the case of bulimia nervosa), of near equal importance is the individual's pathological overemphasis on body image. A third category, which is being actively researched but has not been officially added to the DSM-IV-TR, is binge-eating disorder (included in the appendix of Criteria Sets and Axes Provided for Further Study). Like bulimia nervosa, individuals with binge-eating disorder have frequent episodes of binge-eating. However, unlike bulimia nervosa, these individuals do not do anything significant to counteract the effects of their binge-eating (i.e., they do not purge, use laxatives or diet pills, or excessively exercise).

### Sleep Disorders

Sleep disorders are grouped into four sections on the basis of presumed etiology (primary, related to another mental disorder, due to a general medical condition, and substance-induced). Two types of primary sleep disorders are included in DSM-IV-TR: dyssomnias (problems in regulation of amount and quality of sleep) and parasomnias (events that occur during sleep). The dyssomnias include primary insomnia, primary hypersomnia, circadian rhythm sleep disorder, narcolepsy and breathing-related sleep disorder, whereas the parasomnias include nightmare disorder, sleep terror disorder and sleepwalking disorder.

### Impulse Control Disorders Not Elsewhere Classified

As is suggested by the title of this diagnostic grouping, no one diagnostic class in DSM-IV comprehensively includes all of the impulse control disorders. A number of disorders characterized by impulse control problems are classified elsewhere (e.g., conduct disorder, attention-deficit/hyperactivity disorder, oppositional-defiant disorder, delirium, dementia, substance-related disorders, schizophrenia and other psychotic disorders, mood disorders, antisocial and borderline personality disorders). What ties together the disorders in this class is that they present with clinically significant impulsive behavior and that they are not better accounted for by one of the mental disorders included in other parts of DSM-IV-TR. Five such disorders are included here: intermittent explosive disorder, pathological gambling, pyromania, kleptomania and trichotillomania.

### Adjustment Disorders

All DSM-IV categories (except NOS categories) take priority over adjustment disorder. This category is intended to apply to maladaptive reactions to psychosocial stressors that do not meet the criteria for any specific DSM-IV-TR disorder.

### Personality Disorders

This diagnostic class is for personality patterns that significantly deviate from the expectations of the person's culture, are pervasive and lead to significant impairment or distress. Ten specific

personality disorders are included in DSM-IV: paranoid personality disorder (pervasive distrust and suspiciousness of others), schizoid personality disorder (detachment from social relationships and a restricted expression of emotions), schizotypal personality disorder (acute discomfort with close relationships, perceptual distortions and eccentricities of behavior), antisocial personality disorder (disregard for the rights of others), borderline personality disorder (instability of personal relationships, instability of self-image and marked impulsivity), histrionic personality disorder (extensive emotionality and attention seeking), narcissistic personality disorder (grandiosity, need for admiration and lack of empathy), avoidant personality disorder (social inhibition, feelings of inadequacy and hypersensitivity to negative evaluation), dependent personality disorder (excessive need to be taken care of), and obsessive-compulsive personality disorder (preoccupation with orderliness, perfectionism, and mental and personal control at the expense of flexibility, openness and efficiency).

### Other Conditions That May Be a Focus of Clinical Attention

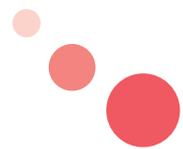

This section of DSM-IV is for problems that are not mental disorders but that may be a focus of attention for treatment by a mental health professional. *Psychological factors affecting medical condition* is intended to allow the psychiatrist to note the presence of psychological factors (e.g., Axis I or II disorder) that adversely affect the course of a general medical condition, including factors that interfere with treatment and factors that constitute health risks to the individual. Six specific *medication-induced movement disorders* are also included because of their importance in treatment and differential diagnosis; five are related to neuroleptic administration and one (medication-induced postural tremor) is most often associated with the use of lithium carbonate. Although these are best considered medical conditions, by DSM-IV-TR convention they are coded on Axis I.

Relational problems include parent-child, partner and sibling relational problems. Relational problem related to a mental disorder or general medical condition applies to situations in which one member of the relational unit has a mental disorder or a general medical condition. In such situations, the relational dynamics can negatively affect the individual's condition or vice versa (or both). *Problems related to abuse or neglect* (physical abuse, sexual abuse and child neglect).

# Diagnostic Classification in Infancy and Early Childhood

---

Knowledge about the mental health and development of infants has grown exponentially in the past two decades. Through systematic observation, research and clinical intervention a more sophisticated understanding has emerged of the factors that contribute to adaptive and maladaptive patterns of development and of the meaning of individual differences in infancy. This knowledge has led to an increasing awareness of the importance of prevention and early treatment in creating or restoring favorable conditions for the young child's development and mental health. Timely assessment and accurate diagnosis can provide the foundation for effective intervention before early deviations become consolidated into maladaptive patterns of functioning.

As a result of this growing knowledge base, a new diagnostic framework was formulated through an 8-year effort of ZERO TO THREE: National Center for Infants, Toddlers, and Families. This framework is presented in detail in *Diagnostic Classification of Mental Health and Developmental Disorders of Infancy and Early Childhood* (DC:0–3) (1994). It seeks to address the need for a systematic, developmentally based approach to the classification of mental health and developmental difficulties in the first 3 years of life. It is designed to complement existing medical and developmental frameworks for understanding mental health and developmental problems in the earliest years.

DC:0–3 categorizes emotional and behavioral patterns that represent significant deviations from normative development in the earliest years of life. Some of the categories presented represent new formulations of mental health and developmental difficulties. Other categories describe the earliest manifestations of mental health problems that have been identified among older children and adults but have not been fully described in infants and young children. In infancy and early childhood, these problems may have different characteristics, and prognosis may be more optimistic if effective early intervention can occur. This chapter summarizes the principles of assessment and diagnosis as well as the new diagnostic classifications for the first 3 years of life.

Discussions of diagnostic categories can be most helpful if they identify challenges to be overcome in the context of an understanding of adaptive coping and development. Understanding both adaptive capacities and challenges is part of the essential foundation for planning and implementing effective interventions. A detailed discussion of the principles of assessment, diagnosis and intervention, along with case studies, is presented in *Infancy and Early Childhood* (Greenspan, 1992).

Reflecting our current state of knowledge, the diagnostic categories presented in this chapter are descriptive, that is, they record presenting patterns of symptoms and behaviors. Some of the categories (e.g., those involving trauma) imply potential etiological factors; some (e.g., regulatory disorders) imply pathophysiological processes. However, at the moment, all that can be stated is that associations have been observed between some of these symptoms and processes (e.g., between a traumatic event and a group of symptoms, or between a sensory or motor pattern and a group of symptoms). Only further research will establish possible pathophysiological or etiological links among these observed phenomena.

As an evolving framework, this conceptualization is not intended to include all possible conditions or disorders. It is an initial guide for mental health professionals and researchers to facilitate clinical diagnosis and planning as well as communication and further research. It is not intended to have legal or nonclinical applications.

## Principles of Assessment

Many different assumptions and theories contribute to our approach to diagnosis and treatment. These assumptions come from both clinical practice and research. Developmental, psychodynamic, family systems, relationship and attachment theory inform our work, as do observations of the way infants organize their experience, infant–caregiver interaction patterns, temperament, regulatory patterns and individual differences in many domains of development.

This chapter describes a new diagnostic classification for the first 4 years of life. It is meant to complement the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (DSM-IV-TR). *Diagnostic Classification of Mental Health and Developmental Disorders of Infancy and Early Childhood*, published in 1994 by ZERO TO THREE/National Center for Clinical Infant Programs (now ZERO TO THREE: National Center for Infants, Toddlers, and Families, Washington DC), describes types of behaviors and problems not addressed in other schemas as well as the earliest manifestations of problems and behaviors that have heretofore been ascribed to older children. Because of the new system's comprehensive clinical and developmental approach, the authors have decided to include this overview, adapted from DC:0-3 with permission from ZERO TO THREE: National Center for Infants, Toddlers, and Families, here. More information about DC:0-3 is available from ZERO TO THREE: National Center for Infants, Toddlers, and Families, 734 15th Street, NW, 10th Floor, Washington DC 20005, Tel: 1-800-899-4301.

We have formulated a model to characterize the different factors that must be taken into account and understood in an infant's, toddler's, or preschooler's functioning within the context of his family, community and world. We call this model the Developmental, Individual Difference, Relationship-based (DIR) model.

### The DIR Model

The DIR model attempts to facilitate understanding of children and their family by identifying, systematizing and integrating the essential functional developmental capacities. These include the child's 1) functional–emotional developmental level; 2) the child's individual differences in sensory reactivity, processing and motor planning; and 3) the child's relationships and interactions with caregivers, family members and others.

## Functional Developmental Capacities

### Functional–Emotional Developmental Level

The child's functional–emotional developmental level examines how children integrate all their capacities (motor, cognitive, language, spatial, sensory) to carry out emotionally meaningful goals. The support for these functional–emotional developmental levels is reviewed elsewhere (Greenspan, 1979, 1989, 1992, 1997). These capacities include the ability to:

1. Attend to multisensory affective experience and, at the same time, organize a calm, regulated state (e.g., looking at, listening to, and following movement of a caregiver).
2. Engage with and evidence affective preference and pleasure for a caregiver or caregivers (e.g., joyful smiles and affection with a stable caregiver).
3. Initiate and respond to two-way presymbolic gestural communication (e.g., back-and-forth use of smiles and sounds).
4. Organize chains of two-way social problem-solving communications (opening and closing many circles of communication in a row), maintain communication across space, integrate affective polarities, and synthesize an emerging prerepresentational organization of self and other (e.g., taking dad by the hand to reach a toy on the shelf).
5. Create and functionally use ideas as a basis for creative or imaginative thinking, giving meaning to symbols (e.g., pretend play, using words to meet needs, "Juice!").
6. Build bridges between ideas as a basis for logic, reality testing, thinking and judgment (e.g., engage in debates, opinion-oriented conversations and/or elaborate, planned pretend dramas).

### Individual Differences in Sensory, Modulation, Processing and Motor Planning

These biologically-based individual differences are the result of genetic, prenatal perinatal and maturational variations and/or deficits and can be characterized in at least four ways:

1. Sensory modulation, including hypo- and hyperreactivity in each sensory modality, including touch, sound, smell, vision and movement in space;
2. Sensory processing in each sensory modality, including auditory processing and language and visual–spatial processing. Processing includes the capacity to register, decode, and comprehend sequences and abstract patterns);

3. Sensory–affective processing in each modality (e.g., the ability to process and react to affect, including the capacity to connect "intent" or affect to motor planning and sequencing, language and symbols). This processing capacity may be especially relevant for ASD (Greenspan and Wieder, 1997, 1998).
4. Motor planning and sequencing, including the capacity to sequence actions, behaviors and symbols, including symbols in the form of thoughts, words, visual images and spatial concepts.

## Relationships and Interactions

Relationship and affective interaction patterns include developmentally appropriate, or inappropriate, interactive relationships with caregiver, parent and family patterns. Interaction patterns between the child and caregivers and family members bring the child's biology into the larger developmental progression and can contribute to the negotiation of the child's functional developmental capacities. Developmentally appropriate interactions mobilize the child's intentions and affects and enable the child to broaden his/her range of experience at each level of development and move from one functional developmental level to the next. In contrast, interactions that do not deal with the child's functional developmental level or individual differences can undermine progress. For example, a caregiver who is aloof may not be able to engage an infant who is underreactive and self-absorbed.

The DIR model examines the developmental capacities of the children in the context of their unique biologically-based processing profile and their family relationships and interactive patterns. As a functional approach, it uses the complex interactions between biology and experience to understand behavior. Implementation of an appropriate assessment of all the relevant functional areas requires a number of sessions with the child and family. These sessions must begin with discussions and observations.

The assessment process which is described in detail elsewhere (ZERO TO THREE, 1994; Greenspan and Wieder, 1997) includes: 1) two or more clinical observations, of 45 minutes each, of child–caregiver and/or clinician–child interactions; 2) developmental history and review of current functioning; 3) review of family and caregiver functioning; 4) review of current programs and patterns of interaction; 5) consultation with speech pathologists, occupational and physical therapists, educators and mental health colleagues, including the use of structured tests on an as-needed, rather than routine basis; and 6) biomedical evaluation.

## The Functional Developmental Profile

The assessment then leads to an individualized functional profile which captures each child's unique developmental features and serves as a basis for creating individually-tailored intervention programs (i.e., tailoring the program to the child rather than fitting the child to a general program). The profile describes the child's functional developmental capacities and contributing biological processing differences and environmental interactive patterns, including the different interaction patterns available to the child at home, at school, with peers, and in other settings. The profile should include all areas of challenge, not simply the ones that are more obviously associated with symptoms of one or another syndrome or disease. For example, the preschooler's lack of ability to symbolize a broad range of emotional interests and themes in either pretend play or talk is just as important, if not more important, than that same preschooler's tendency to be perseverative or self-stimulatory. In fact, clinically we have often seen that as the child's range of symbolic expression broadens, perseverative and self-stimulatory tendencies decrease.

The functional approach to creating a profile enables the clinician to consider each functional challenge separately, explore different explanations for it, and resist the temptation to assume that difficulties are necessarily tied together as part of a syndrome (unless all alternative explanations have been ruled out). For example, hand flapping is often related to motor problems and is seen when children with a variety of motor problems become excited or overloaded. Many conditions, including cerebral palsy, autism, hypotonia and dyspraxia involve motor problems and, at times, hand flapping. Yet this symptom is often assumed to be uniquely a part of the autistic spectrum. Similarly, sensory over- or under-reactivity is present in many disorders and developmental variations. Yet it is also often assumed to be a unique part of autism. The functional approach does not detract from understanding existing syndromes. In fact, over time, it may clarify what symptoms are unique to particular syndromes, lead to new classifications, and further tease out biological and functional patterns.

Constructing the child's profile of functional capacities through appropriate clinical assessments enables the clinician to tailor the intervention program to the child's and family's unique features, rather than have the child fit the program, based on some broad, but nonspecific, diagnostic criteria.

As the DIR model suggests, any intervention or treatment program should be based on as complex an understanding of the child's and family's circumstances as is possible to achieve. It is the responsibility of any psychiatrist who is charged with doing a full diagnostic work-up and planning an appropriate intervention program to take into account **all** the relevant areas of a child's functioning, using state-of-the-art knowledge in each area. These areas include the following:

- Presenting symptoms and behaviors
- Developmental history: past and current affective, language, cognitive, motor, sensory, family and interactive functioning
- Family functioning and cultural and community patterns
- Parents as individuals
- Caregiver–infant (child) relationship and interactive patterns
- The infant's constitutional–maturational characteristics
- Affective, language, cognitive, motor and sensory patterns
- The family's psychosocial and medical history, the history of the pregnancy and delivery, and current environmental conditions and stressors

The process of gaining an understanding of how each area of functioning is developing for an infant or toddler usually requires a number of sessions. A few questions to the parents or caregiver about each area may be appropriate for screening but not for a full evaluation. A full evaluation usually requires a minimum of three to five sessions of 45 minutes or more each. A complete evaluation will usually involve taking the history; direct observation of functioning (i.e., of family and parental dynamics; caregiver–infant relationship and interaction patterns; the infant's constitutional–maturational characteristics; and language, cognitive and affective patterns); and hands-on interaction assessment of the infant, including assessment of sensory reactivity and processing, motor tone and planning, language, cognition and affective expression. Standardized developmental assessments, if needed, should always build on the clinical process described. They may be indicated when they are the most effective way to answer specific questions and when the child is sufficiently interactive and can respond to the requirements of the test.

The result of such a comprehensive evaluation should lead to preliminary notions about the following:

1. The nature of the infant's or child's difficulties as well as her or his strengths; the level of the child's overall adaptive capacity; and functioning in the major areas of development, including social–emotional relationships and cognitive, language, sensory and motor abilities in comparison to age-expected developmental patterns.
2. The relative contribution of the different areas assessed (e.g., family relationships, interactive patterns, constitutional–maturational patterns, stress) to the child's difficulties and competencies.
3. A comprehensive treatment or preventive intervention plan to deal with 1 and 2.

## Overview of the Classification System

DC:0–3 proposes a provisional multiaxial classification system. We refer to the classification system as provisional because it is assumed that categories may change as more knowledge accumulates. The diagnostic framework consists of the following:

Axis I	Primary diagnosis
Axis II	Relationship disorder classification
Axis III	Physical, neurological, developmental, and mental health disorders or conditions (described in other classification systems)
Axis IV	Psychosocial stressors
Axis V	Functional–emotional developmental level

The axes in this system are not intended to be entirely symmetrical with such other systems as DSM-IV and the *International Statistical Classification of Diseases and Related Health Problems*, 10th Revision (ICD-10) because this system, in dealing with infants and young children, focuses on developmental issues. Dynamic processes, such as relationship and developmentally based conceptualizations of adaptive patterns (i.e., functional–emotional developmental level), are therefore of central importance.

Use of the system will provide the psychiatrist with a “diagnostic profile” of an infant or toddler. Such a diagnostic profile focuses the psychiatrist's attention on the various factors that are contributing to the infant's difficulties as well as on areas in which intervention may be needed.

## Axis I: Primary Diagnoses

The following are the Axis I primary diagnoses that have thus far been suggested:

### 100. Traumatic Stress Disorder

A continuum of symptoms related to a single event, a series of connected traumatic events, or chronic enduring stress.

1. Reexperiencing of the trauma, as evidenced by
  - a. post traumatic play
  - b. recurrent recollections of the traumatic event outside play
  - c. repeated nightmares

- d. distress at reminders of the trauma
- e. flashbacks or dissociation
- 2. Numbing of responsiveness or interference with developmental momentum
  - a. increased social withdrawal
  - b. restricted range of affect
  - c. temporary loss of previously acquired developmental skills
  - d. a decrease in play
- 3. Symptoms of increased arousal
  - a. night terrors
  - b. difficulty going to sleep
  - c. repeated night waking
  - d. significant attentional difficulties
  - e. hypervigilance
  - f. exaggerated startle response
- 4. Symptoms not present before
  - a. aggression toward peers, adults, or animals
  - b. separation anxiety
  - c. fear of toileting alone
  - d. fear of the dark
  - e. other new fears
  - f. self-defeating behavior or masochistic provocativeness
  - g. sexual and aggressive behaviors
  - h. other nonverbal reactions (e.g., somatic symptoms, motor reenactment, skin stigmas, pain, or posturing)

## 200. Disorders of Affect

Focuses on the infant's experience and on symptoms that are a general feature of the child's functioning rather than specific to a situation or relationship.

### 201. Anxiety Disorders of Infancy and Early Childhood

Levels of anxiety or fear, beyond expectable reactions to normal developmental challenges.

1. Multiple or specific fears
2. Excessive separation or stranger anxiety
3. Excessive anxiety or panic without clear precipitant
4. Excessive inhibition or constriction of behavior
5. Lack of development of basic ego functions
6. Agitation, uncontrollable crying or screaming, sleeping and eating disturbances, recklessness, and other behaviors

*Criterion:* Should persist for at least 2 weeks and interfere with appropriate functioning.

### 202. Mood Disorder: Prolonged Bereavement–Grief Reaction

1. Possible crying, calling and searching for the absent parent, refusing comfort
2. Emotional withdrawal, with lethargy, sad facial expression, and lack of interest in age-appropriate activities
3. Eating and sleeping possibly disrupted
4. Regression in developmental milestones
5. Constricted affective range
6. Detachment
7. Sensitivity to any reminder of the caregiver

### 203. Mood Disorder: Depression of Infancy and Early Childhood

Pattern of depressed or irritable mood with diminished interest or pleasure in developmentally appropriate

activities, diminished capacity to protest, excessive whining, and diminished social interactions and initiative. Disturbances in sleep or eating.

*Criterion:* At least 2 weeks.

### 204. Mixed Disorder of Emotional Expressiveness

Ongoing difficulty expressing developmentally appropriate emotions.

1. The absence or near-absence of one or more specific types of affects
2. Constricted range of emotional expression
3. Disturbed intensity
4. Reversal of affect or inappropriate affect

### 205. Childhood Gender Identity Disorder

Becomes manifest during the sensitive period of gender identity development (between approximately 2 and 4 years).

1. A strong and persistent cross-sex identification
  - a. repeatedly states desire to be, or insistence that he or she is, the opposite sex
  - b. in boys, preference for cross-dressing or simulating female attire; in girls, insistence on wearing stereotypical masculine clothing
  - c. strong and persistent preferences for cross-sex roles in fantasy play or persistent fantasies of being the opposite sex
  - d. intense desire to participate in the games and pastimes of the opposite sex
  - e. strong preference for playmates of the opposite sex
4. Persistent discomfort with one's assigned sex or sense of inappropriateness in that role
5. Absence of nonpsychiatric medical condition

### 206. Reactive Attachment Deprivation–Maltreatment Disorder of Infancy

1. Persistent parental neglect or abuse, of a physical or psychological nature, undermines the child's basic sense of security and attachment.
2. Frequent changes in, or the inconsistent availability of, the primary caregiver.
3. Other environmental compromises that prevent stable attachments.

## 300. Adjustment Disorder

Mild, transient situational disturbances related to a clear environmental event and lasting no longer than 4 months.

## 400. Regulatory Disorders

Difficulties in regulating physiological, sensory, attentional, motor, or affective processes and in organizing a calm, alert, or affectively positive state. Observe at least one sensory, sensory–motor, or processing difficulty from the following list, in addition to behavioral symptoms.

1. Overreactivity or underreactivity to loud or high- or low-pitched noises
2. Overreactivity or underreactivity to bright lights or new and striking visual images
3. Tactile defensiveness or oral hypersensitivity
4. Oral–motor difficulties or incoordination influenced by poor muscle tone and oral-tactile hypersensitivity
5. Underreactivity to touch or pain

6. Gravitational insecurity
7. Underreactivity or overreactivity to odors
8. Underreactivity or overreactivity to temperature
9. Poor muscle tone and muscle stability
10. Qualitative deficits in motor planning skills
11. Qualitative deficits in ability to modulate motor activity
12. Qualitative deficits in fine motor skills
13. Qualitative deficits in auditory–verbal processing
14. Qualitative deficits in articulation capacities
15. Qualitative deficits in visual–spatial processing capacities
16. Qualitative deficits in capacity to attend and focus

#### 401. Type I: Hypersensitive

- Fearful and cautious
  - Behavioral patterns: excessive cautiousness, inhibition, or fearfulness
  - Motor and sensory patterns: overreactivity to touch, loud noises, or bright lights
- Negative and defiant
  - Behavioral patterns: negativistic, stubborn, controlling and defiant; difficulty in making transitions; prefers repetition to change
  - Motor and sensory patterns: overreactivity to touch and sound; intact visual–spatial capacities; compromised auditory processing capacity; good muscle tone and motor planning ability; shows some delay in fine motor coordination

#### 402. Type II: Underreactive

- Withdrawn and difficult to engage
  - Behavioral patterns: seeming disinterest in relationships; limited exploratory activity or flexibility in play; appears apathetic, easily exhausted and withdrawn
  - Motor and sensory patterns: underreactivity to sounds and movement in space; either overreactive or underreactive to touch; intact visual–spatial processing capacities, but auditory–verbal processing difficulties; poor motor quality and motor planning
- Self-absorbed
  - Behavioral patterns: creative and imaginative, with a tendency to tune into her or his own sensations, thoughts, and emotions
  - Motor and sensory patterns: decreased auditory–verbal processing capacities

#### 403. Type III: Motorically Disorganized, Impulsive

Mixed sensory reactivity and motor processing difficulties. Some appear more aggressive, fearless and destructive; others appear more impulsive and fearful.

- Behavioral patterns: high activity, seeking contact and stimulation through deep pressure; appears to lack caution
- Motor and sensory patterns: sensory underreactivity and motor discharge

#### 404. Type IV: Other

### 500. Sleep Behavior Disorder

Only presenting problem; younger than 3 years of age; no accompanying sensory reactivity or sensory processing

difficulties. Difficulty in initiating or maintaining sleep; may also have problems in calming themselves and dealing with transitions from one stage of arousal to another.

### 600. Eating Behavior Disorder

Shows difficulties in establishing regular feeding patterns with adequate or appropriate food intake. Absence of general regulatory difficulties or interpersonal precipitants (e.g., separation, negativism, trauma).

### 700. Disorders of Relating and Communicating

1. DSM-IV conceptualization pervasive developmental disorder, or
2. Multisystem developmental disorder

#### *Multisystem Developmental Disorder*

1. Significant impairment in, but not complete lack of, the ability to form and maintain an emotional and social relationship with primary caregiver
2. Significant impairment in forming, maintaining, or developing communication
3. Significant dysfunction in auditory processing
4. Significant dysfunction in the processing of other sensations and in motor planning

#### 701. Pattern A

These children are aimless and unrelated most of the time, with severe difficulty in motor planning, so that even simple intentional gestures are difficult.

#### 702. Pattern B

These children are intermittently related and capable, some of the time, of simple intentional gestures.

#### 703. Pattern C

These children evidence a more consistent sense of relatedness, even when they are avoidant or rigid.

## Axis II: Relationship Disorder Classification

The diagnostic system also includes an Axis II for relationships classification. Three aspects of a relationship are considered: 1) behavioral quality of the interaction, 2) affective tone, and 3) psychological involvement. The types of relationship problems are as follows:

#### 901. Overinvolved Relationship

Physical or psychological overinvolvement.

1. Parent interferes with infant's goals and desires
2. Overcontrols
3. Makes developmentally inappropriate demands
4. Infant appears diffuse, unfocused and undifferentiated
5. Displays submissive, overly compliant behaviors
6. May lack motor skills or language expressiveness

**902. Underinvolved Relationship**

Sporadic or infrequent genuine involvement.

1. Parent insensitive or unresponsive
2. Lack of consistency between expressed attitudes about infant and quality of actual interactions
3. Ignores, rejects, or fails to comfort
4. Does not reflect infant's internal feeling states
5. Does not adequately protect
6. Interactions underregulated
7. Parent and infant appear to be disengaged
8. Infant appears physically or psychologically uncared for
9. Delayed or precocious in motor and language skills

**903. Anxious–Tense Relationship**

Tense, constricted with little sense of relaxed enjoyment or mutuality.

1. Parent is overprotective and oversensitive
2. Awkward or tense handling
3. Some verbally and emotionally negative interactions
4. Poor temperamental fit between parent and child
5. Infant compliant or anxious

**904. Angry–Hostile Relationship**

Harsh and abrupt, often lacking in emotional reciprocity.

1. Parent insensitive to infant's cues
2. Handling is abrupt
3. Infant frightened, anxious, inhibited, impulsive, or diffusely aggressive
4. Defiant or resistant behavior
5. Demanding or aggressive behaviors
6. Fearful, vigilant and avoidant behaviors
7. Tendency toward concrete behavior

**905. Mixed Relationship**

Combination of the features described above.

**906. Abusive Relationships**

1. Verbally abusive relationship.
  - a. Intended to severely belittle, blame, attack, overcontrol and reject the infant or toddler
  - b. Reactions vary from constriction and vigilance to severe acting-out behaviors
2. Physically abusive relationship.
  - a. Physically harms by slapping, spanking, hitting, pinching, biting, kicking, physical restraint, isolation
  - b. Denies food, medical care, or opportunity to rest
  - c. May include verbal and emotional abuse or sexual abuse
3. Sexually abusive relationship.
  - a. Parent engages in sexually seductive and overstimulating behavior – coercing or forcing child to touch parent sexually, accept sexual touching, or observe others' sexual behaviors
  - b. Young child may evidence sexually driven behaviors such as exhibiting himself or herself or trying to look at or touch other children
  - c. May include verbal and emotional abuse or physical abuse

**Axis III: Medical and Developmental Diagnoses**

On Axis III, one indicates any coexisting physical (including medical and neurological), mental health, or developmental disorders. DSM-IV, ICD-9 or ICD-10 for the primary care setting classifications are used. Occupational therapy, physical therapy, special education and other designations are specified.

**Axis IV: Psychosocial Stressors**

On Axis IV, one identifies (1) the source of stress (e.g., abduction, adoption, loss of parent, natural disaster, parent's illness), (2) severity (mild to catastrophic), (3) duration (acute to enduring), and (4) overall impact (none, mild, moderate, severe).

**Overall Impact of Stress**

Mild effects	Causes recognizable strain, tension, or anxiety but does not interfere with infant's overall adaptation
Moderate effects	Derails child in areas of adaptation but not in core areas of relatedness and communication
Severe effects	Significant derailment in areas of adaptation

**Axis V: Functional–Emotional Developmental Level**

Axis V profiles the child's functional and emotional developmental level. It involves the following:

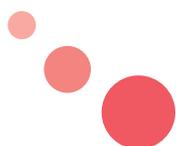

- A. Essential processes or capacities
  1. Mutual attention: ability of dyad to attend to one another
  2. Mutual engagement: joint emotional involvement
  3. Interactive intentionality and reciprocity: ability for cause-and-effect interaction; infant signals and responds purposefully
  4. Representational–affective communication: language and play communicate emotional themes
  5. Representational elaboration: pretend play and symbolic communication that go beyond basic needs and deal with more complex intentions, wishes, or feelings
  6. Representational differentiation I: pretend play and symbolic communication in which ideas are logically related; knows what is real and unreal
  7. Representational differentiation II: complex pretend play; three or more ideas are logically connected and informed by concepts of causality, time and space
- B. Functional–Emotional Developmental Level Summary, which documents the child's achievement
  1. Has fully reached expected levels
  2. At expected level but with constrictions – not full range of affect; not at this level under stress; only with certain caregivers or with exceptional support
  3. Not at expected level but has achieved all prior levels
  4. Not at current expected level but some prior levels
  5. Has not mastered any prior levels

## Conclusion

We have briefly reviewed the principles of assessment and diagnosis and outlined the new diagnostic classification system for infants, young children and their families. The field of clinical work with infants and young children is a relatively new one. It has strong empirical support in the numerous studies of both normal and disturbed development and the rapidly expanding experience with a variety of clinical cases. As more experience is accumulated, the classification of challenges and difficulties will be refined and additional clinical strategies developed.

# Childhood Disorders: Mental Retardation

## Concept of Mental Retardation

Following are the basic concepts of mental retardation and the psychiatric approaches to it, on which this chapter is based:

1. Mental retardation is not a single, specific disorder. The term refers to a behavioral syndrome, describing the level of a person's functioning in defined domains. It does not have a single cause, mechanism, course, or prognosis and does not necessarily last a lifetime.
2. Mental retardation is not a unitary concept. Persons diagnosed as having mental retardation do not constitute a homogeneous group but represent a wide spectrum of abilities, clinical presentations and behavioral patterns.
3. Persons with mental retardation do not have unique personalities or behavioral patterns that are specific to mental retardation, although certain patterns may be frequently seen in certain mental retardation-associated syndromes.
4. Maladaptive behaviors should not automatically be seen as part of the retardation or an expression of "organicity". As in all individuals, these behaviors may be related to life experiences; they can also be a symptom of mental illness comorbid with the mental retardation.
5. Mental disorders seen in persons with mental retardation are the same as those in the general population.

Some common misconceptions about mental retardation are that it is a specific and lifelong disorder with unique personality pattern, and that comorbid mental disorders existing with mental retardation are different from those encountered in other individuals. Although mental retardation is listed as a mental disorder in the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR) (American Psychiatric Association, 2000), it is not a unique nosological entity. Instead, diagnosis of mental retardation refers to the level of a person's intellectual and adaptive functioning below a cutoff point that is not even natural but is arbitrarily chosen in relation to the average level of functioning of the population at large. Its chief function is administrative, defining a group of persons who are in need of support and educational services. Thus, mental retardation does not have a single cause, mechanism, course, or prognosis. It has to be differentiated from the diagnosis (if known) of the underlying medical condition.

## Epidemiology of Mental Retardation

### Prevalence

The results of epidemiological studies of mental retardation depend on two major factors: the definition of mental retardation that is used and how the results are ascertained. There have been various models for estimating the prevalence of mental retardation. A model based on IQ score alone used the expected statistical distribution of intelligence levels. The past definition based only on an IQ that was one standard deviation or greater below the mean implied that almost 15% of the population could be classified as having mental retardation. With the introduction of the diagnostic criterion of impairment in adaptive behavior and an IQ cutoff at two standard deviations below the mean (approximately 70), the prevalence of mental retardation was commonly thought to be 3% of the population. More recent population-based studies, using multiple methods of ascertainment and a current definition of mental retardation, suggest that the prevalence might be closer to 1%. In the study of McLaren and Bryson (1987), the prevalence of mild mental retardation was 0.37 to 0.59%, whereas the prevalence of moderate, severe and profound retardation was 0.3 to 0.4%. When age is considered, the highest prevalence is in the school-age group, when the child cannot meet the expectations of academic learning. United States Department of Education indicated the prevalence of mental retardation among school-age children (6–17 years of age) to be 1.14%, with variations reported by different states (Massey and McDermott, 1995). Conversely, some persons who are diagnosed with mild mental retardation when of school age lose that diagnosis in adulthood when their good adaptive skills are more relevant than their academic achievement.

## Etiology and Pathophysiology of Mental Retardation

### General Considerations

Intellectual abilities depend to a great degree on the integrity of the CNS. A variety of biomedical causes can disrupt this integrity and start the process leading to mental retardation. It should be kept in mind, however, that the term mental retardation describes the overall level of functioning, encompassing current intellectual and adaptive skills. These, in turn, are shaped by other factors besides CNS integrity, such as the patient's general state of health and associated disabilities, environmental factors (such

as nurturing, learning opportunities, supports) and psychological factors (such as the person's self-image, psychopathological characteristics, motivation). Thus, a biomedical cause, whether genetic or acquired, may be a primary cause that will start the process of developmental delay but will not necessarily be the only factor responsible for the functional outcome, which will depend on the synergistic or cumulative effects of all factors involved. It is important to know as much as possible about the "primary" cause for a number of reasons:

Treatment possibilities can include early institution of diet in phenylketonuria (PKU) and thyroid hormone supplementation in congenital hypothyroidism. Primary prevention of the recurrence of the same condition using, for example, parental education to prevent fetal alcohol syndrome and enable genetic counseling for the family. Early recognition and treatment of complications known to be associated with the particular mental retardation syndrome, such as hypothyroidism in Down syndrome. Research on causation and prevention Assessment of epidemiology, which is important in public policy (planning for services) as well as in prevention Understanding of prognosis in association with a particular disorder Support for the family and other caregivers by dispelling misconceptions and anxieties related to uncertainty about the cause

- Treatment possibilities, which can include early institution of diet in phenylketonuria (PKU) and thyroid hormone supplementation in congenital hypothyroidism.

- Prevention, such as primary prevention of the recurrence of the same condition using, for example, parental education to prevent fetal alcohol syndrome and enabling genetic counseling for the family.
- Early recognition and treatment of complications known to be associated with the particular mental retardation syndrome, such as hypothyroidism in Down syndrome.
- Research on causation and prevention.
- Assessment of epidemiology, which is important in public policy (planning for services) as well as in prevention.
- Understanding of prognosis in association with a particular disorder.
- Support for the family and other caregivers by dispelling misconceptions and anxieties related to uncertainty about the cause.

### Approaches to Classification of the Causation of Mental Retardation

The prevalence of diagnosable (using current techniques) biomedical causes of mental retardation varies with the degree of the disability. When the retardation is severe, a prenatal cause can be identified in 59 to 73% of patients, but in mild mental retardation such a cause can be identified in only 23 to 43% of patients.

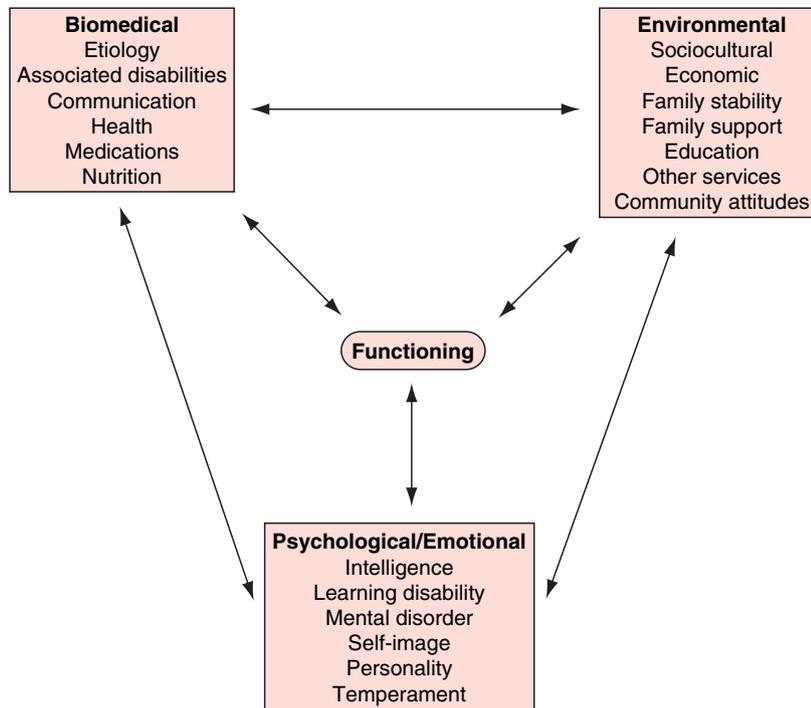

Table 24.1 illustrates the most commonly employed classification system of the etiology of mental retardation. It reflects

**Table 24.1 Etiological Classification of Mental Retardation Based on the Timing and Type of the Central Nervous System Insult\*\*†**

Division and Group	Percent	Examples
<b>Prenatal: Genetic Disorders</b>	32	
Chromosomal aberrations		Trisomy 21, trisomy 13m cri du chat syndromes
Malformations due to microdeletions		Angelman's and Prader-Willi syndromes, William's syndrome, Rubinstein-Taybi syndrome
Monogenic mutations		Tuberous sclerosis, metabolic disorders, fragile X syndrome
Multifactorial mental retardation		"Familial" mental retardation
<b>Malformations, Cause Unknown</b>	8	
Malformations of the CNS		Holoprosencephaly, lissencephaly, neural tube defects
Multiple malformation syndromes		de Lange's syndrome, Sotos' syndrome
<b>Prenatal: Disorders due to External Causes</b>	12	
Maternal infections		Rubella and HIV, cytomegalovirus and <i>Toxoplasma</i> infections
Toxins		Fetal alcohol syndrome, fetal hydantoin syndrome
Toxemia, placental insufficiency		IUGR, prematurity
Other		Radiation, trauma
<b>Perinatal Causes</b>	11	
Infections		Meningitis, herpes
Delivery problems		Asphyxia, trauma
Other		Hypoglycemia, hyperbilirubinemia
<b>Postnatal Causes</b>	8	
Infections		Meningitis, encephalitis
Toxins		Lead poisoning
Other CNS disorders		Cerebrovascular accidents, tumors, traumas
Psychosocial problems		
<b>Unknown Causes</b>	25	

\*These data are based on the Finnish National Board of Social Welfare registry of persons, with mental retardation, who were receiving special services in the 1980s. There were about 19 000 persons in that registry. In about 4%, no etiological information was recorded (unpublished data).

†CNS, central nervous system; HIV, human immunodeficiency virus; IUGR, intrauterine growth retardation.

**Figure 24.1** Schematic representation of transactional relationship of various factors influencing the development of adaptive and maladaptive behaviors in persons with mental retardation.

both the timing and the type of the causative process which will affect the development and function of the CNS (Wilska and Kaski, 1999). The goal of the etiological assessment is to elucidate the earliest developmental cause as well as other coexisting causative factors because their effects are usually interactive and cumulative (McLaren and Bryson, 1987)

### Phenomenology and Variations in Presentation

The clinical presentation of persons with mental retardation is influenced by multiple factors, which can be grossly divided into biological (such as syndromes underlying the retardation), psychological (the level of the person's intellectual and adaptive functioning), and environmental (such as cultural expectations and services received). Their mutual relationship is illustrated in Figure 24.1.

The more severe the mental retardation, the earlier the child will come to medical attention because the developmental delay will be obvious earlier, and associated physical impairments will be more prevalent. Conversely, children with mild mental retardation may not be diagnosed until they reach school age, when they fail in academic learning. If the sociocultural environment does not value and stress early academic learning and early education is not available, mild mental retardation might go undetected, especially if the person has relatively good adaptive skills. A false-positive diagnosis of mental retardation can also occur, especially if psychological tests are not sensitive to cultural background, and there is a language barrier between the child and the tester.

The importance of the earliest diagnosis possible cannot be overstated because the prognosis will be much better if the intervention which results from the diagnostic knowledge is begun as early as possible.

### Assessment of Mental Retardation

#### American Association on Mental Retardation's Classification of Mental Retardation

The American Association on Mental Retardation has published in 2002 a new edition of its manual *Mental Retardation: Definition, Classification and Systems of Supports*. Several dimensions of mental retardation are described, which might also serve as an outline for its assessment:

- Dimension I: Intellectual abilities
- Dimension II: Adaptive behavior (Conceptual, social and practical skills)
- Dimension III: Participation, interactions and social roles.
- Dimension IV: Health (physical health, mental health, etiological factors).
- Dimension V: Context (environments and culture).

This is a comprehensive description of the person's current environment: its nature, strengths, and weaknesses, supports for person's development and well-being (including factors such as poverty, family and its attitudes, availability of education and other services).

In all aspects of the assessment, attention should be paid both to the strengths as well as to the weaknesses and the impairments.

#### Biomedical Etiological Assessment of Mental Retardation

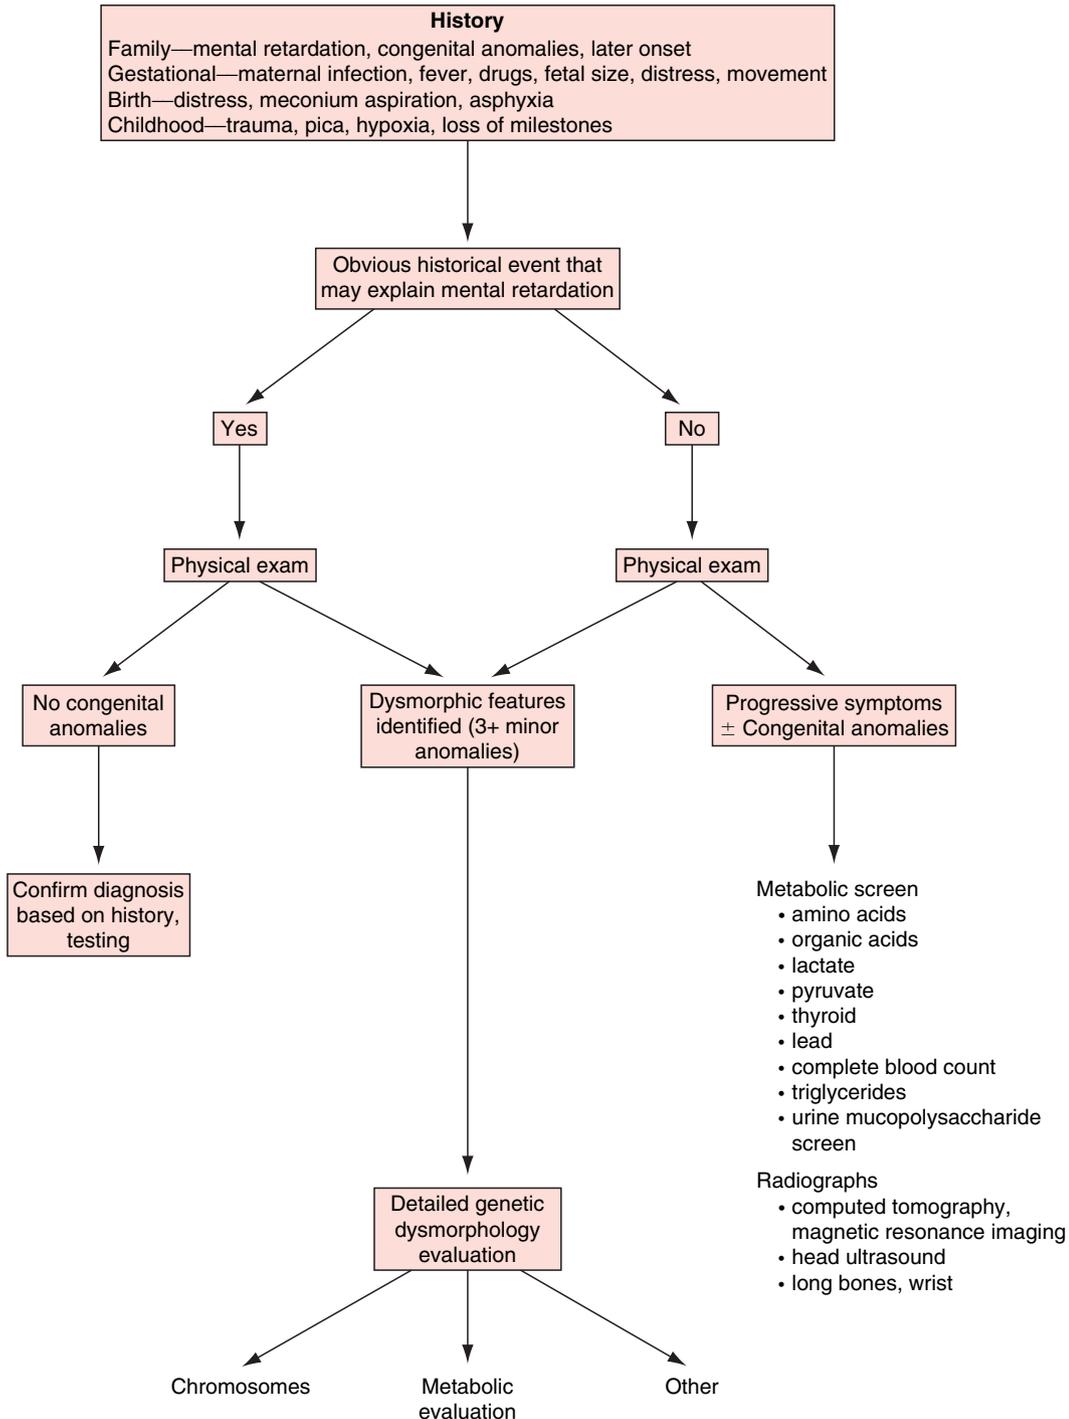

Mental retardation associated with syndromes and disorders with obvious phenotypical features is usually recognized earliest, such

as in the case of Down syndrome. The diagnosis is then confirmed by chromosomal or other appropriate laboratory studies. If there was a suspicion of a family's risk for a genetic disorder before the birth (such as through prior genetic counseling), appropriate studies are performed in the neonatal period. Some cases of congenital mental retardation (e.g., PKU) are discovered in the course of routine neonatal screening. Newborns with perinatal risk factors like prematurity and asphyxia should be followed up closely for later manifestations of developmental delay. Other children might come to medical attention because of a delay in

achieving developmental milestones or regression in a previously normal developmental pattern. Finally, many children with mental retardation will be referred for diagnostic assessment when they reach school age because of failure in academic learning.

### Elements of Biomedical Assessment

The scheme for assessing the etiology of mental retardation is summarized in Figure 24.2. This work-up has been used by Finnish physicians for 20 years (Wilska and Kaski, 1999).

**Figure 24.2** Diagnostic approach to mental retardation of all ages. (Source: Szymanski LS and Kaplan [1991] *Mental retardation*. Reprinted with permission from the *Text book of Child and Adolescent Psychiatry*, p. 157. Weiner JM (ed). Copyright 1991, American Psychiatric Press.)

## Overall Goals of Treatment of Mental Retardation

Mental retardation is a functional disability: thus, the goal of treatment should be to reduce or eliminate the disability. There are three aspects to the treatment:

1. Treatment of the underlying disorder that is causative of mental retardation (e.g., phenylketonuria – PKU).
2. Treatment of the comorbid disorders that add to the functional disability, whether physical or mental.
3. Interventions targeted at the functional disability of the mental retardation itself: educational, habilitative and supportive approaches depending on the person's individualized needs.

The current approach to the services for persons with mental retardation is based on the following principles:

1. Inclusion into normal aspects of society and opportunities for success
2. Right to community living
3. Education and training for all children
4. Employment of adults in the community
5. Use of normal community services and facilities
6. Advocacy and appropriate protective measures.

## Variations in Presentation

There is no evidence that mental disorders seen in persons who have mental retardation are basically different from mental disorders seen in the general population. However, the clinical manifestations may be modified by many factors that include: cognitive impairment; communication skills; associated sensory, motor, and other disabilities; environment; life experiences and circumstances. The most important of these factors is the presence or absence of verbal language. This is to be expected since many if not most of current diagnostic criteria of mental disorders are based on a patient's verbal productions. For instance, it might be impossible to recognize the presence of thought disorder in a nonverbal person (similar problems are encountered with young children).

## Behavior Disorders

A common reason for referral for psychiatric consultation is to determine whether a person with mental retardation has "a behavior disorder or a mental disorder". The DSM-IV does not have the diagnostic category of "behavior disorder", although it is included in the ICD-10 (World Health Organization, 1992).

Although there is no clear definition of "behavior disorder", it is usually meant to refer to a behavioral problem that is severe enough to warrant intervention, but which is not a part of diagnosable mental disorder. It is often applied to a deliberate misbehavior, learned response and "attention-getting" behavior. However, in the clinical presentation of every defined mental disorder, there might be elements of learned behavior, for example, caused by the responses of persons in the patient's environment. The danger of such ill-defined, nonspecific category is that clinicians faced with a difficult case might be tempted to use it, rather than attempt to make a more specific diagnosis that might lead to a more focused treatment. Thus, it is preferable to avoid dichotomizing abnormal behaviors into "behavior" and "mental" disorders, but rather to try to decide to which mental disorder the behavioral manifestations form a part (Szymanski,

1994). Possibly "behavior disorder" could be employed to denote a maladaptive behavior that is clearly a function of situation and environment, and not primarily the individual. A commonly seen example might be an individual living in a large residential institution who, in a well-staffed workshop, is very cooperative, happy and hardworking, but becomes irritable, negativistic, even aggressive in the afternoon, when he returns to the overcrowded and understaffed ward where he lives. A maladaptive behavior may also serve as a form of communication if the person has poor language skills or when the carers do not respond to other attempts to communicate. In any case, it is essential that a comprehensive psychiatric diagnostic assessment be made to ensure that the behavior in question is not a part of a diagnosable mental disorder.

## Assessment

### Special Issues in the Psychiatric Assessment of Persons with Mental Retardation

The basic principles of the psychiatric diagnostic assessment of persons who have mental retardation are the same as those for persons who do not have mental retardation. However, the clinical approaches may have to be modified. The scope of the assessment might have to take into account multiple needs and problems and, in addition, these individuals depend on multiple providers for multiple services. The clinical techniques have to be modified according to the patient's discrete developmental levels in various domains, and in particular, communication skills (Szymanski, 1980). In accordance with the principle of biopsychosocial integration, all factors and their mutual interaction and contribution to the patient's problems and general functioning must be considered. Thus, the presenting problems must be assessed in the comprehensive context of a patient's abilities and disabilities and not as an isolated issue (Szymanski and Crocker, 1989).

### Approaches to Obtaining a History

All involved caregivers should be interviewed if possible (parents, teachers, direct care workers, supervisors in workshops). Direct care staff members (e.g., from the group home and workshop supervisors) are particularly important because they can provide a firsthand description of a person's behavior. Exploring the following areas is important.

- Reasons for Current Referral
- Behavioral Symptoms
- Medication History
- General History
- Nature of the Disability
- Medical History
- Past and Current Services
- Milieu Events
- The Family

### Approaches to the Patient's Interview

The way in which the patient's interview is approached will depend on the patient's communication skills and cooperation and might range from an age-appropriate verbal interview to observation only. The communication skills have to be explored first through brief, noncommittal conversation and questioning of the

caregivers. If necessary, the caregivers might be used as interpreters of the patient's poorly intelligible speech or sign language. Directiveness and structure are often necessary to help the patient focus, but leading questions or suppression of spontaneous expression must be avoided. While firm and clear behavioral limits may have to be established at the interview's onset if necessary, a great deal of support is needed. Noncondescending verbal and social reinforcement, as appropriate for developmental age, will let the patient know that the interviewer is appreciative of her or his abilities. The patients should be approached respectfully – if possible, in a manner appropriate to the chronological age – and not as children. However, communication with them should be on the level they can understand, and their understanding should be ascertained. For instance, persons with mental retardation are afraid to be perceived as inadequate and instead of saying that they did not understand the question, they tend to agree with the interviewer's last statement. Thus, asking open-ended questions is preferable to giving a choice of answers. For the same reason structured mental-status type of questions might be counter-productive. Leading questions should be avoided. One should explore the patient's self-image, including understanding of his or her own disability as well as strengths.

Nonverbal interviewing techniques include behavioral observations, spontaneous and directed (structured) play (as developmentally and age appropriate), and other structured tasks.

### Evaluation of Clinical Data

The clinical observations should be interpreted in light of a patient's life experiences, learning, understanding and communication level. The global IQ or overall mental age alone is not a good guide here. In particular, the psychiatrist should:

1. Assess clinical presentation in light of the patient's communication ability, cognitive level, associated disabilities (e.g., sensory), life experiences, environmental factors and cultural background. One should differentiate between behaviors appropriate for an earlier age and those that are pathological in any age (e.g., true hallucinations). Not all disruptive behaviors are an expression of a mental disorder: for example, an overworked staff might promote aggressive acting out by attending to the patients only when they become aggressive. However, one should not simply explain all such behaviors as attention-seeking behaviors. Conversely, persons who do not manifest disruptive behaviors might have a mental disorder, for example, a depressed individual who is considered behaving well because he is very quiet.
2. Obtain, if needed, evaluations and consultations with other disciplines, for example, language pathologists, psychologists and neurologists.
3. Assess and understand the dynamic, ongoing transactional relationships among the various factors contributing to the person's development (see Figure 24.1).
4. Try to make a formal Axis I and/or Axis II DSM-IV diagnosis (besides mental retardation) whenever clinically justified. The diagnostic criteria can usually be adapted to the patient's developmental level, just as one does with child patients). However, diagnosis does not mean listing the disorder's code and name only. To be constructive, the diagnostic statement should include description of strengths, impairments, and need for supports and services in each discrete domain of the individu-

al's functioning, as well as in the environment (community and family). It should not merely copy the diagnostic criteria but describe how they are satisfied in the particular case by history and clinical observation, as well as why other diagnoses in the differential are ruled out.

### Aggression

"Aggression" to people or property (destructiveness) is one of the most frequent reasons (if not the most frequent) for referring persons with mental retardation to a psychiatrist. On closer investigation, the actual behavior ranges from occasional swearing (verbal aggression) to serious violence (Harris, 1995). Whether a particular behavior is called aggression (except for clear physical aggression) depends on the caregiver's perception. Thus, in obtaining the history it is necessary to obtain a concrete description of the behavior in question, preferably from several informants. Prolonged direct observation of the patient may be necessary to resolve unclear cases. There is no single entity called aggression in this population that would have one explanation. It would be a mistake to talk about a single treatment for aggression (except for symptomatic emergency measures). Psychiatrists are often asked how they treat aggression in persons with mental retardation. The answer is, of course, that it is done in the same manner as in persons without mental retardation: an accurate diagnostic assessment comes first. Different factors must be considered in assessing the cause of aggressive behavior (Harris, 1995). It might be associated with a defined mental disorder, for example, aggression following a command hallucination, paranoid delusion, anxiety, borderline or antisocial personality, or depression. The factor of learning will reinforce aggressive behavior if it brings a desired response by the caregivers. A pathological brain condition, such as rage attacks after brain trauma or associated with temporo-limbic seizure disorder, may also lead to aggression. Often, several causative factors are involved, all of which require evaluation and intervention.

The DSM-IV-TR has a category of intermittent explosive disorder that can be used provided that another mental disorder has been ruled out as the cause of the aggressive behavior.

### Overall Goals of Psychiatric Treatment of Persons with Mental Retardation

The most common mistake made by mental health clinicians treating persons with mental retardation is to consider suppression (usually with medications) of single problems (as a rule disruptive behaviors) as the only goal of treatment. This approach used to be the rule in the past when people with mental retardation were not expected to achieve any measure of independence and keeping them docile was the goal. Lately such approaches are reemerging, partly related to the insurer's pressure to achieve a fast and inexpensive symptomatic improvement, even if short lived.

The goal of any form of psychiatric treatment of persons with mental retardation is to contribute to this sense of satisfaction with one's own life, or happiness, in the context of a comprehensive treatment program. Suppression of behaviors inconvenient to caregivers is not enough, especially if they are a response to an inadequate habilitation program and the treatment (usually medications) is used in lieu of such program. Furthermore, medications may suppress a person's functioning through side effects such as drowsiness. The mental health clinician should not as-

sume that “nonpsychiatric” problems are taken care of by someone else, but should take an active part in the team’s assessment of various factors contributing to the clinical presentation, as well as the person’s need for various supports. This is not to say that the psychiatrist should be in charge of behavioral modification or vocational rehabilitation, but that these approaches should be closely coordinated with specific psychiatric treatments and should be targeted toward the common therapeutic goal.

### Prerequisites for a Successful Treatment Program

- Comprehensive diagnostic understanding
- Developing goals of treatment
- Developing treatment priorities
- Monitoring treatment results
- Avoidance of indefinite treatment
- Team collaboration

#### Clinical Vignette

Barbara was diagnosed at 3 years of age with severe mental retardation due to marked delay in her global development. Exhaustive genetic evaluation failed to clarify its etiology. She never developed expressive speech, but understood simple commands and knew about 30 signs. She lived with her very supportive parents, attended special classes and was a friendly, well-related and pleasant person. At 17 years of age she became gradually withdrawn, cried often, did not enjoy car rides with her parents (previously her favorite activity), lost appetite and weight, and slept poorly. When she was pressed to complete school tasks she became aggressive, prompting psychiatric referral. She was diagnosed with a major depressive episode and was put on imipramine. Over the next 2 months she gradually improved. Her appetite returned, she became cooperative and slept better. However, in the third month she again developed insomnia, roamed the house at night singing or screaming, was hyperactive, laughed for no obvious reason, and became aggressive if told to go to sleep. Detailed medical evaluation failed to disclose any general medical condition. There was no history of traumatic environmental events. She was diagnosed as having a psychotic episode and treated with risperidone. She improved dramatically at first, but in a month she was where she started; presenting with the same symptoms that led initially to the diagnosis of depression. This time a diagnosis of bipolar disorder NOS was made and she was treated with carbamazepine. She improved rapidly. Her mood stabilized, she slept and ate well, again became cooperative at school and home and returned to her “old self”.

### Principles of the Use of Psychotropic Drugs in Persons with Mental Retardation

This outline is based largely on an excellent review of Kalachnik and coworkers (1998), Rinck (1998), as well as on the American Academy of Child and Adolescent Psychiatry (1999), and the Health Care Financing Administration (1997).

### Purpose of Drug Use

These drugs are used to treat a diagnosed mental disorder toward the goal of maximizing a person’s quality of life. They should not be used merely to suppress a single, objectionable behavior without regard to the effect on a person’s global adjustment, functioning and quality of life. They cannot be used as punishment, for staff convenience (such as in understaffed facilities), in lieu of appropriate rehabilitative program (if such is unavailable), or in dosages that interfere with such programs and with a person’s quality of life (Rinck, 1998, p. 52).

### Context of Drug Use

These drugs are always used as part of a comprehensive, treatment/habilitation program designed and supervised by an interdisciplinary team of which the psychiatric clinician is an integral part. They should not be prescribed merely in brief “psychopharmacology consultation” or “medication review”, in isolation from other aspects of the treatment.

### Prerequisites for Drug Use

1. Comprehensive psychiatric diagnostic assessment, following the guidelines described earlier (see also Figure 24.1), and resulting in a psychiatric diagnosis.
2. Presence of a comprehensive treatment plan and evidence that less intrusive measures have not been effective (such as behavior modification, psychotherapies, milieu supports, etc.).
3. Comprehensive evaluation to rule out medical conditions that could have caused the presenting symptoms.
4. Existence of a reliable system to collect behavioral data individualized to the particular patient that measures occurrence of symptoms considered an index of the person’s mental disorder. This should also provide reliable baseline data and functional analysis of behavior that would assess the influence of immediate and more remote antecedents and consequences of the patient’s behaviors and other symptoms.
5. Satisfaction of all relevant regulatory and legal requirements, especially obtaining informed consent of the patient and/or legal guardian.

### Follow-up on Drug Effectiveness

1. The members of the interdisciplinary treatment team should follow the patient’s progress regularly (at least quarterly), based on changes in individualized index behaviors, symptoms, general adjustment, functioning and well-being. Presence of side effects and their findings should be communicated among the members of the team. Behavioral changes should be documented by reliable data. The follow-up should include a direct psychiatric interview and/or observation of the patient. The implementation of all aspects of the treatment program and not just the medications should be monitored and adjusted as needed to ensure that medications are not used in lieu of, but concurrently with, a habilitation program.
2. The medication should be tried at an effective dose for an adequate period of time. If there is no clear evidence of effectiveness it should be discontinued appropriately. It should be kept in mind that “ups and downs” are to be expected, such as in reaction to environmental and physical stressors common in the lives of these patients. Medication effectiveness

should therefore be judged by a pattern evident over reasonable period of time and not by one-point observations. For the same reason, preset dosage schedules linking dosage changes to specific frequencies of index behaviors are impractical. Multiple medications should be tried only if there is evidence that a combination is known to be more effective than a single medication.

## Dosages and Discontinuation

1. The optimal dosage is the lowest one that achieves the best a compromise between improving the patient's quality of life and side effects.
2. A trial of dose reduction and possibly discontinuation should be regularly considered but should be implemented only if not contraindicated clinically. Discontinuation, if attempted, should be gradual, and it may need a prolonged period depending on the type of medication and expected withdrawal effects. It is essential that all involved caregivers be aware of the possibility of such effects and be ready to deal with them, rather than demand immediate cessation of the discontinuation trial (this is particularly important with antipsychotics). As-needed (.3.prn) use of the medication is best avoided to prevent unnecessary use, or limited to clear situations, such as premedication prior to medical tests if stressful for the patient.

## Monitoring Side Effects

Side effects should be monitored regularly through direct examination (especially important with nonverbal persons), laboratory tests, tardive dyskinesia examination, and so on, as appropriate for the particular drug. Possible drug interactions should be monitored as these patients are often on multiple medications.

## Psychosocial Interventions

### Programmatic and Educational Approaches

The goal of these interventions is to provide a proper living and programmatic environment. For instance, certain persons easily become over-stimulated, anxious and disruptive in noisy and confused large workshops; arranging for a smaller and quieter workroom is preferable to a prescription for a neuroleptic. The vocational and educational program should be individualized and focus on developing the person's strengths and providing an opportunity for success. In turn, this will lead to results such as an improvement in self-image. Many persons with severe mental retardation are placed in prevocational training indefinitely, for example, screwing or unscrewing nuts and bolts, although no one expects them ever to be employed on an assembly line. They often engage in a struggle with caregivers because of their noncompliance and may resort to aggression, which leads to removal for a "time out" and thus avoidance of a boring task. Creating a more suitable task – even such as making rounds of the workshop to collect or deliver materials – might be more interesting and appropriate. Functional analysis of behavior is an invaluable guide to these interventions. As discussed previously, such approaches should be explored prior to resorting to use of medications for disruptive behaviors.

## Psychotherapies

Psychotherapy in this population is not different in nature from psychotherapy in persons with average intelligence and is similar to treating children, inasmuch as in both cases the techniques and the therapist have to adapt to the developmental needs of the patient. The treatment should be driven by the patient's needs and responses and not by the therapist's theoretical orientation. The indications are: the presence of concerns and conflicts, especially about oneself; impairments in interpersonal skills; or other mental disturbances that are known to improve through psychotherapy. The prerequisites include communication skills permitting a meaningful interchange with the therapist, an ability to develop even a minimal relationship, and the availability of a trained, experienced and unprejudiced therapist who is comfortable working in a team setting.

## Behavioral Treatment

This treatment should optimally use rewards which should be age appropriate, preferably social, and the frequency of rewarding should be adapted to a person's cognitive level, so that he or she can understand why they are given. Consistency and generalization among different settings are essential. Thus, if such techniques are successfully used at the school, the family or other caregivers should be trained to use them at home as well. The focus should not be on elimination of objectionable behaviors only but on teaching appropriate replacement behaviors. Aversive techniques involving active punishment (electric shocks, spraying of noxious substances into a person's face) are not used except in a few controversial settings. There is a professional consensus that these techniques should not be used at all, or only when all other techniques have failed and the patient's behavior poses severe danger to herself or himself or to others (such as intractable SIB). Even then, these techniques should be used only if proved effective and for a limited time.

## Psychiatrist–Patient Relationship: Models of Delivery of Psychiatric Services

The psychiatric care of persons with mental retardation has often followed a path different from the care provided to the general population. A common service model has been the medication clinic, in which the psychiatrist is given little, if any, time to examine the patient and to interview the caregivers. Instead, behavioral information, which is often brief and sketchy, is presented by caregivers and focuses primarily on disruptive behaviors. The psychiatrist is expected to prescribe medications and has no voice in, or knowledge of, other interventions that might be used. In some cases, the psychiatrist does the actual prescribing; in others, the psychiatrist serves as a consultant to primary physicians who may or may not follow the recommendations given. This model is obviously inadequate, even if there is another professional providing psychotherapy or behavioral therapy. It also exposes the psychiatrist to legal responsibility (Woodward *et al.*, 1993). This model has been used in institutions, especially to save on the expense of having a staff psychiatrist to provide adequate services.

The proper psychiatric care of persons with mental retardation is actually more time-consuming than the care of persons without mental retardation because of the multifactor nature of the treatment described previously. To understand the patient's

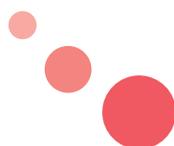

clinical presentation and provide the input necessary to all relevant aspects of treatment, the psychiatrist has to have adequate time to interview all involved caregivers, observe and interview the patient, make a home or program visit if necessary, and discuss the recommendation with all involved. Thus, the interdisciplinary team approach is necessary. It might not be realistic for all patients seen in the community, but it should be followed in all treatment-resistant cases and in residential facilities where, as a rule, there are more difficult patients (Szymanski *et al.*, 1980; Szymanski and Leaverton, 1980). In most cases in the community, if a team forges a good working relationship and regular communication, exchange of information and coordination via e-mail or telephone might be sufficiently productive. Some states have developed successful models of such coordinated care (that provide for health, housing, vocational and social services) for persons who have both mental retardation and mental illness (Polgar *et al.*, 2000). In all situations, psychiatrists will use their knowledge and training in biological and behavioral aspects of medicine to help other professionals synthesize the biopsychosocial aspects of a patient's clinical presentation and treatment program.

### Comparison of DSM-IV/ICD-10 Diagnostic Criteria

The methods of defining the levels of severity differs slightly between the two systems. The ICD-10 Diagnostic Criteria for Research define the levels using exact cutoff scores: Mild is defined as 50 to 69, Moderate is defined as 35 to 49, Severe is defined as 20 to 34, and Profound is defined as below 20. In contrast, DSM-IV-TR provides somewhat greater flexibility in relating severity to a given IQ score by defining severity levels using overlapping scores (i.e., Mild is 50–55, Moderate is 35–40 to 50–55, Severe is 20–25 to 35–40, and Profound is below 20–25). Within the overlapping range, the severity is determined by the level of adaptive functioning.

# Childhood Disorders: Learning and Motor Skills Disorders

For children and adolescents, school is their “workplace”. Successful school performance is essential for psychological growth and development. Social competency and social skills are developed and then shaped within the family and in the school but practiced and mastered in the school. The development of self-image and self-esteem is based on successes in school. Feedback from the school concerning academic performance and social interactions influences the parents’ image of their child or adolescent. Thus, if something interferes with success in school, the impact will affect the emotional, social and family functioning of a child or adolescent.

Academic performance requires the integrated interactions of the cognitive, motor and language functions of the brain. As detailed in the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (DSM-IV), if brain dysfunction results in cognitive difficulties, it is called a learning disorder; in motor difficulties, a motor skills disorder; and in language difficulties, a language disorder. This chapter focuses on the learning disorders and motor skills disorders.

Key for the mental health professional is the understanding that the underlying neurological dysfunctions that result in learning disorders and motor skills disorder have an impact on more than academic performance. These disabilities affect every aspect of the individual’s life during each stage of psychosocial development (Silver, 1989, 1993b).

## Definitions

Public education laws use the term learning disabilities. DSM-IV uses the terms learning disorders and motor skills disorder. It is helpful to understand that these terms reflect the diagnostic system used but refer to the same set of difficulties.

Public school systems use the federal definition based on Public Law 94–142, Education for All Handicapped Children, and its revision, Public Law 101–476, Individuals with Disabilities Education Act. In the latter, a learning disability is defined by the following inclusionary and exclusionary criteria:

Specific learning disabilities means a disorder in one or more of the basic psychological processes involved in understanding or in using language, spoken or written, which may manifest itself in an imperfect ability to listen, think, speak, read, write, spell, or to do mathematical calculations. The term includes such conditions as perceptual handicaps, brain injury, minimal brain dysfunction, dyslexia, and developmental aphasia. The term does not include children who have learning problems which

are primarily the result of visual, hearing, or motor handicaps, of mental retardation, of emotional disturbance, or of environmental, cultural, or economic disadvantage.

## DSM-IV-TR Criteria

The criteria in DSM-IV-TR for establishing the diagnosis of a learning disorder are shown as a summary of three criteria sets. For each of these diagnostic categories, the criteria in DSM-IV-TR is that if a general medical (e.g., neurological) condition or sensory deficit is present, the disorder should be coded on Axis III.

### DSM-IV-TR Criteria

#### Learning Disorders

- A. Academic achievement (i.e., reading, mathematics, or written expression), as measured by individually administered standardized tests, is substantially below that expected given the person’s chronological age, measured intelligence and age-appropriate education.
- B. The disturbance in Criterion A significantly interferes with academic achievement or activities of daily living.
- C. If sensory deficit is present, the difficulties are in excess of those usually associated with it.

Coding Note: If a general medical (e.g., neurological) condition or sensory deficit is present, code the condition on Axis III.

Reprinted from DSM-IV Guidebook (1995) Frances A, First MB, Pincus HA. American Psychiatric Press Inc, Washington, DC, p. 384.

#### Educational Criteria

The most recent federal guidelines for determining whether a student in a public school is eligible for special programs for learning disabilities list four criteria (Silver and Hagin, 1992):

1. Documented evidence indicating that general education has been attempted and found to be ineffective in meeting the student’s educational needs.
2. Evidence of a disorder in one or more of the basic psychological processes required for learning. A psychological process is a set of mental operations that transform, access, or manipulate information. The disorder is relatively enduring and

limits ability to perform specific academic or developmental learning tasks. It may be manifested differently at different developmental levels.

3. Evidence of academic achievement significantly below the student's level of intellectual function (a difference of 1.5 to 1.75 standard deviations between achievement and intellectual functioning is considered significant) on basic reading skills, reading comprehension, mathematical calculation, mathematical reasoning, or written expression.
4. Evidence that the learning problems are not due primarily to other handicapping conditions (i.e., impairment of visual acuity or auditory acuity, physical impairment, emotional handicap, mental retardation, cultural differences, or environmental deprivation).

The presence of a central nervous system processing deficit is essential for the diagnosis of a learning disability. A child might meet the discrepancy criteria, but without central processing deficits in functions required for learning, he or she is not considered to have a learning disability. The question of the significant discrepancy between potential and actual achievement determines eligibility for services. Different school systems use different models for determining the extent of discrepancy (Silver and Hagin, 1992, 1993).

### Diagnosis of a Learning Disorder or Motor Skills Disorder

If a child or adolescent is experiencing academic difficulty, she or he would normally be referred to the special education professionals within the school system. However, the student with academic difficulties often presents with emotional or behavior problems and is more likely to be referred to a mental health professional. It is critical to understand this potential referral bias. This mental health professional must clarify whether the observed emotional, social, or family problems are causing the academic difficulties or whether they are a consequence of the academic difficulties and the resulting frustrations and failures experienced by the individual, the teacher and the parents (Silver, 1989, 1993b, 1998; Bender, 1987; Hunt and Cohen, 1984; Valletutti, 1983).

The evaluation of a child or adolescent with academic difficulties and emotional or behavior problems includes a comprehensive assessment of the presenting emotional, behavior, social, or family problems as well as a mental status examination. The psychiatrist should obtain information from the child or adolescent, parents, teachers and other education professionals to help clarify whether there might be a learning disorder or a motor skills disorder and whether further psychological or educational studies are needed. Descriptions by teachers, parents and the child or adolescent being evaluated will give the psychiatrist clues that there might be one of the learning disorders or a motor skills disorder.

Children who experience problems in reading typically have difficulty in decoding the letter-sound associations involved in phonic analysis (Rourke and Strang, 1983). As a result, they may read in a disjointed manner, knowing a few words on sight and stumbling across other unfamiliar words. They may guess. If they have difficulty with visual tracking, they may skip words or lines. If comprehension is a problem, they report that they have to read material over and over before they understand.

Children with mathematical difficulties may have problems learning math concepts or retaining this information. They may make "careless mistakes" when doing calculations. Math is

a written language in that one is graded on what is put on paper. Thus, problems with visual-spatial tasks or with sequencing might interfere with producing on paper what is known. A problem may not be completed or steps skipped. They might have difficulty shifting from one operation to the next and, as a result, add when they should subtract. A visual-spatial difficulty might result in misaligned columns or rows, or decimals put in the wrong place.

Children who have difficulties with writing may have a problem with handwriting. They grasp the pencil or pen differently and tightly. They write slowly, and their hands get tired. Often, they prefer printing rather than cursive writing. Most also have problems with the language of writing. They have difficulty with spelling, often spelling phonetically. They may have difficulty with grammar, punctuation and capitalization (Poplin *et al.*, 1980).

Many if not most students with a learning disorder also have difficulties with memory or organization. The child or adolescent with a memory problem has difficulty following multistep directions or reads a chapter in a book but forgets what was read. Others might have sequencing problems, performing instructions out of order. In speaking or writing, the facts may come out but in the wrong sequence. Students with organizational difficulties may not be able to organize their life (notebook, locker, desk, bedroom); they forget things or lose things; they have difficulty with time planning; or they have difficulty using parts of information from a whole concept or putting parts of information together into a whole concept.

Children and adolescents with a developmental coordination disorder may show evidence of gross motor or fine motor difficulties. The gross motor problems might result in difficulty with walking, running, jumping, or climbing. The fine motor problems may result in difficulty with buttoning, zipping, tying, holding a pencil or pen or crayon, arts and crafts activities, or handwriting. Both gross and fine motor difficulties may result in the individual performing poorly in certain sports activities.

Ostrander (1993) and Silver (1993a) suggested a set of "systems review"-type questions (Table 25.1) to be used during an interview with parents or the child or adolescent with academic difficulties suspected of having a learning disorder (learning disability) or a developmental coordination disorder. These questions focus both on the specific areas of skills and on the possible underlying processing problems.

### Evaluation of the Child or Adolescent

Difficulties in academic performance of children or adolescents can be related to a range of psychiatric, medical, or cognitive factors. To determine best the primary source of academic difficulties, the evaluation should involve a comprehensive examination of these areas. The psychiatric evaluation should clarify whether there is a psychopathological process. If one is present, it is useful first to determine whether the problems relate to a disruptive behavior disorder or to another psychiatric disorder. In particular, the disruptive behavior disorders have high comorbidity with academic difficulties. A full assessment should clarify whether a disruptive behavior disorder is causing the difficulty with academic performance or is secondary to this difficulty. Disruptive behavior disorders can result in the student being unavailable for learning or being so disruptive as to require his/her removal from traditional learning environments. The frustration and failures caused by a learning disorder can be manifested by a disruptive behavior disorder. In some cases, the disruptive behavior disorder coexists with the learning

**Table 25.1 Screening Questions**

---

**Reading**

---

Do you like to read?  
Can you sound out words as well as your classmates can?  
Do you know the word on sight, or not at all?  
Do you skip words or lines?  
Does it take you longer than other children to read?  
Can you remember what you read?

---

**Mathematics**

---

Do you know the basic facts in addition, subtraction, multiplication and division?  
Do you often add when you should subtract or multiply?  
Do you often forget some of the steps when doing mathematics problems?  
Do you often make careless errors?  
Is your mathematics homework messy?

---

**Writing**

---

How is your handwriting? Can people read it?  
Can you write fast enough?  
How is your spelling? When you make spelling mistakes, can other people figure out what word you were trying to spell?  
Do you make many mistakes in capitalization, punctuation, or grammar?

---

**Sequencing**

---

When you speak or write, do you sometimes have difficulty getting everything in the right order or do you start in the middle, go to the beginning, then jump to the end?  
Can you name the months of the year? (Let child do.) Fine, now what comes after August? (Ask how he or she got the answer. Was it necessary to return to January and count up?)  
Do you have difficulty using the alphabet when using a dictionary? Do you have to return to “a” often to know whether the next letter is above or below the letter you are on?

---

**Abstraction**

---

Do you understand jokes when your friends tell them?  
Do you sometimes get confused when people seem to say something, yet they tell you they meant something, else?

---

**Organization**

---

What does your notebook look like? Is it a mess with papers in the wrong place or falling out?  
What about your desk? Your locker? Your bedroom?  
Do you have difficulty organizing your thoughts or the facts you are learning into a whole concept so that you can learn it?  
Do you find that you can read a chapter and answer the questions at the end of the chapter but that you are still not sure what the chapter is about?

---

**Memory**

---

Do you find that you can learn something at night and then go to school the next day and forget what you have learned?  
When talking, do you sometimes know what you want to say but halfway through you forget what you are saying? If so, do you cover up by saying things like “Oh, forget it” or “It’s not important”?

---

**Language**

---

When the teacher is speaking in class, do you have trouble understanding or keeping up?  
Do you sometimes misunderstand people and therefore give the wrong answer?  
When people are talking, do you find that you have to concentrate so hard on what they say that you sometimes fall behind and have to skip quickly to what they are saying now to keep up?  
Does this sometimes cause you to get lost in class?  
Do you sometimes have trouble getting your thoughts organized when you speak?  
Do you have a problem finding the word you want to use?

---

**Motor**

---

Do you feel that you can run, jump and climb as well as your friends can?  
Would you describe yourself as clumsy?  
Do you find that you often knock things over or bump into things?  
Do you have difficulty with dressing, especially with buttoning, zipping, tying? How about cutting food and eating?  
In sports do you have difficulty with throwing, hitting and catching a ball?  
How would you describe your handwriting? Do you hold your pencil or pen differently from others? Does your hand get tired? Do you write slower than you need to in class?

disorder and the relation is less clear. Children and adolescents with attention-deficit/hyperactivity disorder (ADHD) have particular difficulty maintaining attention, and possibly with processing information. As a result, the same variables that have an impact on their attention also have an impact on their ability to learn. In such instances, they may have a learning disorder and ADHD.

Internalizing disorders such as depression or anxiety may result in an uncharacteristic disinterest in or avoidance of school expectations. If one of the internalizing disorders is present, it is important to clarify whether it is secondary or primary to the academic difficulty. Cognitive and language deficits as well as social skills deficits are often associated with learning disorders and can contribute to a dysphoric or anxious presentation.

The medical evaluation is necessary to explore the influence of health factors on the individual's availability and ability to learn. Problems in acquiring academic content can be significantly affected by most visual or hearing deficits. Generally poor health can influence the stamina, motivation and concentration needed to focus adequately on academic demands. Medications used for any purpose might cause sedation or other side effects that may affect the child's ability to learn. Early developmental insults can result in global or focal deficits in neurological development. Undiagnosed seizures, especially petit mal and partial complex seizures, can result in difficulties in general cognitive functioning, specific deficits in memory and problems with attention.

The evaluation of cognitive, academic and neuropsychological functioning is critical to any assessment of learning problems. Results of this psychoeducational assessment will indicate the parameters of the individual's academic and cognitive liabilities while identifying her or his assets. In some instances, borderline cognitive development or mental retardation may be the primary explanation for learning difficulties. Developmental delays are particularly evident with a preschool child; rapid and uneven developmental changes can lead to considerable variability in findings derived by measures of intellectual functioning. If any of the clinical evaluations yield results suggestive of a learning disorder, a more involved psychoeducational assessment is needed. An appropriate psychoeducational evaluation will reveal the magnitude of the child's learning difficulties as well as the nature of the child's cognitive assets and deficits. From this understanding, appropriate interventions can be designed and special accommodations can be initiated.

A family evaluation is an integral part of evaluation and must include an assessment of the parents and of the entire family. The first clinical question is whether the family is functional or dysfunctional. If the family is largely functional, there may be "normal" parenting issues that may be contributing to the child's difficulty.

A normal parenting issue may be their lack of time or energy to address the child's academic difficulties.

### Environmental and Cultural Assessment

Learning problems are attributed to cognitive deficits or behavior problems in the child or adolescent. Environmental factors involving the school or community, however, can also contribute to academic difficulties. Thus, the psychiatrist should be aware of how social, cultural, or institutional structures can influence learning.

A child or adolescent with specific needs may be further impaired because of a limited range of services offered by the school system.

### Social Problems

The learning disabilities that result in learning disorders or motor skills disorder may directly contribute to peer problems by interfering with success in doing activities required to interact with certain age groups (e.g., visual perception and visual-motor problems interfering with ability quickly to do such eye-hand activities as catching, hitting, or throwing a ball).

Many children and adolescents with learning disorders have difficulty learning social skills and being socially competent (Hazel and Schumaker, 1988). These individuals do not pick up such social cues as facial expressions, tone of voice, or body language and therefore do not adapt their behaviors appropriately. Rourke (1987, 1988, 1989) and Rourke and Fuerst (1991), using the definition of learning disabilities, identified a specific subtype of learning disabilities, called nonverbal learning disabilities. These students do not have the difficulties with interpersonal interactions found in pervasive developmental disorders. This pattern of learning disabilities includes deficits in tactile perception, visual perception, complex psychomotor tasks and accommodation to novel material as well as difficulty in simple motor skills, auditory perception and mastery of rote material. A small subset of these students show difficulty in social and emotional functioning that includes a predisposition toward adolescent and adult depression and suicide risk (Rourke and Fuerst, 1991).

### Other Psychiatric or Medical Disorders

The first neurologically based disorder recognized as frequently associated with a learning disability (learning disorder) was ADHD (Silver, 1981; Halperin *et al.*, 1984). Studies suggest that there is a continuum of disorders associated with neurological dysfunction that are often found together. Thus, when one is diagnosed, the others must be considered in the diagnostic process.

The specific constructs for understanding the probable cognitive and language bases for the specific learning disorders and motor skills disorder are discussed under each subtype in the section on treatment. The premise is that there are neurologically based processing problems that result in the disabilities.

---

#### Clinical Vignette 1

Billy started first grade and did not do well. He did not master the early skills of reading and writing. The school decision was to have him repeat first grade. He did not make much more progress during his second year in first grade. Because of his age, he was promoted to second grade. He struggled through this year but fell further and further behind. When he entered third grade, he was overwhelmed. He knew that he was a year older than the other students. He was unable to do the work in class or at home and felt frustrated and stupid. Soon, he began to clown around in class and to get into fights with the other students.

Two other things happened during this third-grade year. First, his teacher became frustrated. She was trying to help him learn and he was not making progress. He was disrupting the class and preventing her from teaching the other children. The teacher handled her frustration by blaming it on the parents. She began to call them.

**Clinical Vignette 1** *continued*

“Billy is not completing his schoolwork.” “His homework is incorrect.” “He is teasing and fighting with the other children.” She seemed to be saying to the parents, “Do something. Fix your kid.” She did not realize that the parents were just as confused and frustrated as the teacher. Secondly, the parents began to disagree on parenting decisions. One felt that the best way to help Billy was to be firm and strict, and the other felt that the best way was to be understanding and permissive. They began to argue with each other and became less available to support each other.

Finally, the principal asked the parents to come to school. They were informed that Billy was not making academic progress. They were also told that the reason for his failure was that he was emotionally disturbed because of the marital conflicts. The parents were encouraged to see a mental health professional.

This psychiatrist noted that Billy had difficulty with reading, reading comprehension, handwriting and written language. He found Billy to be frustrated with a poor self-image and low self-esteem. The parents seemed to be competent people who were also frustrated with Billy’s difficulties. A full psychoeducational testing was requested. The results showed Billy to be of above-average ability but with significant learning disabilities.

The psychiatrist concluded that the primary diagnosis was the learning disability. The emotional, behavioral, social and family problems were secondary to the frustrations and failures experienced by Billy, his parents and his teacher. By working with the family, he helped to get Billy identified as having a disability and to obtain the necessary services to help him. His behavior problems diminished and then ceased.

**Treatment**

Treatment is directed at the underlying disabilities by use of educational interventions. Psychological interventions are also directed at any existing emotional, social, or family difficulties. In addition, social skills training may be helpful.

**Educational Interventions**

The goal of special educational interventions is to help children and adolescents overcome or compensate for their learning disorders or motor skills disorder so that they can succeed in school. These efforts involve remedial and compensatory approaches and use a multisensory approach that facilitates building on all areas of strength while compensating for any areas of weakness. These efforts are to be provided in as close to a regular classroom setting as possible. It is essential that the classroom teacher knows how best to adapt the classroom, curriculum and teaching style to accommodate each student’s areas of difficulty.

**Psychotherapeutic Interventions**

Learning disorders affect all aspects of the child’s or adolescent’s life. The same processing problems that interfere with reading, writing, mathematics and language may interfere with communicating with peers and family, with success in sports and

activities, and with such daily life skills as dressing oneself or cutting food (Silver, 1993b).

Lack of success in school can lead to a poor self-image and low self-esteem (Black, 1974; Bryan and Pearl, 1979; Rogers and Saklofske, 1985; Shaw *et al.* 1982). These individuals might feel that they have minimal control over their life and compensate by trying to be in more control (Silver, 1993c). Some individuals may become anxious or depressed, or a disruptive behavior disorder may develop.

Genetic and family studies show that in about 40% of children and adolescents with learning disabilities (learning disorders), there is a familial pattern (Johnson, 1988). Thus, from an early identification perspective, each sibling must be considered as possibly having a learning disorder. Also, there is a 40% likelihood that one of the parents may also have a learning disorder. This parent may not have known of this problem. If this is true, the parent for the first time may be able to understand a lifetime of difficulties or underachievement. Further, when the psychiatrist offers suggestions for this parent, the parent’s areas of difficulty must be considered. Do not ask a mother to be more organized when she has been just as disorganized as her child all of her life.

Some children or adolescents may need specific individual, behavioral, group, or family therapy. If so, it is critical that the therapist understand the impact that the learning disorder has had on the individual and how these disabilities might affect the process of therapy (Silver, 1993a). As noted earlier, many students with a learning disorder have difficulties with peers and social skills problems. Social skills training might be helpful.

**Use of Medications**

No medication has been found to be effective for treating the learning disorders or motor skills disorder. If the individual with these disorders also has ADHD, it is important that medication be used to minimize the hyperactivity, distractibility, or impulsivity so that the student can be available for learning.

**Comparison of DSM-IV/ICD-10 Diagnostic Criteria**

In ICD-10, DSM-IV-TR Reading Disorder is referred to as “Specific Reading Disorder” and DSM-IV-TR Mathematics Disorders as “Specific Disorder of Arithmetic Skills”. For both of these learning skills disorders, the ICD-10 Diagnostic Criteria for Research suggest that the cutoff be two standard deviations below the expected level of reading achievement and mathematics achievement respectively. In contrast, DSM-IV-TR does not specify a score cutoff, instead recommending that the score be “substantially below that expected given the person’s chronological age, measured intelligence, and age-appropriate education”. Furthermore, in contrast to DSM-IV-TR which permits both to be diagnosed of present, ICD-10 Reading Disorder takes precedence over Mathematics Disorder so that if criteria are met for both, only Reading Disorder is diagnosed.

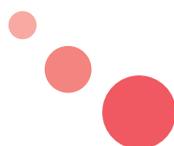

ICD-10 does not include a Disorder of Written Expression (as in DSM-IV-TR), but instead includes a Specific Spelling Disorder. DSM-IV-TR includes spelling problems as part of the definition of Disorder of Written Expression but requires writing problems in addition to spelling in order to warrant this diagnosis.

Finally, DSM-IV-TR Coordination Disorder is referred to as “Specific Developmental Disorder of motor function” in ICD-10. Furthermore, the ICD-10 Diagnostic Criteria for

Research suggest that the cutoff be two standard deviations below the expected level on a standardized test of fine or gross motor coordination.

# Childhood Disorders: Communication Disorders

## Definitions

Psychiatric practice depends upon communication and language. Language and or learning disorders have been linked in the past, but in DSM-IV-TR (American Psychiatric Association, 2000) they are regarded as separate although often associated conditions. This section covers: Expressive Language Disorder, Mixed Receptive-Expressive Language Disorders, Phonological Disorder, Stuttering and Communication Disorder NOS. These disorders share many common features, as noted in Table 26.1. They are defined by criteria in DSM-IV-TR. In all cases a test score or assessment measure alone does not define these conditions. An individual must also experience social, academic or occupational difficulties directly related to the condition.

DSM-IV-TR does not consider receptive language disorders in isolation. Receptive language disorders in children seldom, if ever, can occur without concurrent (and perhaps resultant) problems with expression. This is in direct contrast with such entities as Wernicke's aphasia in adults, which affect reception alone.

**Table 26.1** Features Common to All Communication Disorders

<p>Inadequate development of some aspect of communication Absence (in developmental types) of any demonstrable causes of physical disorder, neurological disorder, global mental retardation, or severe environmental deprivation Onset in childhood Long duration Clinical features resembling the functional levels of younger normal children Impairments in adaptive functioning, especially in school Tendency to occur in families Predisposition toward boys Multiple presumed etiological factors Increased prevalence in younger age range Diagnosis requiring a range of standardized techniques Tendency toward certain specific associated problems, such as attention-deficit/hyperactivity disorder Wide range of subtypes and severity</p>
---

Adapted from Baker L (1990) Specific communication disorders, in *Psychiatric Disorders in Children and Adolescents* (eds Garfinkel BD, Carlson GA and Weller EB). Copyright 1990, with permission from Elsevier.

Outside of DSM-IV-TR, the term “phonologic disorder” may refer to a condition characterized by difficulty in generating sound combinations, as for example in the case of laryngeal dysfunction.

## Epidemiology

### Prevalence

Prevalences varying from 1 to 13% have been reported for language disorders, and numbers as high as 32% for speech disorders (Baker, 1990). In development of the DSM-IV-TR, researchers found that:

- Acquired language disorders appear less common than the developmental types.
- 3–7% of all children were suspected of having a developmental Expressive Language Disorder.
- Mixed Expressive – Receptive Language Disorder appears in up to 3% of school-age children.
- Phonological Disorder occurs in approximately 2% of six and seven-year olds, falling to 0.5% by age 17.
- Stuttering occurs in approximately 1% of children 10 and younger, declining to 0.8% in later adolescence.
- All of these conditions have a male to female predominance; that of stuttering is as high as 3 : 1.

## Comorbidity

### General

Cantwell and Baker (1991) demonstrated that approximately half of the children with a speech or language disorder have some other definable Axis I clinical disorder. Similarly, among children with a psychiatric diagnosis first made, there is a remarkably increased likelihood of speech and language disorders, which often go undetected. Beitchman (1985) found more than four times the prevalence of psychiatric illness in kindergartners with communication disorders compared with nondisordered children. Cantwell and Baker also found that psychiatric illness in their population was associated with greater severity of communication problems.

Conversely, the presence of communication disorders may be associated with increased severity of some psychiatric conditions, most notably the Disruptive Behavior Disorders. Physicians must recognize that these disorders do not occur in an isolated context.

## Expressive Language Disorder and Mixed Receptive-expressive Language Disorder

Phonological Disorder and Learning Disorders are common among children with this disorder. Other neurodevelopmental conditions are also seen, such as motor delays, coordination disorders and enuresis, although the rate of association is uncertain. These disorders and the stresses they create frequently lead to Adjustment Disorders and social withdrawal. Cantwell and Baker (1991) found that the most common psychiatric disorder among children with communication disorders overall was Attention Deficit Hyperactivity Disorder (ADHD), representing 19% of their sample of 600 children referred for a communication evaluation. Some authors have speculated that ADHD may be concordant with an entity known as Central Auditory Processing Disorder (CAPD), which refers to deficits in the processing of audible signals, and which can be subsumed under the DSM-IV language disorders. A total concordance is unlikely, but Riccio *et al.* (1994) suggest that 50% of children with CAPD also have ADHD.

## Phonologic Disorder

Children with this problem may have clear causal factors, such as anatomic, neurological, or cognitive disorders, although most do not. They do have a higher prevalence of language disorders, with all their associated problems, than do normal controls. They appear more likely to have ADHD, though probably not as commonly as do children with language disorders. Children with Phonological Disorders, especially when associated with stuttering or hyperactivity, are prone to social discrimination and isolation, with subsequent consequences.

## Stuttering

Other communication disorders are more frequently reported in those with stuttering than in normal controls. Stuttering is frequently accompanied by many linguistic mechanisms and social maneuvers to avoid its manifestation, and is often exacerbated by anxiety or stress. Persons with stuttering face social discrimination. They have been mocked in drama and cinema (including cartoons) for centuries, and all too often are regarded as intellectually impaired.

## Etiology and Pathophysiology

### Genetic Influences

No clear mechanisms of genetic transmission have been elucidated, but a number of instances of family aggregation have been reported. At least one of these (Gopnik and Crago, 1991) suggested the presence of a single dominant autosomal gene. Tomblin (1989) reported increased concordance of language disorders among siblings. An increasing number of family studies now suggest that these disorders are familial, including the Twins Early Development Study (TEDS) in the United Kingdom (Plomin and Dale, 2000). These reports cannot absolutely prove any genetic hypothesis but are provocative and suggest a polygenetic basis.

A genetic basis for stuttering has been proposed for many years. The Yale Family Study of Stuttering suggested that 15% of first degree relatives of probands are affected at some time in their lives (Kidd, 1983).

## Pathophysiologic influences

### Neurophysiological Factors

Communication disorders arise from at least three interrelated sets of factors: neurophysiologic (including structural), cognitive-perceptual and environmental. However, the great majority of children with communication disorders exhibit no specific CNS damage, and thus minimal or subclinical damage has been postulated. The relative frequency of “soft” neurologic signs and lateral dominance problems in this population provokes this speculation. However, no clear neurophysiologic mechanisms or pathology can be correlated with these disorders. Some interesting findings are emerging, including suggested anatomical differences in the left cerebral cortex in stuttering, prenatal alcohol exposure and the physical sequelae of abuse and neglect.

### Cognitive and Perceptual Factors

Perceptual hypotheses relate communication disorders to various deficits in the reception, acquisition, processing, storage, or recall of different elements of communication. Table 26.2 notes various perceptual deficits that have been implicated, including auditory

**Table 26.2 Hypotheses About Influencing Factors in Communication Disorders**

Types of Hypotheses	Specific Hypotheses
Neurological impairments	Specific localizable brain damage Subclinical (minimal) brain damage
Perceptual deficits	Deficits in auditory discrimination Deficits in auditory attention Deficits in auditory figure-ground Deficits in auditory memory Deficits in auditory–visual association Deficits in the processing of specific linguistic units
Cognitive deficits	Deficits in symbolic or concept development Deficits in anticipatory imagery Deficits in sorting or categorizing Deficits in hierarchical processing
Environmental factors	Inadequate parent–child interaction Socioeconomic factors (large family size, lower social class, late birth order, environmental deprivation) Medical factors (e.g., prematurity, history of recurrent otitis media)
Multifactorial etiology	Combinations of all of the above

Adapted from Baker L (1990) Specific communication disorders, in *Psychiatric Disorders in Children and Adolescents* (eds Garfinkel BD, Carlson GA and Weller EB). Copyright 1990, with permission from Elsevier.

discrimination, attention, memory and visual association. More purely cognitive hypotheses have also been proposed, involving deficits in symbolization, categorizing, hierarchical processing and related areas. Some authors (Friel-Patti, 1992; Helmuth, 2001) propose that there are certain language-specific cognitive deficits. The special phenomenology of stuttering suggests the possibility of dyssynchrony between phonation and articulation, as reported by Perkins (2001).

### Environmental Factors

This category refers both to the psychosocial environment of the child and to general medical factors such as perinatal complications or recurrent otitis media.

The relationship of socioeconomic status to the occurrence of communication disorders is uncertain. Variables such as class, family size, income and birth order all clearly affect the amount of verbal interaction children receive and have been implicated. The association between the exacerbation of stuttering and stress is well known, although work in this area has frequently confounded predisposing, triggering and maintaining factors.

Review of these influences reveals a considerable amount of overlap, and clinical observation seldom if ever suggests a unitary causality of Communication Disorders in real patients.

## Diagnosis

### Phenomenology

#### Expressive Language Disorder

This condition varies with age and severity. Vocabulary, word-finding, sentence length, variety of expression and grammatical complexity may all be reduced. Most children with the developmental subtype of this disorder demonstrate delayed language development. Often auxiliary words or prepositions are omitted, resulting in telegraphic speech: “he was going to school” becomes “he going school”. Word order may be garbled: “Him like too me” for “I like him, too”. Words or phrases may be repeated to the degree that speech may be echolalic, perseverative, or both. Conversation may be tangential, with sudden inappropriate changes of topic, or conversely, perseveration. Pragmatic difficulties, such as in initiating or terminating conversations, are seen, as is avoidance of conversation. These children frequently are regarded as socially inappropriate or inept, and at times may be suspected of having a formal thought disorder or a Pervasive Developmental Disorder. They frequently have academic problems because of their difficulty in responding verbally to exercises. They may have motor coordination problems and various other neurodevelopmental abnormalities, documented upon neurological examination, EEG, or neuroimaging, although no consistent patterns are seen.

#### Mixed Receptive-expressive Language Disorder

Children with this disorder may have all the problems of Expressive Language Disorder. In addition, they do not understand all that they hear. The deficits may be mild or severe, and at times deceptively subtle, since patients may conceal them or avoid interaction. All areas and levels of language comprehension may be disturbed. Thus the child may not understand speech that is rapid, certain words or categories of words, such as abstract quantities, or types of statements, such as conditional clauses. These children may seem not to hear or attend, or to misbehave by not following commands correctly. At times, when conversation is

redirected to them in a slower or more concise fashion, they may understand and respond belatedly, and thereby be accused of willful avoidance. More severely impaired children may not follow the rules of syntax or word order, and thus confuse subjects and objects or questions and declarations. Often in more severe cases, disabilities may be multiple and pervasive, affecting processing, recall and association. Such deficits have immense social consequences.

### Phonologic Disorders

This category is characterized by persistent errors in the production of speech. These include omission, substitution or distortion of sounds. Omissions include single or multiple sounds: “I go o coo o the but” (I go to school on the bus); or “I re a boo” (I read a book). Substitutions include w/l, t/s, w/r, and d/g: “I taw a wittle wed wadio. It pwayed dood music”. Lispings, the frontal or lateral misarticulation of sibilants, is a common distortion. Defects in the order of sounds or insertions of extraneous sounds may also be heard: “catht” for “cats”. The occurrence of these errors is persistent but not constant. Usually only some sounds are affected. Some articulation errors are expected in early childhood, especially involving sounds that are usually mastered at a later age (in English, /l/, /r/, /s/, /z/, /th/, /ch/); these errors are not regarded as pathological unless they persist and result in adverse consequences to the individual. Ninety percent or more of children have mastered the more difficult sounds by age 6 to 8.

### Stuttering

Stuttering is the most easily recognized communication disorder. It varies in severity among individuals. It may vary over time and circumstance. It is typically more severe when the affected child is stressed or anxious, and especially when communication is expected. Because of its often gradual onset, children are at first frequently not aware of its presence. Over time they may become more anxious and withdraw from conversation, as the degree of social discrimination they experience increases. Stuttering may be accompanied by various movements which may seem either to express or discharge anxiety, such as blinking, grimacing, or hyperventilation. Children who stutter may sing or talk to themselves without difficulty. Sometimes children may attempt to stop stuttering by slowing down or pausing in their speech; but this is frequently unsuccessful and leads to an exacerbation. Thus a pattern of habitual fear and avoidance emerges.

### Communication Disorder Not Otherwise Specified

This category, used to include disorders that do not fit the criteria for any of the other Communication Disorders, is generally used only to describe disorders of voice, including pitch, intonation, volume, or resonance. Hyponasality is characterized by the “adenoidal” speech simulated by speaking with the nose pinched. Hypernasality, secondary to velopharyngeal insufficiency, may be associated with serious voice problems. Air escapes into the nasal cavity, resulting in nasal air emission, snorting or a nasal grimace during speech.

## Assessment

### Interview and Observation

The psychiatrist seeing children must be familiar with normal milestones of speech and language development and ask the

parents or guardians about the child's speech and language, both past and current. Much can be learned from even a few questions: Does the child seem to hear and understand what is being said? Does the child require visual prompts? Does the child in fact use spoken language to communicate? How long and complicated are his sentences? Does the child "make sense" to outsiders? Can she be clearly understood, even by strangers? Which sounds does the child find difficult? Does the child use unusual volume, pitch, or nasality? Does he observe the rules of conversation? Parent-child communication should also be observed.

For younger children, assessment may best be carried out in a play situation. Rutter (1987) recommends that the clinician assess inner language, comprehension, production, phonation and pragmatics. Inner language means symbolization, which may be observed in the child's representational use of play materials. Comprehension is assessed through conversation and the use of developmentally appropriate questions and commands, especially with nonverbal augments or prompts. The clinician should note how well a child can follow and draw inferences from a conversation. Production refers to speech, its fluency and intelligibility. Pragmatics are those aspects of language that render it useful for social communication beyond the most concrete level. Does the child appreciate the nuances of her partner's conversation, as, for example, when they signal beginnings and endings of conversations, topic changes, or the patient's turn to talk? Pragmatic language involves nonverbal elements. Deficiencies in this area impair abstraction and may render the individual almost "robot-like".

In all cases, observations should be made in as relaxed a fashion as possible, avoiding interrogation or rote exercises. If a child fails to communicate a given item, necessary help, including nonverbal prompts, should be offered, so that the child has the experience of success. A sense of failure will stifle communication.

All of the phenomena seen in a clinical interview may also be pursued in school settings, and teacher input is essential in the evaluation of these children.

### Developmental and Cultural Influences

The need for a clinician to be aware of normal developmental expectations has been cited. Special sensitivity must be exercised for the range of accents, dialects and conversational styles encountered. English is spoken in an extraordinary range of patterns even within each dialect group. It is essential that one does not pathologize differences in intonation or dialect. Many American children grow up in multilingual environments, and speak with a synthesis of languages, especially during their preschool years. Finally, children of minority groups who have suffered social discrimination and children who live in physically dangerous environments may necessarily be cautious and less forthcoming with language; this may be adaptive in some cases and not a disorder at all.

### Differential Diagnosis

#### Expressive Language Disorders and Mixed Receptive-expressive Disorders

These disorders are distinguished from each other by the presence or absence of receptive problems. Children with autism may have any or all of the characteristics of the language disorders. However, they have many additional problems

### Clinical Vignette 1 Phonation Disorder

RD presented as a 5-year-old girl, the only child of professional parents who had attempted for many years prior to her birth to conceive a child. Her birth was received with joy and relief, and her parents admitted to having indulged her, even by their privileged standards. Her developmental history was unremarkable, except for some slight delay in toilet training compared with her age-mates. She received appropriate well-child care, and had no major illnesses or injuries. Her adjustment to preschool was considered appropriate when she entered at age 3, and she got along well with the other children for 2 years. She enjoyed the preschool, where individuality was accepted and encouraged. Her parents sought psychiatric evaluation for her after she reported being fearful about returning to school. When her parents questioned her, she stated that new children had come to her school for kindergarten and they were teasing her. The teacher informed the parents that new students were in fact present, but that no teasing had been observed. Upon evaluation, a picture emerged of concerned parents who were sensitive to their child's emotional state, and had sought to remedy their inexperience with children through a great deal of study and inquiry. RD appeared initially as a somewhat anxious child, who separated from her mother with mild trepidation, but who soon relaxed with the psychiatrist. She was able to relate openly, gave no evidence of a major thought or affective disorder, and seemed to be of average intelligence. She exhibited a number of articulation errors, substituting /w/ for /l/ and /r/, and /th/ for /s/, and omitting or dropping a number of closing sounds. She stated that she was shocked at the comments of her new classmates that her speech was infantile. These children were as of yet unaccustomed to the uncritical atmosphere of the school. She had never thought that her speech was unusual, nor had her parents who believed it was normal for a child of her age. The teacher explained that she had noticed some errors in RD's speech, but did not wish to offend her or her parents by pointing them out. The psychiatrist intervened by helping the child to understand that some children adopted "grown-up" speech later than others, and that her progress could be assisted by a helping adult. He referred the family to a speech and language pathologist, whose session the parents described to the child as a "conversation party". The psychiatrist worked with the parents in joint brief focal psychotherapy, addressing issues related to the parents' sense of failure because of their child's problem and their delay in recognizing it. After 6 months, RD's speech had improved and was accepted as normal by her classmates. By age 9 her speech was regarded as entirely normal by her parents and teachers and she was functioning well in all spheres. However, she continued to have subtle phonological findings as an adolescent.

including the use of language in a restricted and often stereotypic fashion, rather than for communicative purposes. They also have difficulties with a wider range of interactions with persons and objects in their environment, and exhibit a restricted range of behaviors. The language impairments of mental retardation, oral-motor deficits, or environmental

deprivation are not diagnosed in this category unless they are well in excess of what is expected. Language impairment due to environmental deprivation tends to improve dramatically with environmental improvement. Sensory deficits, especially hearing impairment, may restrict language development. Any indication of potential hearing impairment, no matter how tenuous, should prompt a referral for an audiologic evaluation. Obviously, hearing and language disorders can and do coexist. Some children develop an acquired aphasia as a complication of general medical illness. This condition is usually temporary; only if it persists beyond the acute course of the medical illness is a language disorder diagnosed. A very severe acquired language disorder is seen in Landau-Kleffner Syndrome (acquired epileptic aphasia), accompanied by seizures and other CNS dysfunctions, and usually occurring between the ages of three and nine.

### Phonological Disorder and Stuttering

The conditions should be distinguished from normal dysfluencies in young children. For example, misarticulation of some sounds, such as /l/, /r/, /s/, /z/, /th/, and /ch/, is common among preschoolers and resolves with age. As with the language disorders, these diagnoses are given in the case of motor or sensory deficit,

mental retardation, or environmental deprivation only if the disorder is much more severe than expected in these conditions. Problems limited to voice alone are included under Communication Disorder NOS.

### Formal Speech and Language Assessment

A number of instruments are available for the assessment of communication. Some of these are listed in Table 26.3. Most are beyond the training of physicians, whose most important contributions are interview skills and medical assessment; but a familiarity with them can help the physician develop a repertoire and knowledge of screening measures. Because of the complex comorbidity of these disorders, they are often best assessed by an interdisciplinary team (McKirby, 1985; Klyklyo, 2005). The team's activities are usually coordinated by a case manager, often a pediatrician or a child and adolescent psychiatrist. Often the team includes an audiologist, a psychologist, medical specialists including pediatric neurologists and otorhinolaryngologists, an educational specialist or liaison special educator, and a speech and language pathologist.

The speech and language pathologist (SLP) has a graduate professional degree and should be certified by The American

**Table 26.3** Language Tests

Tests	Ages	Functions Assessed
<b>Language Tests</b>		
Sequenced Inventory of Communication Development (SICD)	0–4–4–0	Sound discrimination, auditory memory, receptive and expressive language
Test of Early Language Development (TELD)	3–0–7–11	Receptive and expressive language; oral and pointing responses
Test of Language Development (TOLD)	4–0–9–0	Auditory discrimination and memory, receptive and expressive language; oral and pointing responses
Test of Adolescent Language (TOAL)	11–0–17–5	Receptive and expressive language; oral and written responses
Clinical Evaluation of Language Function (CELF)	5–0–17–0	Screening test for auditory memory, receptive and expressive language; oral responses
Fluharty Preschool Speech and Language Screening Test	2–0–6–0	Screening test for articulation and language disorder
<b>Tests of Specific Functions</b>		
Peabody Picture Vocabulary Test (PPVT)	1–9–18–0	Receptive auditory vocabulary; pointing to pictures
Token Test	3–0–12–0	Receptive auditory syntax; following verbal instructions
Goldman-Fristoe-Woodcock Auditory Selective Attention Test	3–0–12–0	Auditory memory; pointing to pictures
Goldman-Fristoe-Woodcock Test of Auditory Discrimination	3–0–adult	Auditory discrimination of words; pointing to pictures
Expressive One-Word Vocabulary Test (EOWVT)	3–0–12–0	Expressive vocabulary; picture naming
Arizona Articulation Proficiency Scale	3–0–11–0	Speech articulation; picture naming

Speech, Language and Hearing Association (ASHA). The SLP uses a combination of interview techniques, behavioral observations and standardized instruments to identify Communication Disorders, as well as patterns of communication that are not pathologic. The assessment of an SLP is usually the definitive measure of the presence or absence of a Communication Disorder. Families may consult an SLP directly or be referred by other clinicians. The responsibility of psychiatrists and other professionals in this process is simple and straightforward: any suspicion of any communication problem in any patient should prompt referral to a qualified SLP. Even when a disorder appears to be limited and benign, communication evaluation by an SLP can disclose subtle impairments that could have profound consequences. Table 26.4 lists indication for referral.

## Course and Natural History

### Expressive and Mixed Receptive-expressive Language Disorders

Contrary to some popular beliefs, language disorders do not usually spontaneously resolve. In general, the course of these disorders is lengthy, and the more severe disorders are usually the more persistent. Language disorders of the developmental type generally appear gradually early in life, while those secondary to other medical illnesses tend to occur more precipitously and at any age. In the case of Expressive Language Disorder, DSM-IV-TR reports that most children with this condition acquire more or less normal language abilities by late adolescence, but that subtle deficits may persist. In the case of Mixed Receptive-expressive

**Table 26.4** Indications for Referral for Communication Evaluation

#### Language

- The child does not use any single words by 16–18 mo.
- At 18 months, the child cannot follow simple instructions such as “Give me your shoe”, or cannot point to body parts or common objects following a verbal request.
- The child does not combine words for short utterances by the age of 2.
- The child does not communicate with complete sentences by the age of 3.
- At 3, the child echoes parts of questions or commands rather than responding appropriately. For example, when asked “What’s your name?” The child responds, “Your name”.
- Sentence structures are still short and noticeably defective at the age of 4.
- At 4, the child uses words incorrectly, or frequently substitutes an associative word for the intended word. For example, the child may say “cut” for “scissors” or “dog” for “cow”.

#### Articulation

- The child does not babble using consonant sounds (particularly b, m, d, and n) by 8 or 9 mo of age.
- The child uses mostly vowel sounds and gestures for communication after 18 mo.
- The speech is usually unintelligible at the age of 3.
- The child frequently omits consonants in words at the age of 3.
- The speech is difficult to understand at the age of 4.
- At the age of 6, the child is still unable to produce many sounds.
- The child is omitting, substituting, or distorting any sounds after the age of 7.
- The child is embarrassed or disturbed by his speech at any age.

#### Voice

- The voice is hoarse, harsh, breathy, or of poor quality.
- The voice is always too loud or too soft.
- The pitch is inappropriate for the child’s age or sex.
- Pitch breaks occur frequently.
- The voice is hyponasal or hypernasal.
- There is nasal air emission, a nasal “rustle”, snorting, or a nasal grimace during speech.

#### Stuttering

- The parents have expressed a concern about stuttering.
- The child has an abnormal number of repetitions, hesitations, prolongations, blocks, or disruptions in the natural flow of speech.
- The child exhibits tension during speech.
- The child avoids speaking situations due to a fear of stuttering.
- The child considers himself to be a stutterer.

Source: Feinstein C and Aldershof A (1991) Developmental disorders of learning and language, in *Textbook of Child and Adolescent Psychiatry* (ed Wiener JM). American Psychiatric Press, Washington DC.

Language Disorders only a minority of children are free of communication problems in adulthood. Even when their communication skills seem grossly normal, subtle deficits may persist, and they may experience educational difficulties. The prognosis for individuals with acquired language disorders often depends upon the severity of injury or illness, as well as their premorbid state.

### Phonation Disorder

The course of Phonation Disorder is much more encouraging than those of other communication disorders. Milder cases may not be discovered until the child starts school. These cases often recover spontaneously, especially if the child does not encounter adverse psychosocial consequences because of his speech. Severe cases associated with anatomic malformations may at times require surgical intervention. Between these two extremes are children who gradually improve, often to the point of total remission, and whose improvement may be accelerated by speech therapy.

### Stuttering

Stuttering usually appears in early childhood, at as early as two years of age and frequently around five, with a typically gradual onset. A study by Yairi *et al.* (1993) suggested that often early-appearing stuttering takes on a moderate to severe form. Children are generally not aware of this condition in themselves until it is pointed out to them by others. The disorder can wax and wane during childhood. By early adolescence, it abates spontaneously in some cases, and from 60 to 80% of individuals eventually recover totally or to a major extent. DSM-IV-TR asserts that spontaneous recovery typically occurs before the age of 16. Stuttering may persist into adulthood, often leading to adverse social and occupational consequences.

## Treatment

### Speech and Language Therapy

Speech and language therapy typically has three major goals:

- the development of communication skills with concurrent remediation of deficits;
- the development of alternative or augmentative communication strategies, where required; and
- the social habilitation of the individual with regard to communication.

The speech and language pathologist plays the most direct role in treatment of these conditions. SLPs employ a wide range of techniques with children that require both science and art. As in child psychotherapy, the participation of parents is necessary. Parent–infant work involves demonstration and modeling of language-stimulation techniques. Individual therapy can usually be begun by three years of age, and early initiation of therapy is frequently recommended. Individual sessions can include formal exercises along with seemingly less structured but nonetheless carefully directed verbal and play interactions. Group therapy can also be used, especially in the development of language skills applied to a social context; but it should not be regarded as a low-budget substitute for individual treatment. Treatment requires regular reassessment, ongoing support to parents and regular consultation with other professionals.

The need for clinicians to avoid regarding variations in accent and dialect as pathologic has been cited. Very little empirical

literature on cultural variations in communication therapy is extant. McCrary (1992) and others have pointed out the need for cultural sensitivity in treatment, citing the efforts of ASHA in this area.

The treatment of stuttering addresses both the mechanics of speech and associated attitudinal and affective patterns. Guitar (1985) notes that therapists attempt to modify speech rhythm and speed, leading subjects to regularize rhythm and, as a temporary measure, prolong their speech. Treatment also addresses respiration, airflow and “gentle” onset of phonation. Success rates for various treatments of up to 70% have been reported, though with varying follow-up periods and relapse rates. Some speech and language pathologists specialize in the treatment of this disorder.

### The Role of the Psychiatrist

Children with these disorders may present for treatment of psychiatric disorders based on or related to communication problems. Thus, the psychiatrist may in the first place be a case finder or case manager, facilitating the evaluation and treatment of these disorders by a multidisciplinary team. The psychiatric comorbidity of these disorders will necessitate the psychiatrist’s involvement on many levels, both as a clinician primarily treating a child, and as a therapist, counselor, and agent of advice and support for the entire family.

Individual and family psychotherapy may be a useful augment in reducing the stress these children encounter, even though psychotherapy does not directly address language disorders. The psychotherapist must, in any event, be sensitive to the manner in which communication disorders can affect or interfere with the therapeutic process. Nonverbal augments or prompts should be sensitively provided children who need them.

The role of psychotropic medication in the management of these disorders is mainly limited to the treatment of comorbid psychiatric problems according to standard practices. From time to time, some interest in the use of drugs specifically for these conditions has arisen. The author has received occasional reports of treatment of stuttering in the past with tricyclic antidepressants and, more recently, selective serotonin re-uptake inhibitors. The rationale for these treatments appears to be a hypothetical connection between stuttering and similar compulsive behaviors. These accounts are provocative but do not suggest any real indication for these medications for stuttering alone.

### Outcome

Outcome studies of communication therapy, especially for the language disorders, have often been complicated by multiple theories of language development, diagnostic and methodologic variations, lack of standardization of therapeutic techniques, and comorbidity. Thus the literature in this area is relatively sparse and not always conclusive. Nonresponse to initial treatment may be common, requiring patience and persistence. It is important to note in assessing these issues that, even when communication therapy does not lead to apparent improvements in language beyond developmental improvements, it may still facilitate the child’s use of extant language for environmental and self-control.

### Academic Comorbidity and Outcome

Not surprisingly, children with communication disorders, especially language disorders, are academically vulnerable. Bashir and Scavuzzo (1992) suggest that this vulnerability arises from

the persistence of these disorders in the face of the continuing need for language in school. Even if a language disorder has been remediated, children may have failed in the meantime; and it is immensely hard for many children in many schools to succeed again, once they have failed for any reason. A further complication is the comorbidity of Learning Disorders in these children. Of children with language disorders 50% to 75% will have persistent academic problems. They tend to learn less at any given time and learn more slowly than their peers. These children need ongoing comprehensive special educational services and regular re-evaluation of their educational needs.

Children with Phonologic Disorder may also have persistent problems. These are generally less severe than those of language-disordered children, unless both types of disorders are present. Lewis and Fairbairn (1992) reported mild but persistent problems with reading and spelling in individuals with phonologic disorder, even into young adulthood. Subjects tended to improve steadily over time however. Although most of the subjects and all of the adolescents and adults were considered normal speakers, they tended to show subtle phonologic problems on specialized tests. Again, children with an associated language disorder fared less well.

The academic and social consequences of these conditions, as well as their psychiatric comorbidities, require the clinician to be sensitive to their presence and diligent in their remediation.

### Comparison of DSM-IV/ICD-10 Diagnostic Criteria

Regarding expressive language disorder, the ICD-10 Diagnostic Criteria for Research suggest specific cutoffs for the expressive language scores: 2 standard deviations below the expected level and 1 standard deviation below nonverbal IQ. Furthermore, in contrast to DSM-IV-TR, the diagnosis cannot be made if there are any neurological, sensory, or physical impairments that directly affect the use of spoken language or if there is mental retardation.

For DSM-IV-TR mixed receptive expressive language disorder, the corresponding ICD-10 disorder is “receptive language disorder”. In contrast to DSM-IV which specifies both expressive and receptive language difficulties because these generally occur together, the ICD-10 definition only mentions deviations in language comprehension. As with expressive language disorder, the ICD-10 Diagnostic Criteria for Research suggest a cutoff of receptive language scores of 2 standard deviations below the expected level and 1 standard deviation below nonverbal IQ. Furthermore, in contrast to DSM-IV-TR, the diagnosis cannot be made if there are any neurological, sensory, or physical impairments that directly affect receptive language or if there is mental retardation.

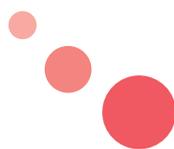

As compared with DSM-IV-TR phonological disorder, in which no mention is made in place of the ICD-10 Diagnostic Criteria for Research suggest that articulation skills, as assessed on standardized tests, be 2 standard deviations below the expected level and 1 standard deviation below nonverbal IQ. Furthermore, in contrast to DSM-IV-TR, the diagnosis cannot be made if there are any neurological, sensory, or physical impairments that directly affect receptive language or if there is mental retardation.

Regarding stuttering, in contrast to DSM-IV-TR which establishes clinical significance based on interference with academic

or occupational achievement or with social communication, the ICD-10 Diagnostic Criteria for Research establish clinical significance by requiring a minimum duration of at least 3 months.

# Childhood Disorders: The Autism Spectrum Disorders

## Definition

The autism spectrum disorders (ASDs) are a group of neurodevelopmental syndromes characterized by disturbances in social interactions, language and communication, and the presence of stereotyped behaviors and interests. Diagnoses include autistic disorder, Rett's disorder, childhood disintegrative disorder, Asperger's disorder and pervasive developmental disorder not otherwise specified (PDD NOS) (Table 27.1).

## History

The contemporary conceptualization of ASD began with Leo Kanner's (1943) description of 11 children with "fascinating peculiarities" that he labeled **early infantile autism**. Kanner noted the lack of social relatedness in these children, including their seeming not to acknowledge the presence of others and their difficulties in recognizing the feelings of others. These children had language irregularities that included a paucity of communicative speech, echolalia and pronoun reversal. Kanner also described their need for sameness and routines, and their engagement in rituals and repetitive activities. The following year, Asperger (1944) described a similar syndrome, but this group had more language and communication skills than the patients reported by Kanner. Asperger called this collection of symptoms **autistic psychopathy**, now referred to as Asperger's disorder.

More recently, the ASDs have been conceptualized as a spectrum of conditions that are related by the common features of the disorders: difficulties in social interactions and use of language, and restricted interests and repetitive behaviors. Despite the enormous heterogeneity evident in this area, there is increasing evidence that conceptualizing these disorders as a spectrum is useful and valid.

## Phenomenology

ASDs are notoriously heterogeneous in their presentation: there may be variability in the particular symptoms manifested in any individual at a given point in time and there may be significant levels of comorbidity. Accurate diagnosis requires that the clinician looks for the particular symptoms and signs that characterize it: peculiar and deficient modes of social interaction, deficits in communication and the focused behaviors and interests.

Many consider the disturbance of social development, including difficulty in developing meaningful attachments and interpersonal reciprocity, to be the central impairment in ASD. While many children with ASD will seem aloof and unattached to

their parents, many will display age-appropriate separation anxiety. Typically, a child with autistic disorder has abnormal patterns of eye contact and facial expression. When compared with normal children, children with autism fail consistently to maintain eye contact or vary facial expression to establish social. These children seem to have considerable difficulty effectively coordinating social cues. They have difficulty demonstrating empathy or perceiving or anticipating others' moods or responses. The child with ASD often acts in a socially inappropriate manner or lacks the social responsiveness needed to succeed in social settings, leading to difficulty in the development of close, meaningful relationships. Some children with ASD eventually develop warm, friendly relationships with family while their relationships with peers lag behind considerably, and these deficits typically persist across time.

It is estimated that only about half of children with autistic disorder develop functional speech. If autistic children do begin to speak, their babble is frequently decreased in quantity and lacking in vocal experimentation. When children with autistic disorder do acquire some speech, it is often peculiar and lacking in social perspective. Some children with autistic disorder are even loquacious, although their speech tends to be repetitious and self-directed rather than aimed at maintaining a reciprocal dialogue. People with autistic disorder commonly make use of stereotyped speech, including immediate and delayed echolalia, pronoun reversal and neologisms. Speech usage is often idiosyncratic, may consist of concrete and poorly constructed grammar, may not be used to convey social meaning, and is often literal, lacking in inference, and lacking in imagination. The delivery of speech is frequently abnormal with atypical tone, pitch and cadence. Paradoxically, children with autistic disorder often have echolalia, in which prosody and other aspects of speech are frequently imitated verbatim.

Individuals with autistic disorder routinely engage in unusual patterns of behavior. Most people with ASD also resist or have significant difficulty with new experiences or transitions. They are commonly resistant to changes in their environment. They often repeatedly perform stereotyped motor acts such as hand clapping or flapping, or peculiar finger movements. These movements frequently occur at the periphery of their vision near their own face. Some children with autistic disorder engage in self-injurious behaviors including biting or striking themselves or banging their heads. This is most likely to occur with severe or profound mental retardation but is also seen in children with autistic disorder without mental retardation. Their play only occasionally involves traditional toys, and objects may be used in

**Table 27.1** Comparison of Domains of Diagnostic Criteria for Pervasive Developmental Disorders

	Autistic Disorder	Rett's Disorder	Childhood Disintegrative Disorder	Asperger's Disorder	Pervasive Developmental Disorder NOS
Age at onset	Delays social interaction, language, or play by age or abnormal functioning in 3 yr	Apparently normal prenatal development. Apparently normal motor development for first 5 mo. Deceleration of head growth between ages 5 and 48 mo	Apparently normal development for at least the first 2 yr. Clinically significant loss of previously acquired skills before age 10 yr	No language, cognitive development, or clinically significant delay in development of age-appropriate self-help skills, adaptive behavior, and curiosity about the environment in childhood	Category pervasive impairment in social interaction, and used in cases of communication, with presence of stereotyped behaviors or interests when criteria are not met for a specific disorder
Social interaction	Qualitative least two interaction, as manifested by at impairment in social of the following: <ul style="list-style-type: none"> <li>• Marked impairment in the use of multiple nonverbal behaviors (e.g., eye-to-eye gaze)</li> <li>• Failure to develop peer relationships appropriate to developmental level</li> <li>• Lack of spontaneous seeking to share enjoyment with other people</li> <li>• Lack of social or emotional reciprocity</li> </ul>	Loss in the course (although often social of social engagement early interaction develops later)	Same with loss of social skills (previously acquired) as autistic disorder along	Same as autistic disorder	
Communication	Qualitative communication as manifested by at least one of the impairments of following: <ul style="list-style-type: none"> <li>• Delay in, or total lack of, the development of spoken language</li> </ul>	Severely and receptive language development and severe impaired expressive psychomotor retardation	Same with loss of expressive or receptive as autistic disorder along language previously acquired	No language clinically significant delay in

Data from American Psychiatric Association (1994) *Diagnostic and Statistical Manual of Mental Disorders*, 4th edn. Copyright, American Psychiatric Association, Washington DC.

ways other than intended (for instance, a doll is used as a hammer), and there is a paucity of make-believe play. Individuals with autistic disorder seem to have unusual sensitivity to some sensory experiences, particularly specific sounds.

Other problems in ASD include impairment in “joint attention”, the sharing or mutual focus on an object or event by two or more people, and the ability to shift attention when the social situation calls for it. Many children with ASD also have symptoms of hyperactivity and difficulty sustaining attention, but these should be distinguished from the joint attentional dysfunction found in all patients with autistic disorder. Examples of joint attention include social exchanges that require pointing, referential gaze and gestures showing interest.

Children with Asperger’s disorder begin to speak at about the same time as other children do and eventually gain a full complement of language and syntax. However, they display unusual use of pronouns, continuous repetition of certain words or phrases, and exhaustive focus of speech on particular topics. These children have difficulty in social reciprocity, engage in repetitive play and focus on certain interests excessively. Thus, the predominant differentiating feature between autistic disorder and Asperger’s disorder is that those with Asperger’s disorder do not have a delay in general (i.e., nonsocial) language development.

Rett’s disorder is a developmental disorder that preferentially strikes girls and differs substantially from autistic disorder past the toddler stage. The disorder was first described by Rett when 22 patients were reported in 1966 (Rett, 1966). Typically, a child with Rett’s disorder has an uneventful prenatal and perinatal course that continues through at least the first 6 months. With onset of the classic form of the disease, there is deceleration of head growth, usually between 5 months and 4 years of age. In toddlerhood, the manifestations can be similar to autistic disorder in which there is frequently impairment in language and social development, along with the presence of stereotyped motor movements. In particular, there is a loss of acquired language, restricted interest in social contact or interactions, and the start of handwringing, clapping, or tapping in the midline of the body. This type of activity begins after purposeful hand movement is lost. Serious psychomotor retardation sets in as well as receptive and expressive language impairments. Between the ages of 1 and 4 years, truncal apraxia and gait apraxia typically ensue. Since the vast majority of Rett’s disorder cases have mutations in *MECP2*, it has been possible to confirm that many variants of Rett’s disorder, including those with preserved ambulation and preserved speech, are due to mutations in the same gene (Amir *et al.*, 1999; Kim and Cook, 2000).

Childhood disintegrative disorder and autistic disorder share some similar deficits in social interaction and communication as well as repetitive behaviors. However, the symptoms of childhood disintegrative disorder appear abruptly or in the period of a few months’ time after 2 years or more of normal development. There is generally no prior serious illness or insult, although a few cases have been linked to certain brain ailments such as measles, encephalitis, leukodystrophies, or other diseases. With the onset of childhood disintegrative disorder, the child loses previously mastered cognitive, language and motor skills and regresses to such a degree that there is loss of bowel and bladder control (Volkmar and Cohen, 1989). Children with childhood disintegrative disorder tend to lose abilities that would normally allow them to take care of themselves, and their motor activity contains fewer complex, repetitive behaviors

than autistic disorder. Some children with this disorder experience regression that occurs for a time and then becomes stable. Another group of children has a poorer outcome, with onset of focal neurological findings and seizures in the face of a worsening course and greater motor impairment. The majority of children with this disorder deteriorate to a severe level of mental retardation; a few retain selected abilities in specific areas. Differential diagnosis of childhood disintegrative disorder requires obtaining a particularly thorough developmental history, history of course of illness and an extensive neurological evaluation and testing.

PDD NOS or atypical autism should be reserved for cases in which there are qualitative impairments in reciprocal social development, and either communication or imaginative and flexible interests are met, but not full criteria for a specific PDD.

### Etiology and Pathophysiology

Currently, the precise etiology and pathogenesis of ASDs are unknown. Strong evidence for genetic bases for the disorders, along with the advent of sophisticated genetic techniques, has led to a shift toward looking for the genetic underpinnings in the disorder. Most contemporary etiological theories strongly suggest a genetic or other early neurodevelopmental disruption with overt clinical manifestations potentially modified by social or environmental experiences.

### Biochemical Findings in ASD

Serotonin dysfunction has been implicated as a possible factor in the genesis of autistic disorder since the finding of significantly elevated whole blood 5-HT in these patients. Hyperserotonemia is a robust finding in autistic disorder and has been consistently replicated.

In nonautistic children, serotonin synthesis capacity, as measured by positron emission tomography (PET), is more than 200% adult levels until the age of 5, when it begins to decline toward adult levels; in autistic children, however, serotonin synthesis capacity has been shown to increase gradually between the ages of 2 and 15, reaching a level of 1.5 times normal adult levels (Chugani *et al.*, 1999). In related studies others have shown that platelet serotonin levels appear to stabilize after the age of 12 (Ritvo *et al.*, 1971).

Hyperserotonemia in autistic disorder appears to have a familial component. Several studies have shown that whole blood serotonin levels have a positive correlation between probands with autism and their parents and siblings (Leventhal *et al.*, 1990). Additionally, individuals with autism who have siblings with autism have higher platelet serotonin than autistic subjects without an autistic sibling, suggesting that hyperserotonemia may be an indicator of autism with a higher risk of sibling recurrence (Cook and Leventhal, 1996).

It is clear that it is serotonin within platelets that is responsible for the findings of increased whole blood hyperserotonemia. More than 99% of whole blood serotonin is contained in platelets, and platelet-poor plasma ultrafiltrate serotonin levels are not elevated in subjects with hyperserotonemia. This suggests that patients with autism exhibit either increased serotonergic uptake in platelets, or decreased serotonergic release from platelets, leading to an increased steady-state level of serotonin. There is evidence for a positive correlation between platelet serotonin levels and the rate of platelet serotonin transport.

## Neuropathological Findings in ASD

Some investigators have found evidence for differences in the hippocampus and amygdala. While noting no gross abnormalities in their study of the brains of six autistic individuals, they have noted increased cell packing and diminished neuronal size in the hippocampus and some nuclei in the amygdala. They also found decreased complexity and extent of dendritic arbors in hippocampal pyramidal cells. They speculated that such lesions might produce changes in behavior similar to those with Klüver Bucy Syndrome (hyperexploratory behavior, severe impairment of social interaction) and some cases of limbic injuries leading to memory loss (and a subsequent “rigidly specific habit memory system”). Others (Bachevalier, 1994) have suggested that such changes might result in difficulty in assigning affective significance to social stimuli.

A number of investigators have noted loss of cerebellar Purkinje cells as well as changes in neurons of the deep cerebellar nuclei. Such findings have led to the hypothesis that these lesions could affect selective attention, in particular leading to stimulus overselectivity and difficulties in shifting attention.

## Functional Neuroimaging Findings in ASD

Haznedar and colleagues (1997) found reductions in portions of the right anterior cingulate during a word list learning task, and Schifter (1994) found hypometabolism in many brain regions during a resting state PET scan of autistic children with both mental retardation and seizure disorders. Chugani and colleagues (1996) conducted PET scans on patients with infantile spasms, and found that 10 of 14 children that had bitemporal hypometabolism met criteria for ASD at a later follow-up. Using PET and functional magnetic resonance imaging, Muller and colleagues (1998) showed that a small group of high functioning ASD adults had reversal of the usual left hemisphere dominance when listening to sentences.

Chugani and colleagues (1997) scanned autistic children utilizing an analog of tryptophan to act as a tracer in order to look at serotonin synthesis in the brain. She found asymmetries in serotonin synthesis in many of the autistic subjects. She also found that the global cerebral serotonin synthesis capacity of ASD children tended to increase with age (versus control subjects that show a steady decrease with age towards adult levels). Similar methods using a tracer to look at dopamine storage and metabolism have revealed that accumulation of this tracer was significantly reduced in the anterior medial prefrontal cortex compared with controls.

## Genetics and ASD

ASD has a relatively low prevalence of approximately two per 1000, yet the recurrence risk to siblings is 4 to 5%. Concordance in monozygotic twin pairs has ranged from 60 to 90%, while dizygotic twin pairs in these studies have generally found a concordance similar to that found in siblings of affected children. Even these concordance numbers are likely underestimates of the genetic contribution, since many pairs discordant for autistic disorder were concordant for another ASD. When considered as a spectrum disorder, twin studies suggest that at least 92% of monozygotic twin pairs are concordant for at least milder but similar deficits in the social and communication realms (compared with a 10% rate in these studies for dizygotic twin pairs).

**Table 27.2 Chromosomal Abnormalities Associated with Autistic Disorder or Other Pervasive Developmental Disorders**

Fragile X syndrome (trinucleotide expansion at Xq27.3)
Down's syndrome (trisomy 21)
Prader-Willi syndrome (deletion or maternal isodisomy of chromosome 15)
Marker chromosome
Duplication of 15q11–13

ASD is currently thought to be a complex genetic disorder. The varying strength of the contributions of different loci is likely also to be responsible for the genetic heterogeneity that characterizes ASD. In ASD, findings so far suggest a disease process with greater than 10, and perhaps as many as 100 loci.

Chromosomal abnormalities have provided some clues as to where some of these susceptibility genes may be (Table 27.2). The most common chromosomal abnormality associated with ASD has been in a region of chromosome 15 (15q11–13). These abnormalities usually involve either an interstitial duplication or a supernumerary pseudodicentric chromosome (an extra chromosome with two centromeres; “pseudo” refers to the fact that only one centromere can be active).

Linkage studies have shown evidence of linkage in several polymorphisms in the area of chromosome 15 noted above, including the gamma-aminobutyric acid receptor subunit gene (*GABRB3*) and transmission disequilibrium for markers in *GABRB3* has also been found. Most recently, evidence of transmission disequilibrium was found to peak at another region of the serotonin transporter gene, supporting evidence of involvement of the gene, but not specifically the *5HTTLPR* variant (Kim *et al.*, 2002).

There has been significant progress in terms of identifying the genetic basis of Rett's syndrome. Mutations in the gene (*MECP2*) encoding X-linked methyl-CpG-binding protein 2 (MeCP2) have been identified as the cause of more than 80% of classic cases of Rett's syndrome.

## Autistic Disorder and MMR Vaccinations

Some have suggested that there is a variant of ASD called **autistic enterocolitis** that involves developmental regression and gastrointestinal symptoms, and that this variant is a consequence of measles–mumps–rubella (MMR) immunization. This hypothesis, which has been postulated to account for the rise in the number of cases of ASD, suggests that there are specific biological findings in these children that result from a persistent measles viral infection. At the current time, investigations into this hypothesis have shown no relationship between MMR vaccinations and the development of ASD; this lack of evidence argues against changes in MMR vaccination programs.

## Assessment and Differential Diagnosis

The diagnosis of ASD first involves completing a comprehensive psychiatric examination (Table 27.3). The clinician should obtain a full developmental history, including all information regarding pregnancy and delivery. While questioning about neonatal development, particular attention should be paid to

**Table 27.3 Suggested Work-up for Children and Adults with Autistic Disorder or Other Pervasive Developmental Disorders**

History
Particular attention to
Developmental phases of language, social interactions, play
Family history of psychiatric and neurological disease
Physical examination
Thorough physical examination including a search for
Neurological problems
Cardiac problems
Congenital anomalies
Skin lesions or abnormalities
Dysmorphism
Psychological evaluation
Autism Diagnostic Interview-revised
Autism Diagnostic Observation Schedule
Cognitive testing (e.g., Differential Abilities Scales)
Vineland Adaptive Behavior Scales
Speech and language evaluation
Audiological evaluation
Visual acuity evaluation

social, communicative and motor milestones. The clinician needs to understand fully the child's adaptive skills, including which tasks can be undertaken independently, including grooming skills, feeding skills and the ability to self-initiate. There should be a sense of the child's vocabulary, receptive and expressive language skills, articulation and pragmatic communication. A full medical history should be obtained, and should include queries regarding any hearing or vision problems, any history of seizures and information regarding the use of any medications.

Because these children dislike novelty, the first visit to the clinician's office is sometimes an anxiety-provoking undertaking. It is not unusual (and is in fact helpful diagnostically) to allow a child with ASD to extensively explore the clinician's office, looking under desks or opening drawers, in an attempt to become familiar with the surroundings. Some children will appear shy and self-absorbed. It is ideal if the clinician can arrange an opportunity to see the child in another environment in addition to the office. Observation of the child interacting with the parents and siblings is helpful in understanding modes of interaction and social skills. If the child is having difficulty, it is usually preferable, especially on the first visit, to allow the parents to intervene. This will allow the clinician to see how (effectively) the family responds to this distress, and how the child responds to the efforts of caregivers to soothe the child. During observation, the clinician needs to assess social interaction, communication, unusual behaviors and all other information in the context of developmental level.

A full physical examination should be undertaken including observations for dysmorphic features and unusual dermatologic lesions. The clinician must maintain a high suspicion for seizures in this population, both when taking the history and during the examination. A full neurological examination should be made with an emphasis on motor impairments. A Wood's light examination for hypopigmented lesions consistent with tuberous sclerosis should be made.

There are no diagnostic laboratory tests for ASD. If the child has not had routine tests (blood count, liver function tests, thyroid, lead level, etc.), these should be completed, as with any child. Patients with mental retardation or dysmorphism should have chromosomal analysis performed. Fragile X testing and fluorescent in situ hybridization (FISH) studies for possible interstitial duplication of 15q11–13 should be suggested after consultation with the family. There should be a low threshold for ordering an electroencephalogram (EEG), and one should always be ordered in the context of unusual movements, regressive behavior, regressive loss of previously acquired sleep, or in the face of unusually poor sleep. Structural brain imaging (i.e., MRI) should take place only if the physical examination or history suggests that a treatable lesion is present. Carried out routinely, these scans have a very low clinical yield, are quite expensive, and in this population often require anesthesia, a seemingly unnecessary risk. Consultative services should be utilized as needed with pediatric neurologists and geneticists. Difficulties with motor development will often mean a referral to an occupational and/or physical therapist. Children with Rett's syndrome will often require referral to neurologists and developmental pediatricians.

All children with autism require a careful language assessment that may include hearing testing and assessment of expressive and receptive, verbal and nonverbal language. Speech and language therapists trained to work with this population are an essential part of the assessment team.

Children with ASD should have a neuropsychological assessment at the time of initial assessment and at periodic intervals thereafter. The initial evaluation helps establish the diagnosis and a baseline level of functioning. Additionally, it can be utilized to make the appropriate adjustments in the child's educational plan. The later evaluations serve to chart progress, evaluate the success of (pharmacological, behavioral and academic) interventions, and to assess for possible regression in particular areas.

While there are many rating scales and structured interviews to assist in making the diagnosis of ASD, the current gold standard in diagnostic assessment is the autism diagnostic observation schedule-generic (ADOS-G) (Lord *et al.*, 2000). This is often given with the autism diagnostic inventory-revised (ADI-R) (Lord *et al.*, 1994), which is a comprehensive, clinician-administered interview of the patient's primary caregiver and covers most developmental and behavioral aspects of autism. The ADI/ADOS combination is now established as a reliable and valid method for making the diagnosis of ASD.

## Differential Diagnosis

There may initially be some difficulty in differentiating ASD from other syndromes (Table 27.4), especially in the context of considerable comorbidity. Mental retardation commonly occurs in ASD, and children with mental retardation may present with stereotyped movements or obsessiveness. However, the child with mental retardation and not with ASD will have social and communicative skills commensurate with their level of overall development.

Differentiating ASD from childhood schizophrenia is not usually difficult. The onset of psychosis in childhood is extraordinarily rare, and hallucinations and delusions are not a part of the ASD picture. It is important not to diagnose some of the atypical features in ASD as psychotic and equally important to recognize that verbal patients with ASD have impaired language that should not be confused with schizophrenia. Selective mutism

**Table 27.4 Differential Diagnosis of Autistic Disorder and Other Pervasive Developmental Disorders**

Developmental language disorder
Mental retardation
Acquired epileptic aphasia (Landau-Kleffner's syndrome)
Fragile X syndrome
Schizophrenia
Selective mutism
Psychosocial deprivation
Hearing impairment
Visual impairment
Traumatic brain injury
Dementia
Metabolic disorders (inborn errors of metabolism, e.g., phenylketonuria)

can be differentiated by the child's ability to interact normally in some environments.

Children exposed to severe neglect can sometimes present with symptoms that look like ASD, but these symptoms will usually show dramatic improvement when the child is in a more appropriate environment.

Perhaps the most difficult differentiation is in a child with severe obsessive-compulsive disorder (OCD) who also has unusual interests and is inflexible to changes in routines or transitions to a new activity. It is even further complicated if attentional problems coexist. In these cases, it is important to emphasize the social difficulties of children with ASD; even if the child with OCD is difficult interpersonally, his or her ability to maintain eye contact, interpret social situations and emotions and otherwise interact socially is relatively preserved.

### Epidemiology and Comorbidity

Large scale epidemiologic studies of early childhood onset neuropsychiatric disorder simply have not been undertaken thus making prevalence rates of many pediatric onset disorders relatively obscure. It is also worth noting that disorders that are relatively uncommon pose particular problems when it comes to the ascertainment of prevalence rates.

Increased awareness of ASD through laudable efforts at better education of mental health workers, pediatricians and school personnel has led to better (and earlier) identification of the core symptoms that had previously gone undiagnosed.

While there is no definitive way to know what accounts for the rise in ASD (and an increase due to, for instance, an environmental insult cannot be ruled out), the current informed consensus is that this increased prevalence rate reflects better recognition and detection together with more inclusive diagnostic definitions.

Boys are affected with ASD more than girls in a 4:1 ratio. The exception is Rett's disorder, which is found almost exclusively in females. Interestingly, the gender ratio in ASD increases when cases with mental retardation are excluded to about 6:1, and decreases to approximately 1.7:1 when only cases with moderate to severe mental retardation are considered.

The prevalence rates of ASD do not appear to be influenced by immigrant status or socioeconomic status.

With the exception of childhood disintegrative disorder (in which all affected children are mentally retarded), there is wide individual variability in intellectual functioning in ASD. Only about 20 to 25% of children with ASD have an IQ over 70, with 30 to 35% having mild to moderate mental retardation, and 40 to 45% having severe to profound mental retardation. However, with more intensive case-finding (i.e., less dependence on mental retardation for referral), the number of patients with ASD who have an IQ over 70 may be as high as 50%. Follow-up studies suggest that IQ levels tend to be constant from the time of diagnosis (when over 5 years old at the time of diagnosis) and are stable over time, and thus are thought to be important predictors of outcome. Particular cognitive deficits are seen in language, abstraction, sequencing and coding operations, while visual-spatial skills are often a relative strength (Lord *et al*; 1997, Rutter 1983).

### Course

Retrospective analysis of some children reveals deficits in the first year of life while those with less severe symptoms may not be diagnosed until their first years of school or, in the case of higher functioning persons with ASD, even later. It is not uncommon (15–22%) for deterioration in functioning with the onset of puberty, characterized by mood lability, aggressiveness and hyperactivity. It has also been suggested that low IQ, female sex, epilepsy and family history of mood difficulties may be risk factors for this pubertal deterioration. Others have reported that some individuals with ASD improve during their teen years.

Episodes of depression are common for patients with ASD in their teens, especially among those with Asperger's syndrome. It has been hypothesized that this may be a function of these patients' better recognition of their social inadequacies. This may also lead to subsequent demoralization and dysphoria.

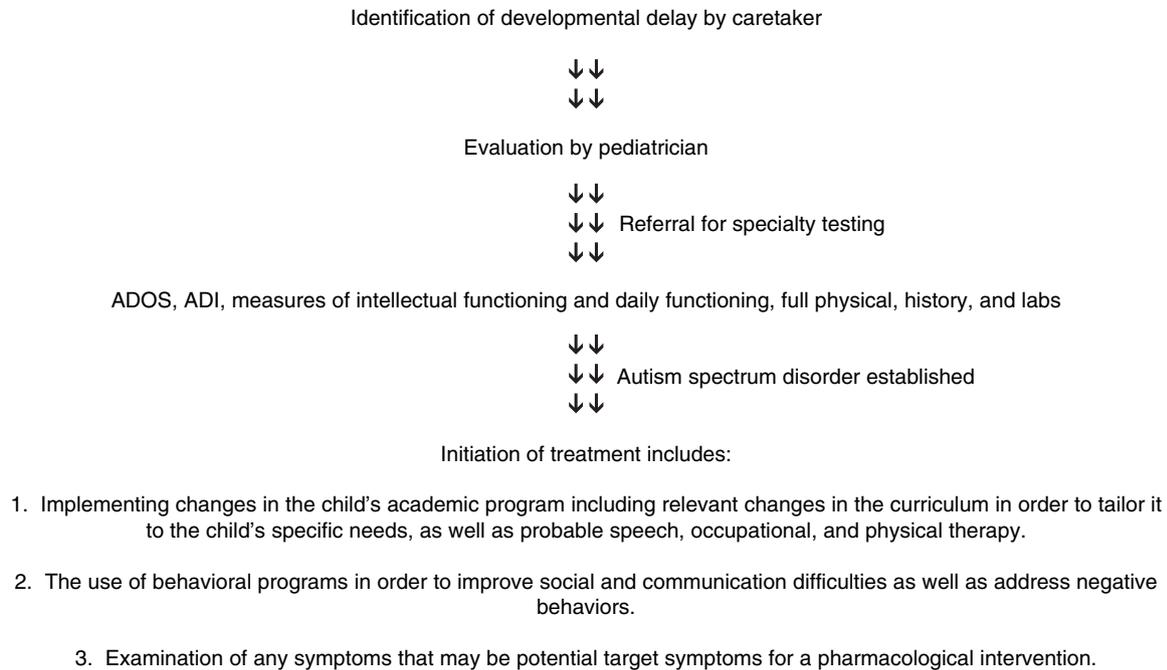

Epilepsy presents in a bimodal fashion, with many children first experiencing seizures before starting school, and another group having their onset at the time of puberty; overall, 25 to 30% of patients will experience seizures before the age of 30. It should be noted that there is an inverse correlation between the incidence of seizures and cognitive level.

Long-term follow-up studies predict for a poor or very poor long-term outcome for up to 75% of cases, and a good outcome (using social life, and school or vocational functioning as outcome measures) in only 5 to 15%. It appears that IQ is the best predictor of outcome. There is wide variability in final outcome, with most patients with low IQs unable to live independently, and with many high functioning patients able to work (sometimes very successfully) and live independently, as well as raise children.

### Treatment

#### Nonpharmacological and Behavioral Treatments

Developing a comprehensive individual intervention program for a child with ASD is a daunting task for the child's parents (Figure 27.1). Each child is unique, with a different set of difficulties, as well as strengths. The child's primary physician must work with the parents to help make this task less overwhelming. The physician can anticipate being asked about a wide array of alternative treatments being offered in the community, which vary enormously in their claims, in the integrity of those making the

**Figure 27.1** An example of the typical progression from identification, to evaluation, to treatment of a child with ASD (ADOS, Autism Diagnostic Observation Schedule; ADI, Autism Diagnostic Inventory).

claims, and in their ultimate safety and utility. The physician who immediately and outright and pejoratively dismisses these alternatives as useless is not helpful to the child or his family (the exception being dangerous or cost-prohibitive prospective treatments). Rather, it is helpful to listen and then educate the family, at a level commensurate with their sophistication, about how to analyze and interpret claims and science underlying these treatments.

Autistic disorder is recognized as a chronic disorder with a changing course requiring a long-term course of treatment that includes the necessity of an intervention with various treatments at different times. At the present time, most treatments for the ASDs are symptom directed. Given that there is no current cure for autistic disorder or the other ASD, goals of treatment should encompass short-term and long-term needs of the individual and his or her family (Table 27.5).

Every attempt should be made to achieve treatment goals on a community-based environment since institutionalization may hinder a child's ability to learn means of functioning and adapting in typical social settings. Community-based treatment can usually be maintained, except in times of extreme stress or need, during which time a child (and family) might benefit from respite care or brief hospitalization. Effective treatment often entails setting appropriate expectations for the child and adjusting the child's environment to foster success.

**Table 27.5** Goals for Treatment

<p>Advancement of normal development, particularly regarding cognition, language and socialization</p> <p>Promotion of learning and problem solving</p> <p>Reduction of behaviors that impede learning</p> <p>Assistance of families coping with autistic disorder</p> <p>Treatment of comorbid psychiatric disorders</p>
---

## Approach to Treatment

Because the autistic individual often requires diverse treatments and services simultaneously, the role of the primary physician is to be the coordinator of services. Frequent visits with the child and the child's caretakers initially allow the physician to assess the individual needs of the child while establishing a therapeutic alliance. An effective approach often calls for the services of a number of professionals working in a multidisciplinary fashion. This group may include psychiatrists, pediatricians, pediatric neurologists, psychologists, special educators, speech and language therapists, social workers, and other specialized therapists (Table 27.6).

**Table 27.6** Summary of Treatment Principles

Psychosocial interventions
<p>Educational</p> <ul style="list-style-type: none"> <li>Curricula that target communication</li> <li>Behavioral techniques</li> <li>Structured milieu</li> <li>Vocational interventions such as speech training and placement: other specialized and language therapy, physical therapy and occupational therapy</li> </ul> <p>Social skills training</p> <p>Individual psychotherapy for high-functioning individuals</p>
Medical Interventions
<ul style="list-style-type: none"> <li>Cohesive physician–patient relationship</li> <li>Supportive measures with families coping with autistic disorder</li> <li>Behavioral treatment</li> <li>Pharmacotherapy to address problem signs and symptoms</li> </ul>

There is significant controversy over what particular forms of therapy are best for children with ASD. Some of this controversy is a result of claims of children making dramatic improvements with some of these therapies.

The most successful interventions use a variety of positive reinforcement schedules to enhance the desired behaviors and extinguish undesirable behaviors. Discrete trial training, an operant conditioning model, is particularly useful in this regard. Generalization of skills from the behavioral training environment to other settings is a key to success. Applied behavioral analysis (ABA) uses careful assessment of adaptive and maladaptive behaviors and specific interventions addressing each behavior and children receiving ABA have shown significant improvement in a number of areas, including IQ, visual–spatial skills, language, and academics (Smith *et al.* 2001).

### Problem Behaviors

A prerequisite to putting a behavioral plan in place with a child with ASD is to identify the problem behaviors. These behaviors often include interfering repetitive actions, self-injurious behaviors, or aggression. While there is little difficulty in identifying these highly visible behaviors, what is much more difficult is 1) determining the antecedents to these behaviors and 2) knowing what constitutes an appropriate reaction or consequence to these behaviors on the part of the caregiver.

To determine the antecedent is often extraordinarily difficult, since it is often not apparent exactly what happened in the environment that stimulated the behavior. This is particularly true if the behavior is chronic and has developed some autonomous function (i.e., no longer a stimulus–response event). To make things more complicated, it could be internal perception or meaning of what happened in a child with autism (poor language and socially nonresponsive) that may have initiated the behavior. For example, imagine a nonverbal child frustrated by his inability to continue a mental routine created by a teacher insisting that the child orient himself to a school task like sitting in reading circle. Further, assume that the child does not have a repertoire of appropriate social responses, and instead responds by biting the teacher on the arm. It will be very difficult for the teacher to know that the child was in the middle of a mental routine and not able to communicate his distress verbally, thus leading to the inappropriate behavior. It takes time and attention to understand these events processes in children with ASD. Once they are clear, appropriate behavioral intervention is possible.

Durand and Carr (1991) attempted to determine the function of problem behaviors in children with ASD. They concluded that most behaviors could be classified as:

1. a need for help;
2. a desire to escape a stressful situation;
3. a desire to obtain an object;
4. an attempt to protest unwanted events;
5. an attempt to obtain stimulation or attention.

There are scales available to help caretakers determine the primary functions behind typical problem behaviors. Despite the notorious difficulty in determining the function of a problem behavior in these children, if the function(s) can be identified, a behavioral intervention will likely be successful in diminishing the atypical, maladaptive behavior and enhance overall adaptation and behavioral functioning.

### Obsessions and Rituals

Children with ASD often engage in rituals and routines which appear to be an attempt to relieve anxiety and/or to exert control over their environment. The key to success is a gradual shaping of the behavior rather than dramatic expectations and harsh consequences. One should begin intervention by evaluating possible, underlying stimuli or predisposing factors for the behavior. Strategies include determining when, where and for how long an activity can take place. Additional strategies include making environmental changes that reduce anxiety and even ignoring behaviors that do not create undue problems. Adjunct pharmacological intervention is often helpful.

### Communication Therapy

Up to 50% of children with ASD will not acquire useful language. For those with some but not fully intact language skills, speech therapy is an important part of therapeutic and academic planning. An emphasis on the social use of language is often helpful, and when the child can articulate some of his or her needs, there is often a reduction in problem behaviors.

Longitudinal studies indicate that children who have not acquired useful language by the age of 7 usually have longstanding verbal communication difficulties. For these children, it is often helpful to devise an alternative means of communication: sign language or use of augmentative communication devices such as computers and picture exchange communication systems or PECS. PECS involves the use of photographs or line drawings on cards. The child then points to or hands the appropriate card or cards to another person in order to effect communication. Once again, children are encouraged to use verbalization, when possible, in conjunction with sharing the cards (Erdmann *et al.*, 1996). Irrespective of the technique used, establishing a consistent method of communication is central to the treatment of individuals with ASD.

### Social Interaction Therapy

Children and adults with ASD lack many of the innate and learned social skills, especially reciprocal social interactions, that most people simply take for granted. Maintaining appropriate interpersonal distance, spontaneously initiating conversation, participating in reciprocal social exchange and other facets of complex social interaction are not easily incorporated in the routine behaviors and activities of individuals with ASDs. Subtlety and changing complexity of social interaction as well as the innateness of many social skills is a central part of daily life and a key to successful adaptation for typically functioning individuals. Helping individuals with ASDs address these challenges is difficult but also critical for enhancing overall functioning.

Odom and Strain (1986) identified the three primary techniques that can be effectively utilized:

1. Proximity. Establish proximity refers to the fact that it is very helpful to have the child with ASD near other children in the environment. The mere proximity increases the likelihood of interaction and imitation as well as positive social reinforcement.
2. Use. The use of prompts relates to have specific prompts and reinforcement cues to use previously learned behaviors in social settings (e.g., “Raise your hand if you have a question”). Attention to reinforcement means that even a less than fully competent attempt at appropriate social behavior, even if response to a prompt, receive clear and effective reinforcement

when it occurs (e.g., calling on the child promptly when he raises his hand to ask a question and also saying “You did a good job when you raised your hand to ask the question”).

3. Encourage peer initiation is helpful to train peers who are likely to interact with the child or adult with ASD in techniques for initiating social contact. For many individuals, this means explaining the disability and dealing with fears or biases. For others, it may mean encouraging them to persist in their attempts at engagement, even in the face of limited, inappropriate, or inadequate responses.

### Academic Needs

Academic resources and placement are important components in the child’s overall treatment. First and foremost, schools are where children go to acquire social skills and acquaintances, as well as academic skills. Secondly, schools often have a variety of skilled professionals who are trained to provide necessary services for the individual with ASD. And, finally, in the USA, all public schools have a statutory obligation to provide all children (even those with disabilities) with a free and appropriate education in the least restrictive environment.

Previously, children with ASD had been put in alternative settings, but more recently there has been increased interest in maintaining many ASD children in regular classroom settings. Studies seem to indicate that ASD children in regular classrooms have increased social interaction, a larger social network and have more advanced individualized education plan goals later in their academic careers (Fryxell and Kennedy, 1995). Whether a child is fully or partially included in a regular classroom or placed in a self-contained setting, each ASD child will need to have an individualized plan of care that carefully and specifically articulates goals and the techniques to be used to reach those goals. In addition, specific measures of goal attainment and regular review of the plan should be a part of this important intervention. In order to establish these goals and plans, a full assessment of the child’s strengths and weaknesses must be completed through the efforts of numerous skilled professionals. Educational plans must incorporate academic, social and behavioral goals.

### Pharmacotherapy

At this time, there are no pharmacological agents with US Food and Drug Administration (FDA)-approved labeling specific for the treatment of ASD in either children or adults. Many of the symptoms commonly seen in ASD (rituals, aggressive behavior and hyperactivity) are also commonly seen in children, adolescents and adults with mental retardation but without a PDD. Some of the pharmacological strategies for the treatment of autistic disorder have been extrapolated from studies of related conditions, largely in adults, but including attention-deficit/hyperactivity disorder and OCD. Clinicians and families should be reminded before any treatment is initiated that:

- Current treatments target symptoms.
- Current treatments do not target a specific etiological mechanism for ASD.
- Anecdotal reports do not establish efficacy, effectiveness, or safety for any treatment.
- Controlled, double-blind trials (preferably with replication) are the contemporary standard for determining if a treatment is safe and appropriate.
- All treatments have side effects.

Before specific pharmacological agents are discussed, it must be stressed that one should not use psychopharmacological agents with the expectation that they will cure children with autistic disorder as many parents and teachers of children with autistic disorder expect medication to eliminate core social, cognitive and communication dysfunction. There is no pharmacological substitute for appropriate educational, behavioral, psychotherapeutic, vocational and recreational programming. It is essential to remember and to remind parents, teachers and others that medication should always be seen as an adjunct to these core interventions that address the developmental challenges associated with these disorders.

Because many individuals with ASD have impairments in language and social communication, the use of rating scales becomes an essential part of the treatment. Standard rating scales provide the pharmacotherapist with a framework in which to assess response to medication and a relatively straightforward way to collect standard information about the patient’s functioning in a variety of settings. The Aberrant Behavior Checklist – Community Version (Aman, 1994) covers many target symptom areas for most patients with ASD. Although rating scales cannot replace careful clinical examination of the patient and interviews with parents and teachers, they may be graphed next to dosages of medications to assist in treatment planning in response to the patient’s clinical condition. This is often not only helpful in making clinical decisions but also gives families and service providers a concrete sense of how a treatment is progressing.

The use of medications to treat autistic disorder and other ASDs appears to have significant potential as an adjunct to educational, environmental and social interventions. It is a reasonable goal for the pharmacotherapist to adopt the judicious use of psychopharmacological agents to assist in alleviating symptoms that have been found to respond to pharmacological intervention (Table 27.7). This focus on facilitating adaptation requires attention to five important principles:

1. Environmental manipulations, including behavioral treatment, may be as effective as, if not more effective than, medication for selected symptomatic treatment.
2. It is essential that the living arrangement for the individual must ensure safe and consistent administration and monitoring of the medication to be used.
3. Individuals with autistic disorder and other ASDs often have other DSM-IV-TR Axis I disorders. If a comorbid DSM-IV-TR Axis I disorder is present, standard treatment for that disorder should be initiated first.
4. Medication should be selected on the basis of potential effects on target symptoms and there should be an established way of specifically monitoring the response to the treatment over time.

**Table 27.7 Summary of Pharmacotherapy Principles**

Psychosocial interventions should accompany medication treatment.  
The individual’s living arrangement must ensure safe, consistent administration of medications.  
Maintain a high index of suspicion for comorbid disorders and treat these appropriately.  
Establish a means of monitoring effects of medications on symptoms over time.  
Assess the risk/benefit ratio of starting medications and educate the patient and family about these.

5. A careful assessment of the risk/benefit ratio must be made before initiating treatment and, to the extent possible, the patient's caretakers and the patient must understand the risks and benefits of the treatment.

### Potent Serotonin Transporter Inhibitors

This class of agents includes selective serotonin reuptake inhibitors (SSRIs) as well as the less selective but potent clomipramine, a tricyclic antidepressant (Table 27.8). This group of medications is most effective when insistence on routines or rituals are present to the point of manifest anxiety or aggression in response to interruption of the routines or rituals, or after the onset of another disorder such as major depressive disorder or OCD. The common side effects associated with SSRIs are motor restlessness, insomnia, elation, irritability and decreased appetite. Because many of these symptoms may be present in the often cyclical natural course of ASD before the medication is initiated, the emergence of new symptoms, a different quality of the symptoms, and occurrence of these symptoms in a new cluster are clues that the symptoms are side effects of medication rather than part of the natural course of the disorder.

### Stimulants

Small but significant reductions in inattention and hyperactivity ratings may be seen in children with autistic disorder in response to stimulants such as methylphenidate and dextroamphetamine.

**Table 27.8 Psychopharmacological Approach to Presenting Symptoms in Pervasive Developmental Disorders**

Rituals, Compulsions, Irritability
Potent serotonin transporter inhibitors
Selective serotonin reuptake inhibitor
Fluoxetine 5–80 mg/d in a single dose
Paroxetine 2.5–50 mg/d in one or two divided doses
Sertraline 25–200 mg/d in one or two divided doses
Fluvoxamine 25–300 mg/d in two or three divided doses
Citalopram 5–40 mg/d in a single or two divided doses
Tricyclic antidepressants
Clomipramine 25–250 mg/d in one or two divided doses
Hyperactivity, Distractibility, Impulsivity
Stimulant medications
Methylphenidate 5–60 mg/d in three to five divided doses
Dextroamphetamine 5–60 mg/d in three to five divided doses
Clonidine 0.05–0.3 mg/d in one to three divided doses or by transdermal skin patch
Naltrexone 0.5–2.0 mg/kg/d in a single dose
Aggression, Irritability
Sympatholytics
Propranolol 20–400 mg/d in three to four divided doses
Nadolol 40–400 mg/d in a single dose
Anticonvulsants
Carbamazepine to a blood level of 4–12 ng/mL
Valproate to a blood level of 50–100 ng/mL
Lithium to a serum level of 0.8–1.2 mEq/L
Neuroleptics
Naltrexone 0.5–2.0 mg/kg/d in a single dose

In a placebo-controlled crossover study, eight of 13 subjects showed a reduction of at least 50% on methylphenidate (Handen *et al.*, 2000). However, stereotypies may worsen, so drug trials for the individual patient must always be assessed to determine whether the therapeutic effects outweigh side effects. A key distinction in assessing attentional problems of children with ASD is the distinction between poor sustained attention (characteristic of children with attention-deficit/hyperactivity disorder) and poor joint attention (characteristic of children with autistic disorder). Problems in joint attention require educational and behavioral interventions or treatment of rituals with an SSRI. Problems in maintenance of attention of the type seen in attention-deficit/hyperactivity disorder are more likely to respond to stimulants.

### Sympatholytics

The alpha<sub>2</sub>-adrenergic receptor agonist clonidine reduced irritability as well as hyperactivity and impulsivity in two double-blind, placebo-controlled trials. However, tolerance developed several months after initiation of the treatment in each child who was treated long term but may have been reduced in several cases by administering clonidine in the morning and then 6 to 8 hours later with a 16- to 18-hour interval between the last dose of one day and the first dose of the next day. If tolerance does develop, the dose should not be increased because tolerance to sedation does not occur, and sedation may lead to increased aggression due to disinhibition or decreased cognitive control of impulses. Adrenergic receptor antagonists, such as propranolol and naldolol, have not been tested in double-blind trials in ASD. However, open trials have reported the use of these medications in the treatment of aggression and impulsivity in developmental disorders including autistic disorder.

### Neuroleptics

#### Typical Neuroleptics

Because they were among the first modern psychopharmacological agents, typical neuroleptics have been among the most extensively studied drugs in autistic disorder. Trifluoperazine, thioridazine, haloperidol and pimozide have been studied in double-blind, controlled trials lasting from 2 to 6 months. Reduction of fidgetiness, interpersonal withdrawal, speech deviance and stereotypies has been documented in response to these. However, patients with autistic disorder are as vulnerable to potentially irreversible tardive dyskinesia as any other group of young patients. Owing to the often earlier age at initiation of pharmacotherapy, patients with ASD treated with typical neuroleptics may be at higher risk because of the potential increased lifetime exposure of medication limiting their routine use in the care of patients with ASD, especially as first-line treatments.

#### Atypical Neuroleptics

Because of the positive response of many children with autistic disorder to typical neuroleptics, similar medications with reduced risk of tardive dyskinesia must be considered. In addition, atypical neuroleptics are often effective in treating the negative symptoms of schizophrenia, which seem similar to several of the social deficits in autistic disorder. Both risperidone and olanzapine have shown promise in open label trials in reducing hyperactivity, impulsivity, aggressiveness and obsessive preoccupations. A double-blind, placebo-controlled study found risperidone to be more effective than placebo in the treatment of repetitive behavior, aggression and irritability (McDougle *et al.*, 1998).

## Anticonvulsants

Because 25 to 33% of patients with autistic disorder have seizures, the psychopharmacological management of patients with autistic disorder or other ASD must take into consideration the past or current history of epilepsy and the potential role of anticonvulsants. In an open trial of divalproex, 10 of 14 patients responded favorably, showing improvements in affective stability, impulsivity and aggression (Hollander *et al.*, 2001). Because barbiturates have been associated with hyperactivity, depression and cognitive impairment, they should be changed to an alternative drug, depending on the seizure and avoided when possible. In addition, phenytoin (Dilantin) is sedating and can cause hypertrophy of the gums and hirsutism, which may contribute to the social challenges for people with autistic disorder. Carbamazepine and valproate may have positive psychotropic effects, particularly when cyclical irritability, insomnia and hyperactivity are present.

## Naltrexone

Double-blind trials have demonstrated that naltrexone, an opiate antagonist, has little efficacy in treating the core social and cognitive symptoms of autistic. While the use of naltrexone as a specific treatment for autistic disorder no longer seems to be likely, it may have a role in the treatment of self-injurious behavior, although the controlled data are equivocal. Controlled trials have shown a modest reduction in symptoms of hyperactivity and restlessness sometimes associated with autistic disorder. Potential side effects include nausea and vomiting. Naltrexone may have an adverse effect on the outcome of Rett's disorder on the basis of a relatively large, randomized, double-blind, placebo-controlled trial (Percy *et al.*, 1994).

## Lithium

Adolescents and adults with autistic disorder often exhibit symptoms in a cyclic manner and so there is much interest in how these patients might respond to agents typically used in bipolar disorder. A single open trial of lithium revealed no significant improvement in symptoms in patients with autistic disorder without bipolar disorder (Campbell *et al.*, 1972).

## Anxiolytics

Benzodiazepines have not been studied systematically in children and adolescents with autistic disorder. However, their use to reduce anxiety in short-term treatment, such as before dental procedures, is similar to their use in management of anxiety in people without a PDD. One open label study has found a decrease in anxiety and irritability in patients receiving the anxiolytic buspirone (Buitelaar *et al.*, 1998).

## Glutamatergic Antagonists

Interest in these agents has been sparked by the hypothesis that ASDs may be a disorder of hypoglutaminergic activity. In a double-blind, placebo-controlled study of the glutamatergic antagonist amantadine hydrochloride, there were substantial improvements in clinician-rated hyperactivity and irritability, although parental reports did not reach statistical significance (King *et al.*, 2001).

## Other Treatments

Pyridoxine, the water-soluble essential vitamin B<sub>6</sub>, has been used extensively as a pharmacological treatment in autistic disorder. In the doses used for autistic disorder, it is not being used as a

cofactor for normally regulated enzyme function or as a vitamin; rather, it is used to modulate the function of neurotransmitter enzymes, such as tryptophan hydroxylase and tyrosine hydroxylase. Recent reviews have concluded that there are little data to support the claim that vitamin B<sub>6</sub> improves developmental course. The same is true for using fenfluramine, naloxone and secretin.

## Comparison of DSM-IV/ICD-10 Diagnostic Criteria

The DSM-IV and ICD-10 item sets and diagnostic algorithms for autistic disorder are almost identical. However, the ICD-10 exclusion criterion is considerably more broad, requiring that a number of other disorders should be considered instead (e.g., early-onset schizophrenia, mental retardation with an associated emotional or behavioral disorder). In ICD-10, this disorder is referred to as childhood autism.

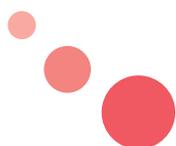

The DSM-IV and ICD-10 item sets and diagnostic algorithms for Rett's disorder and Asperger's disorder are almost identical. In ICD-10, these disorders are referred to as Rett's syndrome and Asperger's syndrome respectively.

Regarding childhood disintegrative disorder, the DSM-IV and ICD-10 item sets and diagnostic algorithms are identical except for the C criterion, in which ICD-10 also allows for a "general loss of interest in objects and the environment". In ICD-10, this disorder is referred to as other childhood disintegrative disorder.

# Childhood Disorders: Attention-deficit and Disruptive Behavior Disorders

## Introduction

Attention-deficit/hyperactivity disorder (ADHD), conduct disorder (CD) and oppositional defiant disorder (ODD) form the attention-deficit and disruptive behavior disorders (AD-DBDs) in DSM-IV-TR (American Psychiatric Association, 2000). As a group, these are the most common disorders of childhood and among the most researched areas of childhood psychopathology. There is also increasing recognition that these disorders continue into adulthood.

Children with ADHD are challenged in their ability to modulate impulsivity, hyperactivity and inattention. Some children, however, can present with either predominate hyperactivity or inattention, the latter more likely to go undiagnosed since they are often less disruptive within the classroom. To establish the diagnosis of ADHD, DSM-IV TR requires that children must have, before the age of seven, at least six signs of hyperactivity/impulsivity and an equal number of signs demonstrating inattention. Children often are diagnosed after the age of seven, however, a carefully elicited history generally reveals symptoms of ADHD earlier in the child's development that clearly distinguish them from their peers. Functional impairment must be present in at least two sectors of the child's life. For younger children, problems at home and at school are the rule. Common symptoms include hyperactivity, as manifested by fidgetiness, excessive talking, inability to participate in leisure activities quietly, inability to remain seated in the classroom or social settings, frequent inappropriate running or climbing. Teachers and parents describe children with ADHD as "always on the go" or seem to be "driven by a motor".

The essential feature of CD is a repetitive and persistent pattern of behavior in which the basic rights of others or major age appropriate societal norms or rules are violated. Behaviors are categorized within the following four groups:

- destruction of property;
- theft and or deceitfulness;
- serious violations of rules;
- aggression directed at animals and people.

Similar to ADHD, symptoms of CD are seen in more than one setting and cause significant impairment in functioning. The diagnosis of CD requires that symptoms be present for at least one year, with one or more symptoms occurring within the previous six months. Adults with conduct problems, whose behavior does not meet criteria

for antisocial personality disorder, may have symptoms that meet criteria for CD and thus qualify for the diagnosis. Subtypes of CD are determined on the basis of age of onset. The childhood onset subtype is diagnosed in children who show at least one of the behaviors before the age of 10 years, while the adolescent onset subtype is characterized by the absence of any CD behaviors before 10 years of age.

The essential feature of ODD is a recurrent pattern of negativistic, defiant, disobedient and hostile behavior toward authority figures that persists for at least 6 months and results in social and academic impairment. Typical behaviors include excessive:

- anger;
- vindictiveness;
- arguing with and disobeying adults;
- loss of temper;
- annoying others;
- blaming of others for poor behavior and mistakes.

The rationale for grouping ADHD, CD and ODD is that similar areas of difficulty are present in children with these disorders. Academic difficulties, poor social skills and overrepresentation of boys are among the shared characteristics. Further, the three disorders demonstrate a commonality of core symptoms, with impulsivity being prominent in all three conditions. Not surprisingly, there is a high degree of comorbidity among the three disorders. In part related to this, there has been extensive debate as to whether these conditions are truly distinct from each other. While there is now a consensus that ADHD and CD are separable diagnoses with distinct correlates and outcome, the relationship of ODD to both disorders is less clear.

## Epidemiology

While DSM-IV-TR estimates the prevalence rates for ADHD to range from 2 to 7% in school-age, rates as high as 17.1% have been reported in community surveys (Cohen *et al.*, 1993). Rates for CD have been estimated to be as low as 0.9% for school-age children but as high as 8.7% in adolescents. The overall prevalence of ODD varies across studies from 5.7 to 9.9%.

In school-age children, boys have higher rates than girls for all three disorders. In clinic settings, the ratio of boys to girls is about 9:1, but in community samples, this decreases to approximately 3:1. Furthermore, teachers tend to identify fewer

girls than boys as having ADHD symptoms. The combined type of ADHD is the most common subtype in both genders. However, in the predominantly hyperactive–impulsive subtype of ADHD, the male to female ratio is approximately 4:1 while in the predominantly inattentive subtype the ratio falls to 2:1. In general, prevalence declines with age, but follow-up studies of children and adolescents indicate that the disorder frequently persists into adulthood. Longitudinal studies have reported rates of childhood cases that persist into adulthood to range from 4 to 75%. Factors that appear to predict the persistence of ADHD into adulthood include a positive family history for ADHD and the presence of psychiatric comorbidity, particularly aggression.

Among the AD-DBDs, approximately 90% of children with CD would also meet the criteria for ODD. Furthermore, 40% of children with ADHD also have ODD and 40% of children with ODD have ADHD. In terms of the comorbidity of the AD-DBD group with other diagnostic categories, it has been estimated that 15 to 20% of children with ADHD have comorbid mood disorders, 20 to 25% have anxiety disorders and 6 to 20% have learning disabilities. Other conditions which may occur comorbidly with the AD-DBDs include Tourette's disorder (TD), drug and alcohol abuse or dependence and mental retardation.

## Etiology

There is no single etiology for any of the AD-DBDs. It is likely that each of these disorders is heterogeneous. Nevertheless, a variety of studies using neurochemical markers, family-genetic analyses, patterns of comorbidity, and family studies have begun to delineate more homogeneous groups.

## Neurobiology

### Attention-deficit Hyperactivity Disorder (ADHD)

ADHD pathophysiologic research has focused on neural circuits centered in the prefrontal cortex and striatum, as well as on the brain stem catecholamine systems that innervate these circuits.

The prefrontal cortex and the striatum are part of a complex neural system that mediates inhibitory control processes. The prefrontal cortex receives higher-order sensory input and inhibits the processing of irrelevant sensory stimuli through reciprocal connections with temporal and parietal association cortices. In turn, the prefrontal cortex exerts inhibitory control over motor functions through well-organized connections with the caudate nucleus, and indirectly with the globus pallidus. The globus pallidus feeds back to the prefrontal cortex via thalamic nuclei. Emerging data from neuroimaging studies suggest that impairments in these prefrontal–striatal regions play a central role in the pathophysiology of ADHD.

Morphological studies using magnetic resonance imaging (MRI) have identified a smaller right prefrontal cortex, caudate nucleus and globus pallidus in children with ADHD which suggests that ADHD may be associated with fewer prefrontal corticostriatal fibers and less pallidal feedback to prefrontal regions. In addition, reduced area in the corresponding anterior genu region of the corpus callosum in children with ADHD indicates the presence of fewer inter-hemispheric fibers in prefrontal regions. Anomalies have also been found in ADHD in regions that project to the prefrontal cortex, including in the parietal–occipital region (i.e., reduced white matter) and the cerebellum (i.e., smaller posterior vermis). The latter findings raise the possibility that brain anomalies in ADHD extend

beyond the prefrontal cortex and striatum to the posterior and subcortical regions that innervate these frontal circuits.

Studies with single photon emission computerized tomography (SPECT) and positron emission tomography (PET) have reported lower basal activity in the prefrontal cortex and striatum of children (Zametkin *et al.*, 1990), but not adolescents with ADHD (Zametkin *et al.*, 1993). More recent studies employing functional MRI (fMRI) have tentatively linked altered prefrontal–striatal activation with deficits in inhibitory control. Reduced striatal activation during response inhibition tasks has been consistently reported in children and adolescents with ADHD. However, prefrontal activation during the same tasks was enhanced in children, but reduced in adolescents with the disorder. Normal age-related declines in prefrontal activation may account for the disparate findings.

The fact that virtually all medications that are efficacious in ADHD affect noradrenaline (NA) and dopamine (DA) transmission strongly suggest that perturbations of these catecholamine inputs play a significant role in the pathophysiology of ADHD, although studies of catecholamine function in ADHD have yielded highly inconsistent findings (Zametkin and Rapoport, 1987). Only more recent studies that used central indices of catecholamine function or that examined more homogeneous subgroups of children with ADHD have provided evidence of DA and NA dysfunction associated with ADHD. For example, cerebrospinal (CSF) levels of the DA metabolite homovanillic acid were positively correlated with ratings of hyperactivity and stimulant response in boys with ADHD (Castellanos *et al.*, 1996). Further, dividing boys with ADHD based on the presence or absence of reading disabilities revealed differences in plasma levels of the NA metabolite 3-methoxy-4-hydroxy-phenylglycol (MHPG) that correlated with differences in clinical characteristics (Halperin *et al.*, 1997).

A promising recent development has been the use of PET and SPECT imaging in combination with DA-selective radiotracers to examine localized DA function in vivo. These studies have revealed preliminary evidence of increased striatal DA transporter binding in adults with ADHD (Dougherty *et al.*, 1999; Krause *et al.*, 2000) and altered DA synthesis in the prefrontal cortex and right midbrain of children and adults with ADHD. These data point to localized DA deficits in the nigrostriatal and mesocortical fiber systems in ADHD.

### Conduct Disorder (CD)

The neurobiologic basis of CD has focused primarily on the neurochemical substrates of aggressive behaviors. An early body of literature pointed to a role for reduced noradrenergic function. Several studies found negative correlations between plasma and CSF concentrations of MHPG and aggression and conduct problems (Kruesi *et al.*, 1990; Rogeness *et al.*, 1987). Children with CD were also reported to exhibit low activity of the enzyme dopamine-beta-hydroxylase, which converts DA into NA. These data suggest that NA dysfunction may play a role in aggression through its involvement in the regulation of behavioral arousal.

More recent research has focused on the role of central serotonergic (5-HT) function in aggression and antisocial behavior (Markowitz and Coccaro, 1995). Aggressive and antisocial adults have consistently been shown to have reduced CSF levels of 5-HT metabolites and blunted responses to 5-HT challenge agents. Studies examining central 5-HT function in aggressive children have had mixed results. Reduced central 5-HT function is associated with numerous risk factors for persistence in aggressive children, including affective lability, adverse child-rearing and parental history of aggression.

## Genetics

Research data support the familial transmission of ADHD and CD and suggest that these disorders may share common familial vulnerabilities (Biederman *et al.*, 1992). Estimates of heritability range from 60 to 80% for ADHD (Sherman *et al.*, 1997) and from 30 to 70% for CD (Slutske *et al.*, 1997).

Newer molecular genetic studies have identified a number of individual genes as potential candidate genes in the AD-DBDs. Evidence of altered DA activity in ADHD has focused on the search for candidate genes among DA system genes, including the DA D2, DA D4 and DA D5 receptor genes and the DA transporter gene (DAT1; with the strongest evidence for the 7-repeat allele of DRD4 (Swanson *et al.*, 1998), which mediates a blunted intracellular response to DA, and the 10-repeat allele of DAT1 (Daly *et al.*, 1999), which is linked to elevated DA reuptake. Preliminary data have also linked the 10-repeat allele of DAT1 with poor response to methylphenidate (Winsberg and Comings, 1999), which acts primarily by inhibiting the DA transporter in the striatum.

Several 5-HT system genes have been identified as candidates for study in CD. These include the genes encoding the enzymes tryptophan hydroxylase (TPH) and monoamine oxidase A (MAOA), which are involved in the synthesis and metabolism of 5-HT, respectively.

## Environmental Factors

Twin studies have provided some of the strongest evidence implicating environmental factors in the etiology of the AD-DBDs. These studies indicate that a moderate-to-significant proportion of the susceptibility to AD-DBDs is accounted for by non-shared factors. Nonshared factors have their greatest effect in CD (Slutske *et al.*, 1997); and are less important contributors to ADHD (Sherman *et al.*, 1997). Examples of nonshared factors include low verbal intelligence, poor school performance, difficult temperament inflated self-esteem and biological events, such as perinatal insults and head trauma. Among the most salient risk factors for CD is the presence of early ODD and ADHD (Hinshaw, 1987).

Shared family, peer and neighborhood risk factors also play a role in the etiology of ODD and CD, and to a lesser degree of ADHD. These so-called adversity factors include large sibships, families that have experienced separation, single-parent households, child neglect, parental conflict and poverty. Parental child-rearing practices, such as harsh physical discipline and poor supervision, have also been implicated in ODD and CD. However, the most salient familial risk factor for CD is parental criminality which likely has both environmental and genetic components. Delinquent peer membership and repeated victimization by peers also add to the etiology of CD and aggression. Finally, residing in a neighborhood with high rates of crime, poverty and/or unemployment is associated with an earlier onset of CD. These factors seem to operate in an additive fashion, with the probability of CD increasing linearly with the aggregation of risk factors (Rutter *et al.*, 1975).

## Course and Natural History

Some behaviors characteristic of the AD-DBDs are observable as early as the preschool years. Hyperactive behaviors such as “moves too much during sleep” have been reported as early as age one and a half years, followed by the appearance of “difficulty playing quietly”

and “excessive climbing/running” by age 3 years. Attentional problems are usually reported after hyperactivity. However, it is likely that these problems are present from early on but are not reported until the child enters school, when there are increased environmental and cognitive demands. Hyperactivity and attentional problems emerge gradually and may overlap with the emergence of oppositional behaviors. Many individuals with ADHD continue to have attentional, behavioral and emotional problems well into adolescence and adulthood. Typically, adults with ADHD are less overtly overactive, although they may retain a subjective sense of restlessness. Impairment in these adults is more often a result of inattention, disorganization and impulsive behavior.

During the preschool years, transient oppositional behavior is very common. However, when the oppositionality is of a persistent nature and lasts beyond the preschool years, the escalation to more disruptive behaviors is more likely. In most oppositional children, who are usually not physically aggressive, oppositional behaviors peak around age 8 years and decline beyond that. In a second group of children, delinquent behaviors follow the onset of oppositional behaviors. Early physical aggression is a key predictor of this latter trajectory, with physically aggressive children being more likely to progress from early oppositional behaviors to more severe and disabling conduct problems. Coexistent ADHD tends to speed this escalation to more severe conduct problems and the development of antisocial personality disorder in adulthood.

Generally, conduct problems first appear in middle childhood. The progression of conduct problems is from rule violations, such as poor school attendance, to aggression toward animals and people. In males, the progression to more serious forms of conduct problems, such as rape or mugging, generally emerge after age 13 years (Loeber, 1990). A different group of children show conduct problems for the first time during adolescence, without preexisting oppositional or aggressive behaviors. This latter group tends to have disorders that are transient and nonaggressive. When conduct disorder is seen in adolescence for the first time, the problems tend to diminish by adulthood. However, if conduct disorder is present from middle childhood, there is a much greater degree of persistence of aggression through adulthood and often a history of arrests and/or incarceration.

Considerable data indicate that a subgroup of hyperactive children show high rates of delinquency and substance abuse during adolescence, and this continues into adulthood. However, it is likely due to the comorbidity with conduct disorder or bipolar disorder that higher rates of substance abuse are found in adolescents with ADHD. Families of these children tend to be less stable, have higher divorce rates and move more frequently. First degree relatives have been found to have higher rates of antisocial behaviors, substance abuse and depression. The difficulties experienced by these adolescents and adults include poor self-esteem, difficulty in interpersonal relationships, difficulties in holding onto jobs, as well as assault and armed robbery in a minority of cases (Hechtman *et al.*, 1981).

## Assessment

The clinical evaluation of a child with possible AD-DBD requires a multisource, multimethod approach. In addition to clinical interviews of parents and children, supplemental information may be obtained from school reports, rating scales completed by teachers and parents, neuropsychological test data and direct observations of the child. Generally, adults are considered to be

the best informants of disruptive behaviors, although children and adolescents may provide important data regarding internalizing symptoms and some infrequent behavior problems, such as antisocial acts (American Academy of Child and Adolescent Psychiatry, 1997; Barkley *et al.*, 1991; Loeber *et al.*, 1991).

### Rating Scales

Rating scales facilitate the systematic acquisition of information about the child's behavior in different settings in a cost-effective manner. Most are standardized and provide scores that are norm-referenced by age and gender. The systematic use of these instruments ensures that a complete set of specific behaviors is assessed at different points in time, enabling comparisons over the course of treatment. Teacher and parent rating scales are complimentary because they yield data from different situations. Parents are knowledgeable about their child's day-to-day behavior, and present information related to the child's behavior at home and his/her interaction with siblings. Teachers are often a valuable source of information regarding attentional problems and disruptive behaviors in a classroom setting.

The most commonly used rating scales are the Conners (1998a, 1998b), and the Achenbach (1991a, 1991b) scales, which are available in parent and teacher versions. The Conners Teachers Rating Scale – Revised (CTRS-R) is a 28-item scale that is normed for children from 3 to 17 years of age and is sensitive to medication effects. The Conners Parent Rating Scale (CPRS-R) contains 48 items is also sensitive to treatment effects and can differentiate groups of ADHD children from normals. The Child Behavior Checklist (CBCL) assesses a broad range of behavioral problems and is useful with children from ages 4 to 16 years. The CBCL is also available in a more recently developed Teacher Report Form (Achenbach, 1991b), which is similar to the parent form and applicable for children aged 4 to 18 years.

Rating scales have several limitations, and diagnoses should not be made on the bases of these data alone. It has been consistently found that elevations on discrete scale factors do not necessarily coincide with specific psychiatric disorders.

### Interviews

Interviews with children and their parents form the core of the clinical evaluation. It is essential that the interviewer directly enquire about all symptoms of ADHD and common comorbidities, and therefore some structured questioning is usually required.

A number of structured and semistructured diagnostic interviews are currently available for use with children, including the Diagnostic Interview Schedule for Children (DISC-II), the Diagnostic Interview for Children and Adolescents (DICA), the Schedule for Affective Disorders and Schizophrenia for School Aged Children (K-SADS), the Child and Adolescent Psychiatric Assessment (CAPA), the Child Assessment Schedule (CAS) and the Diagnostic Interview Schedule for Children (DISC). Among the AD-DBDs, it has been found that CD often has better reliability and validity coefficients than ADHD.

### Psychological/Psychometric Evaluation

Psychological and cognitive test performance is generally not required to determine the presence of an AD-DBD. Nevertheless, because the AD-DBDs are frequently associated with learning problems, neuropsychological testing may be indicated,

particularly when assessment of cognitive functioning is required. Information from a neuropsychological and/or educational evaluation can often be used to supplement the clinical evaluation by providing an understanding of the individual child's level of cognitive and attentional functioning, as well as screening for suspected mental retardation and various learning disabilities.

Other psychometric measures include computerized continuous performance tests (CPTs), of which there are many varieties. Recent interest in creating developmentally appropriate measures of AD-DBDs symptom domains for preschoolers has led to the development of CPTs for use in this population (Harper and Ottinger, 1992). While CPTs have been found to differentiate children with ADHD from normals, their ability to differentiate ADHD from other clinical groups is less clear, and there is little evidence that they are able to identify individuals with enough precision to be useful as diagnostic instruments.

Objective measures of activity level, such as stabilometric chairs, wrist actometers and solid state actigraphs, have also been used in the assessment of ADHD. Although these devices provide a judgment-free assessment of activity level, their validity, as assessed by correlations with ratings of behavior, has been inconsistent. At the present time, it is suggested that these measures not be used to diagnose clinical syndromes.

### Observational Measures

Several studies have used direct behavioral observation in the assessment of the AD-DBDs. In a structured playroom setting, measures include counting the number of times a child crosses grids marked on the floor, recording the number of toys touched, the amount of time played with each toy and the amount of time the child spends focused on a particular task. In the school setting, typical measures include monitoring the amount of time the child spends on-task, remains in his/her seat and so on. These observational measures have consistently been found to differentiate ADHD children from normals, although their utility in discriminating among clinical groups is less clear.

### Laboratory Measures

At the present time, there are no laboratory measures that can serve as diagnostic tools for AD-DBDs. Similarly, findings from neuroimaging studies have neither been consistent enough nor specific enough to warrant their use as diagnostic tools.

### Other Domains of Functioning

Many children with AD-DBDs have impaired social skills and consequently experience difficulties with peer relationships. Data suggest that both hyperactivity and aggression often lead to peer rejection, which may occur as early as the preschool. The level of hyperactivity, age of onset of aggression and the developmental level of the child, all affect the extent of peer rejection experienced. Information regarding social adjustment is crucial in treatment planning, since increased impairment in social and school function is predictive of poor outcome.

Parent-child interactions also play a role in the maintenance of disruptive behaviors, poor social skills, the presence of internalizing symptoms and response to treatment. It has been noted that robust reductions in negative and ineffective parenting practices at home mediate improvement in children's social skills in the school setting (Hinshaw *et al.*, 2000).

## Differential Diagnoses

Proper differential diagnosis of ADHD, CD and ODD requires not only discrimination among the three disorders, but also from a wide range of other psychiatric, developmental and medical conditions. ADHD can be conceptualized as a cognitive/developmental disorder, with an earlier age of onset than CD. ADHD children more frequently show deficits on measures of attentional and cognitive function, have increased motor activity and greater neurodevelopmental abnormalities. In contrast, CD children tend to be characterized by higher levels of aggression and greater familial dysfunction.

A significant proportion of children present with symptoms of both ADHD and CD, and both conditions should be diagnosed when this occurs. Comorbid ADHD and CD is consistently reported to be more disabling with poorer long-term outcome than either disorder alone. These children show persistently increased levels of aggressive behaviors at an early age. This is in contrast to the more typical episodic course seen in children who have CD alone.

It appears that among children with ADHD, those who are most hyperactive/impulsive are at greatest risk for developing ODD. ODD symptoms, such as “loses temper”, “actively defies”, and “swears”, are less characteristic of children with ADHD. In general, the onset of ODD symptoms peaks by age 8 years and shows a declining course thereafter, while hyperactivity and attentional problems appear at a much earlier age and often persist, although the levels of inattentiveness and/or hyperactivity often decrease with age.

A diagnosis of CD supersedes ODD since approximately 90% of children with CD would also meet criteria for ODD, and some question whether they represent a spectrum of severity or distinct diagnoses. Although the majority of ODD children will not develop CD, in some cases ODD appears to represent a developmental precursor of CD. In cases where ODD precedes CD, the onset of CD is typically before age 10 years (childhood onset CD). In children who have the onset of CD after age 10 years, symptoms of ODD and ADHD are usually not present during early childhood. It has been shown that children with ODD demonstrate lower degrees of impairment and are more socially competent as compared with children with CD. Furthermore, children with CD come from less advantaged families, and have greater conflict with school and judicial systems as compared with children with ODD.

Mood and anxiety disorders, learning disorders, mental retardation, pervasive developmental disorders, organic mental disorders and psychotic disorders may all present with impairment of attention, as well as hyperactive/impulsive behaviors. The diagnosis of ADHD in DSM-IV requires that the symptoms of inattention/cognitive disorganization and impulsivity/hyperactivity are not better accounted for by one of the above conditions. Differentiating ADHD from bipolar disorder in childhood is complicated by the low base rate of bipolar disorder and the variability in clinical presentation. A positive family history of bipolar disorder is especially helpful in diagnosing bipolar disorder in children. In addition, a variety of medical conditions such as epilepsy, Tourette's disorder, thyroid disease, postinfectious and/or post traumatic encephalopathy and sensory impairments can present with symptoms similar to ADHD and must also be considered. Finally, many medications which are prescribed to children can mimic ADHD symptomatology. Examples include anticonvulsants (e.g., phenobarbital), antihistamines, decongestants, bronchodilators (e.g., theophylline) and systemic steroids.

## Treatment

Given the heterogeneity of the three disorders that make-up the AD-DBDs, the wide ranging effects of the disruptive behaviors, the high rates of comorbidity and the presence of associated features such as learning disabilities, multimodal treatments (i.e., psychopharmacologic and psychosocial) are almost always warranted. Nevertheless, good response can be achieved with either treatment alone in certain instances (e.g., medication treatment for uncomplicated ADHD or ADHD + ODD; psychosocial treatment for ADHD + anxiety disorder) (MTA Cooperative Group, 1999a, 1999b). A diagnosis of ODD without any comorbid condition will usually be responsive to behavioral intervention without medication. Similarly, treatment of children with CD without comorbidity usually involves psychosocial interventions with the possibility of augmenting treatment with one of several pharmacological agents. In contrast, comorbid ADHD + CD almost always requires medication, and medication response is augmented if psychosocial treatment is offered concomitantly (Jensen *et al.*, 2001).

## Psychopharmacology

Psychopharmacological treatments of the AD-DBDs can be traced to 1930s when benzedrine was successfully used to treat a heterogeneous group of behaviorally disturbed children and adolescents. Psychostimulants remain the medication of choice for the majority of children with ADHD. They have been studied in literally hundreds of controlled trials in all age groups, have documented safety and are now available in extended release preparations that are easy to use and decrease the potential for stigma associated with school administration that previously plagued children and families with ADHD. However, several other currently available medications have demonstrated efficacy for ADHD and are often used off-label to treat this condition. They offer useful alternatives for those who are stimulant nonresponders, or for whom stimulants may be contraindicated.

## Psychostimulants

Methylphenidate (MPH), dextroamphetamine (DEX) and mixture of amphetamine salts (MAS) (which is a mixture of several amphetamine compounds, 75% of which is DEX) have all been shown to be effective in treating ADHD. Of these, MPH is the most often prescribed and accounts for approximately 60% of stimulant use in the USA. MAS has become a popular alternative to MPH, and despite slight differences in mechanism of action, profiles of response and adverse effects, there are no strong data to indicate that any one stimulant preparation is substantially more effective or better tolerated than any other. Despite these similarities, there are sometimes differences in individual response profiles, which demonstrate that one preparation may be substantially better than the others for a particular individual.

The stimulants produce significant improvement in attention, hyperactivity, impulse control and aggressiveness, leading to better organization of behavior, task completion and self-regulation. There is fairly robust improvement in social skills, as evidenced by peer ratings, and parent and teacher ratings of social function. There is also improvement in academic productivity, although change in actual academic performance has been more difficult to demonstrate. Although most data with stimulants have been obtained in samples of school-age children with ADHD, there is increasing recognition that stimulants can be used successfully across the lifespan (Spencer *et al.*, 2001).

The decision to prescribe psychostimulant medication is best undertaken following a comprehensive assessment, with full consideration given to the range of pharmacologic and nonpharmacologic treatment options which are available. Prior to a trial with any of the stimulants, baseline data should be obtained, including general medical status, and more specific evaluations of height, weight, blood pressure and a complete blood count.

The past several years have seen a veritable explosion in the number of stimulant treatment options for individuals with ADHD. Most of the attention has focused on development of sustained release preparations, which eliminate the need to take medication several times over the course of the day, and to provide a more consistent profile of delivery. This has the added benefit of decreasing the need for in-school dosing, and along with it the potential for stigmatization of children with ADHD and diversion of medication. Both MPH and MAS are now available in preparations formulated to last 12 hours. MPH is also available in two new delivery forms that are each intended to last 8 hours. A new immediate-release stimulant treatment, d-MPH (the active stereoisomer of MPH), has also recently come on the market.

The decision regarding which stimulant to select is best determined by considering properties intrinsic to the different medications – such as duration of activity and adverse effect profile – as well as the individual circumstances of the patient (e.g., when is peak medication level needed most, what is the individual's lifestyle, etc.). Nonresponders to one medication may respond well to another, since their mechanisms of action are not identical, and if there is not adequate response to one stimulant medication, another should be tried.

Increasingly, MPH is given in its long-acting forms as a first-line approach. The usual starting dose for Concerta (12-hour formulation) is 18 mg, which is equivalent to 5 mg IR-MPH administered three times daily, and may be increased 18 mg at a time. Various forms and strengths of intermediate-release MPH are also available. Immediate-release (IR) MPH can be used as a primary therapeutic agent, given in either b.i.d. or t.i.d. dosing schedules, however, its niche increasingly is to supplement the longer-acting preparations, either to achieve more rapid onset of effect or to extend duration of action. When IR-MPH is used as a primary option, the usual starting dose is 5 mg. The dose is then increased in 5 mg increments. The upper recommended dose for MPH is 60 mg, although use of higher doses may be required in certain cases.

MAS and DEX can often be administered in a similar manner to MPH, and also come in a variety of IR and extended release formulations. Adderall XR (MAS) is the only amphetamine preparation formulated to act for 12 hours. Brand Adderall or generic MAS are also available in a shorter acting form that lasts approximately 5 to 6 hours. DEX is available in both a spansule, with duration of activity comparable to the shorter acting MAS, and an IR preparation, which lasts approximately 4 hours. A recent study found that DEX spansule and MAS have comparable efficacy and duration. DEX and MAS are more potent than MPH, so the initial starting dose and upper dose limit are lower. The recommended dosage range for DEX is 2.5 to 40 mg. Although DEX has a somewhat longer half-life than MPH, a t.i.d. schedule is still often required.

Adverse effects (AE) of stimulants are generally mild, but occasionally can become problematic. The most commonly observed AEs include headache, abdominal pain, decreased appetite (with or without weight loss) and initial insomnia. There are slight increases in pulse and BP, which are not very meaningful

at the group level, but can take on greater significance for particular individuals. Affective changes, including blunted affect, irritability and mood lability, can also be seen, either at peak dose or when the dose wears off. Use of longer acting psychostimulants tends to minimize mood lability and other AEs that are often considered to be a reflection of the on-off effects which are more frequently seen with IR preparations. Motor or vocal tics can develop. However, there has been a convergence of evidence that stimulant treatment does not necessarily exacerbate tics, and even some suggestions that these conditions are relatively independent. There has been some concern that stimulants can precipitate psychotic symptoms such as hallucinations, although this is very rare and almost always seen as a reflection of excessive dosing or use in individuals with disorders other than ADHD (e.g., psychotic disorders).

### Atomoxetine

Atomoxetine is a new medication with highly potent and selective activity to block the noradrenergic transporter. It is structurally distinct from both the stimulants and the tricyclic antidepressants and has been studied extensively in both children and adults. Atomoxetine was shown to be effective in reducing both inattentive and hyperactive/impulsive symptoms over a 9-week period in a sample of children and adolescents. Doses of 0.5 mg/kg, 1.2 mg/kg and 1.8 mg/kg were studied. All doses had treatment effects that were different from placebo, with treatment effects seen at the first postmedication treatment visit, but the highest degree of improvement was found in the 1.2 mg/kg and the 1.8 mg/kg groups. The medication also produced change in functional measures as well as ADHD symptoms, with the greatest degree of change in the 1.8 mg/kg group.

Atomoxetine can be administered on either a twice daily or once daily schedule, even though that its half-life in the overwhelming majority of individuals is 4 hours. Despite this fact, therapeutic benefit seems to be maintained over the full day. Adverse effects with atomoxetine have been relatively mild, with decreased appetite and a small increase in pulse and BP being the two most consistent findings. Because it is not a stimulant, and because its effects are highly selective for noradrenaline and not dopamine, atomoxetine is thought not to have abuse potential.

### Tricyclic Antidepressants

The noradrenergic tricyclic antidepressants, principally imipramine and desipramine, have been the most extensively studied and, until the mid-1990s, were the most often prescribed non-stimulant medication for individuals with ADHD. For desipramine, doses between 2.5 and 5 mg/kg/day have been recommended. In the case of both of these medications, cardiac side effects are of concern and premedication work-up must include at least an ECG. Tachycardia and postural hypotension are commonly seen, but are not often problematic. Prolongation of the PR and QT intervals may be a greater source of concern and should be reviewed with a pediatric cardiologist. The decision to prescribe tricyclics for ADHD children must be made with the knowledge that several sudden deaths have been reported in children taking desipramine. Although it has been argued that data do not support the conclusion and that tricyclics have a high degree of cardiovascular toxicity in children, proper informed consent should be obtained. It should also be noted that neither imipramine nor desipramine is FDA approved for the treatment of ADHD children.

## Other Antidepressants

Bupropion and venlafaxine have been studied for their potential utility in the AD-DBDs. Investigations of bupropion in ADHD have demonstrated the effectiveness of the medication compared with placebo, but not as effective as stimulants. In contrast to this latter finding, others have found bupropion to be as effective as methylphenidate.

There are similar but more preliminary data indicating that venlafaxine might be useful for ADHD. Significant improvements in attention, concentration and other cognitive functions have been reported in volunteers. Open label studies of adults with ADHD also found venlafaxine to be effective. The most common side effects reported were nausea and sedation. An open label study in 8- to 17-year-old subjects found significant reductions in impulsivity and hyperactivity as rated by parents.

## Serotonin Reuptake Inhibitors

Although there have been no studies using SSRIs in ADHD and comorbid CD/ODD, these medications are of some interest in light of recent findings implicating serotonergic mechanisms in aggression and reported utility of fluoxetine in treating adults with impulsive aggression. At present, there are no controlled trials to support the efficacy of the SSRIs for the core symptoms of ADHD, and their role in treating comorbid ADHD and CD/ODD is inferential only.

## Alpha-2-adrenergic Agonists

Since the mid-1980s, there has been considerable interest in the use of alpha-2-adrenergic agonists in the treatment of ADHD. Initial studies were conducted with clonidine, but the more specific alpha-2 agent guanfacine has recently been the focus of investigation. The alpha-2 agonists are reportedly most effective in treating symptoms of hyperactivity, impulsivity and aggression in children with ADHD. Effects on attentional symptoms have been less clear, although a recent study found that guanfacine treatment was associated with improved ratings and CPT measures of attention (Scahill *et al.*, 2001). Because of their role in treating overarousal and aggression, the alpha-2 agonists seem ideally suited for use in children with comorbid ODD/CD/aggression. They have been effective in treating ADHD patients who either have diagnosed tic disorders, or are at increased risk of developing them, such as those children with a positive family history of tics. This is particularly important, since as many as 40 to 60% of patients with Tourette's syndrome seen in psychiatric settings have significant behavior problems. Although the alpha-2 agonists may be less effective than stimulants in the treatment of ADHD, they may be particularly useful in individuals whose tics worsen on a stimulant medication. These agonists have also been used in combination with a stimulant. However, there have been safety considerations involving this combination. These are primarily involving the possibility of additive risk of rebound hypertension of alpha-2 agonists with the mild increase in pulse and blood pressure from stimulants.

Clonidine has a gradual onset of action which may be related to the time required for receptor down regulation. The usual dose ranges from 0.05 to 0.3 mg/day, often in a three times a day dosing schedule. One of the advantages is that it can be used to treat the initial insomnia, which sometimes results from late afternoon stimulant. Clonidine is available in both tablet form and a depot skin patch preparation. The latter provides sustained coverage for one week, and may be particularly useful for treating children with ADHD whose behavior is characterized

by a variable pattern of extreme lability, especially in the early morning, before stimulants and oral clonidine take effect. Guanfacine comes only in an oral preparation. Guanfacine tablets are of 1.0 mg strength, so care must be taken not to confuse the different doses for clonidine and guanfacine. Since guanfacine has a somewhat longer half-life than clonidine, it can often be given in a two or three times a day dosing schedule.

The most common side effect of the alpha-2 medications is sedation, although this tends to decrease after several weeks. Dry mouth, nausea and photophobia are among the other adverse effects reported. At high doses, hypotension and dizziness are also possible. The skin patch often causes local pruritic dermatitis. Glucose tolerance may decrease, especially in those at risk for diabetes. It is important carefully to evaluate cardiovascular function when using the alpha-2 agonists, especially when used in combination with stimulants treatment as noted earlier. Additionally, there have been reports of sudden death in three cases treated with the combination of clonidine and methylphenidate, although a review of this situation by the FDA concluded these unfortunate events were not attributable to the combination. However, careful monitoring is required. Since clonidine is not FDA approved for use in ADHD, informed consent should clearly indicate that this is an "off-label" treatment.

## Other Agents

Lithium has been found to be effective in well-designed studies of aggressive children, impulsive-aggressive adolescents and young adult delinquents, although there are some questions regarding the magnitude of effect. Antiepileptic medications have also been used in the treatment of behavior problems characterized by aggressiveness and impulsivity. Carbamazepine is considered an effective treatment for aggression in children, but more recent findings have tempered the initial enthusiasm. Sodium valproate is another antiepileptic shown to be effective in the treatment of chronic temper outbursts and mood. Although valproate has been used for the treatment of aggressive patients for over a decade, very few published reports have used a controlled design.

Neuroleptic medications have also been used in the treatment of the AD-DBDs, principally to treat children with severe behavioral problems characterized by aggression and combativeness. Although older neuroleptics such as chlorpromazine, thioridazine and halperidol are FDA approved for the treatment of severe behavior problems in children, they are infrequently used at present. Recently, there has been more interest in the atypical neuroleptic risperidone. In a double blind placebo controlled study, risperidone was found to be superior to placebo in ameliorating aggression in youths with conduct disorder (Findling *et al.*, 2000).

During the course of the last few years, there has been a remarkable increase in the number of medications that are used in the treatment of ADHD and CD. It is important to keep in mind that the majority of the medications are not approved by the FDA for specific use in ADHD and/or CD and as such their use for these two disorders continues to be "off-label". Less than optimal treatment is likely to result in inadequate or partial improvement, as demonstrated in the community standard group of the multimodal treatment study of children with ADHD (i.e., MTA), which is discussed in more detail below. In order to reduce this variability in treatment practices, recently there have been attempts to develop treatment algorithms. The purpose of such algorithms is to integrate relevant research findings and clinical experience in

the development of medication decision trees. Recently, an expert panel has reported on the development and implementation of an algorithm for the treatment of ADHD and its common comorbid conditions (Pliszka *et al.*, 2000a, 2000b).

### Psychosocial Interventions

Among the systematically studied psychosocial interventions found to be useful are home-based interventions/parent training, classroom-based behavior modifications, social skills training and intensive summer treatment programs. Since family, peer and school interactions are important in the morbidity and maintenance of these disorders, it is important to utilize psychosocial treatments to target each of these areas. In contrast to these more structured techniques, individual play therapy with children is generally ineffective in decreasing problem behaviors of the AD-DBDs.

Behavior therapy (BT) relies primarily on training parents and/or teachers to be the agents of change. The focus is on decreasing the frequency of problematic behaviors and/or increasing the rate of desirable behaviors. Parent management training is one of the most common techniques and consists of group and individual sessions with parents in order to offer psychoeducational intervention and to teach the principles and implementation of behavioral programs. Consultation with classroom teachers to set up parallel behavioral programs in the school is also an important adjunct to this treatment. When effective, some parent-based interventions have resulted in benefits that have generalized for periods of over a year. Among the limitations of this technique are the labor-intensive nature of the interventions, nongeneralizability to nontargeted behaviors, and the fact that effectiveness depends upon the competence and willingness of parents and teachers to carry out the behavioral programs.

Another aspect of BT is contingency management (CM), which is implemented directly with the child in the setting in which the problem behaviors occur. CM programs use both reward procedures and negative consequences, such as time-out and response cost or “punishments”. In some situations, maintenance of appropriate behavior following withdrawal of contingencies is better for a negative consequence than for a reward. Similarly to BT, CM approaches are extremely labor-intensive and questions regarding their generalizability remain.

Cognitive-behavioral approaches (CBT) are based on the premise that the difficulties experienced by children with AD-DBDs are a result of deficient self-control and problem-solving skills, or that changes in these domains of function can override other deficits. Examples of CBT include training in self-monitoring, anger control and self-reinforcement. Study results have been mixed, although some CBT procedures, such as anger control, have shown more consistent success.

Short-term gains from psychosocial interventions are often limited to the period during which the programs are actually in effect. Additional problems in implementation include the unwillingness of many teachers to use behavioral programs and the fact that as many as half the parents discontinue parent training due to their labor-intensive nature. However, it is important to note that in the MTA study, the presence of anxiety (as reported by parents on the DISC interview) moderated the outcome of treatment, such that psychosocial interventions were more efficacious than medication alone in children with ADHD who also had symptoms of anxiety (March *et al.*, 2000).

### The MTA Study

The multimodal treatment study of children with ADHD (MTA) was a landmark multisite clinical trial, conducted at six performance sites across the USA and Canada, that examined the comparative response to 14 months of medication and psychosocial treatments, administered alone or together, in 579 7- to 9-year-old children with combined subtype ADHD. The principal objectives of the study were to determine the relative effectiveness of the three active treatments in comparison to one another, and in comparison with community standard care.

The treatment arms were not individual treatments but rather combinations of treatments, or treatment algorithms. Children treated in the medication arm began with a controlled trial of MPH given three times a day, and, if this was not effective, could go on to receive other treatments, such as DEX or other stimulant or nonstimulant medications. The psychosocial arm consisted of a variety of interventions, including an intense parent behavior management training program which trained parents to use behavioral techniques such as contingency management, ongoing consultation to the classroom teacher, a summer treatment program and a paraprofessional program. In the latter program, an aide was placed in each child's classroom for half day each day for 3 months. The combined treatment was the combination of all medication and psychosocial interventions. Finally, the community standard group received evaluations as part of the study, but was treated by community providers of their own choosing outside the study.

Results of the 14-month intent-to-treat analyses indicated that, for ADHD symptoms, treatments that included medication performed better than other treatments in reducing ADHD symptoms (MTA Cooperative Group, 1999). For nonADHD symptoms, only combined treatment was statistically superior to the community standard care, although it was not different from the medication group. Children with comorbid ADHD and anxiety disorders tended to have a relatively better response to the psychosocial treatment administered alone as compared with those without comorbid anxiety. Medication was as effective in treating comorbid ADHD and anxiety as it was in the group with ADHD only. Lower effectiveness was seen in the community standard group, despite the fact that two-thirds of the community-treated children received medication at some time over the 14-month period of the study.

### Impact of Comorbidity on Treatment

Studies of stimulant treatment have shown that ADHD children with and without aggression respond equally well to MPH treatment in terms of ADHD symptoms. Research examining whether aggression in ADHD children can be treated with psychostimulants has mainly yielded positive findings. Finally, one study found that some covert, nonaggressive symptoms (e.g., stealing) were also decreased in ADHD children (independent of comorbidity) following treatment with MPH (Hinshaw *et al.*, 1992). Treatment of comorbid ADHD and CD/ODD in the MTA study was superior when medication was used, although the best outcome was seen with combined treatment (Jensen *et al.*, 2001).

While it is now clear that stimulant treatment can improve performance on a wide array of cognitive measures, treatment of comorbid learning disabilities requires direct, nonpharmacological, academic interventions. There has been some concern regarding the possible dissociation of cognitive and behavioral effects of stimulant medication. One landmark study found

that optimal cognitive performance was achieved at low doses (i.e., 0.3 mg/kg) while optimal behavioral function was achieved at high doses (i.e., 1.0 mg/kg), with an accompanying decline in cognitive function at the higher dose (Sprague and Sleator, 1977). However, other investigators have reported a linear rather than a curvilinear dose-response curve for both behavioral and cognitive functions and have therefore not supported the previously hypothesized “cognitive toxicity”.

In contrast to studies in children with ADHD who are aggressive, studies of stimulant response in ADHD children with comorbid anxiety have produced somewhat inconsistent findings. Recent studies have found that medication is equally effective in comorbid ADHD and anxiety disorders. Other studies have found that children with ADHD and anxiety respond as well as those without comorbid anxiety to the antidepressant DMI (Biederman *et al.*, 1993).

## Conclusion

The AD-DBDs are a group of disorders that together account for the majority of referrals to child and adolescent psychiatry services. They represent a significant public health problem in terms of morbidity, and have substantial risk for poor outcome in adolescence and adulthood. In recent years, there has been considerable progress in more precisely elucidating the clinical presentation as well as the genetic and neurobiological bases of these disorders. One important confound that has made these endeavors difficult has been the frequency and variety of comorbid conditions and the potential impact of comorbidity on natural history and treatment response. A variety of pharmacological and psychosocial interventions have been found to provide success over the short term, and increasingly data indicate that treatment effects can be maintained over more extended periods of time. This is an important finding because successful treatment of the AD-DBDs often requires long-term treatment using multiple modalities.

## Comparison of DSM-IV/ICD-10 Diagnostic Criteria

For attention-deficit/hyperactivity disorder, the item set chosen for the ICD-10 Diagnostic Criteria for Research is almost identical to the items in the DSM-IV-TR criteria set but the algorithm is quite different resulting in a more narrowly defined ICD-10 category. Specifically, whereas the DSM-IV-TR algorithm requires either six inattention items or six hyperactive/impulsive items, the ICD-10 Diagnostic Criteria for Research requires at least six inattention items, at least three hyperactive items, and at least one impulsive item. Instead of subtyping the disorder based on the predominant type, ICD-10 subspecifies the condition based on whether criteria are also met for a conduct disorder.

Although formatted quite differently, the DSM-IV-TR and ICD-10 item sets and diagnostic algorithms for Conduct Disorder are almost identical. Although ICD-10 provides a list of 23 items (in contrast to the 15 included in the DSM-IV-TR criteria for conduct disorder), only the last 15 items count towards a diagnosis of conduct disorder. Although the first eight items on the conduct disorder list are identical to the DSM-IV-TR items for oppositional disorder, ICD-10 oppositional defiant disorder can be considerably more severe because up to two of the items can be drawn from the 15 items that comprise the conduct disorder item set.

# Childhood Disorders: Feeding and Other Disorders of Infancy or Early Childhood

In the literature, the term “feeding disorder” generally encompasses a variety of conditions ranging from problem behaviors during feeding – poor appetite, food refusal, food selectivity, food avoidance, and pica to rumination and vomiting – and is generally used to emphasize the dyadic nature of eating problems in infants and young children. Feeding disorder cannot be attributed to a medical condition and appears most often during the first year of life and before the age of six. Its hallmarks are the failure to eat with resultant inability to gain weight or a significant weight loss for at least one month.

Some authors have used various diagnostic methods and assigned different labels to address the heterogeneity of feeding problems associated with failure to thrive. The pediatric literature has focused primarily on failure to thrive as a diagnostic label. The term “failure to thrive” describes infants and young children who demonstrate failure in physical growth, often associated with delay of social and motor development.

Because of the diversity of feeding disorders associated with failure to thrive and the lack of a subclassification of feeding disorder as defined in DSM-IV-TR, Chatoor proposed a classification of feeding disorders based on the definition of psychiatric disorders. A psychiatric disorder has three properties: it is a limited syndrome with possible links to etiological and pathophysiological factors; the use of treatment depends on proper diagnosis; and the diagnosis is linked to prognosis. Considering these criteria, five different feeding disorders will be described. The first three feeding disorders are associated with various developmental stages. In addition, two feeding disorders are described that are not linked to specific developmental stages: 1) sensory food aversions, a common feeding disorder which becomes evident during the introduction of different milks, baby food, or table food with various tastes and consistencies, and 2) post traumatic feeding disorder, which is characterized by an acute disruption in the regulation of eating and can occur at various ages and stages of feeding development.

## Epidemiology

It is estimated that up to 25% of otherwise normally developing infants and up to 80% of those with developmental handicaps have feeding problems including food refusal, eating “too little” or “too much”, restricted food preferences, delay in self-feeding, objectionable mealtime behaviors and bizarre food habits. It has also been reported that 1 to 2% of infants under 1 year of age demonstrate severe food refusal and poor growth.

## Course and Natural History

Those infants who at 3 to 12 months of age are identified for refusal to eat for at least 4 weeks with no apparent medical cause have significantly more problems in eating patterns, behavior and growth, and are more susceptible to infection at 2 and 4 years of age. A study by Marchi and Cohen (1990), who observed a sample of more than 800 children for a 10-year period from early childhood to late childhood–adolescence, found that feeding problems in young children were stable over time. They reported that gastrointestinal symptoms and picky eating during early childhood correlated with anorectic behavior during adolescence, while problem behaviors during mealtime and pica early in life were associated with bulimia nervosa during the adolescent years.

## Etiology

Hampering our understanding of the etiology, symptoms and treatment of specific feeding disorders are the lack of a standard classification, overlap between feeding disorders and failure to thrive, and the tendency of investigators to address different aspects of the disorders while using differing criteria and methodologies. To clarify the specificity in etiology and its implication for treatment, each feeding disorder as defined by Chatoor and colleagues (1985) is discussed separately.

## Diagnosis

The diagnostic assessment of feeding disorders should include assessment of the infant’s temperament characteristics; the infant’s medical, developmental and feeding history; the caretaker’s psychological functioning and past history, socioeconomic background, stressors and social support system; and the relationship of the infant and his or her primary caretakers during feeding and play.

## Treatment

Treatment begins with the first contact with the infant and his or her caregivers. The establishment of a therapeutic alliance with the caregivers is critical to any successful treatment. The diagnostic evaluation needs to identify the specific dynamics of each feeding disorder in order to develop a specific treatment plan. This is discussed in more detail for each feeding disorder.

## Feeding Disorder of State Regulation

### Diagnostic Criteria

- A. Has difficulty reaching and maintaining a calm state of alertness for feeding; is either too sleepy or too agitated and/or distressed to feed.
- B. The feeding difficulties start in the newborn period.
- C. Shows significant failure to gain weight or exhibits weight loss.

### Epidemiology

The most frequently used label in the pediatric literature for excessive crying in young infants is colic, which is reported to

occur at rates varying from 5 to 19%. Colic is usually defined as crying for more than 3 hours per day, and frequently colic is associated with feeding difficulties during the crying periods. However, a feeding disorder of state regulation should be considered only in more severe cases of colic when it is associated with growth failure.

### Etiology

Both infant and maternal characteristics appear to contribute to the difficulties in the regulation of feeding. After birth, the infant needs to establish regular rhythms of sleep and wakefulness, and of feeding and elimination. In order to feed successfully, the infant needs to reach a state of calm alertness. However, some infants may be too irritable or too difficult to awaken for feedings.

---

### Clinical Vignette 1

Jeff is a 3-month-old baby who was brought into the hospital by his 17-year-old mother and his grandmother because of feeding difficulties and lack of appropriate weight gain starting at birth. On physical examination, he appeared weak and had poor muscle tone but otherwise had no signs of physical illness. His weight was 6 pounds and 9 ounces, which was only 4 ounces above birth weight. The history revealed that Jeff's mother had an uncomplicated pregnancy and delivery. She was a senior in high school and had missed only a few weeks of school before the delivery of Jeff and 6 weeks thereafter. The mother and her three younger siblings lived with their mother. The father of the infant and the father of the mother were out of the picture. The mother and the grandmother shared taking care of Jeff. They reported that, at times, Jeff would be irritable and difficult to calm for feedings. At other times, particularly in recent weeks, he would be so sleepy that it was difficult to waken him enough to feed. Both mother and grandmother appeared distressed about Jeff's feeding difficulties.

The mother admitted that the pregnancy with Jeff was unplanned and that she broke up with Jeff's father soon after she found out that she was pregnant. She had felt anxious throughout the pregnancy because she worried about the baby's future and her own. When she returned to school several weeks ago, she had difficulty concentrating and had done poorly on her grades. In recent weeks, she had difficulty sleeping at night, had felt weak during the day, had been eating poorly and had lost some weight herself. Despite having a good relationship with her mother, she felt lonely and isolated from her peers.

Mother–infant interactions during feeding revealed a sad young mother who gently tried to awaken her lethargic infant by rubbing his hands and feet. When unsuccessful, she held his little body upright. This resulted in the infant's head dropping backward abruptly. He was startled and cried loudly. When the mother successfully calmed the infant, he went right back to sleep without drinking from the bottle. The mother looked despondent and helpless.

### Diagnostic Impression

It appeared that the infant's difficulty in regulating his state, being either too irritable to calm for feedings or too lethargic to awaken for feedings, together with the mother's anxiety and inexperience had resulted in a vicious cycle, leading to increasing depression in the mother and a severe feeding disorder of state regulation in the infant.

### Treatment

Because of his poor nutritional state and his lethargy, Jeff was hospitalized. For a few days, he was given nasogastric tube feedings to supplement his poor oral intake. He was assigned a primary care nurse who was experienced in feeding babies. She would take him into a quiet room on the unit for feedings and gradually increase the physical stimulation to arouse him enough to be interested in drinking from the bottle. If she moved too quickly, he would start to cry and could not be fed. After a week of increasingly successful feedings, both the mother and the grandmother were invited to observe the feedings and were later coached by the nurse to take over the feedings themselves.

At the same time, while the nurse was working with Jeff, a psychiatric resident met regularly with the mother to address her feelings of anxiety and depression. Because of the severity of her depression, the mother was prescribed an antidepressant to which she responded well. When the mother began to sleep better and Jeff became more lively and responsive, she was able to deal with him more effectively. She enjoyed the positive reinforcement by the nurse, who tutored her in how to stimulate Jeff to reach a state of calm alertness that allowed him to feed successfully.

After 3 weeks, both mother and infant had made sufficient gains to be discharged from the hospital. Back at their home, Jeff and his mother were visited weekly by a home care nurse and the mother continued in psychotherapy and pharmacotherapy with the psychiatric resident for the next 7 months. Jeff developed into an engaging little boy who continued to be vulnerable to changes in his caretaking environment, manifested by irritability and poor feeding. His mother recovered from her depression and graduated successfully from high school.

Other infants may tire quickly or become distracted during feeding and terminate feedings without taking in adequate amounts of milk to grow. Some mothers learn to compensate for these vulnerabilities by adjusting the environment and the degree of stimulation of the infant during feeding. However, other mothers become anxious, fatigued, or depressed, and consequently they inadvertently intensify the feeding difficulties of their infants.

## Diagnosis

Young infants who present with feeding difficulties and growth failure dating to the postnatal period need to be considered for the diagnosis of a feeding disorder of state regulation. The evaluation should begin by obtaining a history of the mother's pregnancy and delivery and a report of the infant's history of feeding, development and medical illnesses that might contribute to the feeding problems. In addition, the mother's functioning and her social support system need to be explored. Most important, the mother and her infant should be observed during feeding and during play to assess the infant's special characteristics, the infant's regulation of state and feeding behavior, and the mother's ability to read the infant's signals and to respond to them in a contingent way.

## Course and Natural History

During the first few months of life, the foundation for the regulation of feeding, sleep and emotions is laid. Infants with feeding problems during these early months usually trigger anxiety in their mothers and tend to have difficulties in self-regulation during the transition to self-feeding in the second year of life.

## Treatment

Treatment can be directed toward the infant, toward the mother, and toward the mother–infant interaction. In severe cases, if the infant's growth is seriously impaired, nasogastric tube feeding might have to be used to supplement oral feedings in an infant who tires quickly. This will allow an anxious mother to relax because her infant is receiving adequate nutrition to grow. Subsequently, a more relaxed mother can tune into her infant more readily and break the cycle of dyadic escalation of tension during feedings.

On the other hand, the intervention might have to be directed primarily toward the mother to treat her anxiety, fatigue, or depression to enable her to be more effective in dealing with her infant. In addition, most mothers can be helped by assisting them in problem solving in how to facilitate a feeding environment that provides the optimal amount of stimulation for their vulnerable infants. Videotaping the feeding and observing the tape together with the mother can heighten her awareness of the infant's reactions during feeding and enhance her ability to read the infant's cues. The therapist can then engage the mother in a dialogue on how to respond to the infant's cues most effectively.

## Feeding Disorder of Poor Care Giver–Infant Reciprocity

### Diagnostic Criteria

- A. Shows a lack of developmentally appropriate signs of social reciprocity (e.g., visual engagement, smiling, or babbling) with the primary caregiver during feeding.
- B. Onset under 1 year of age.
- C. Shows significant growth deficiency.

- D. The growth deficiency and lack of engagement with the primary caregiver are not due solely to a physical disorder, or a pervasive developmental disorder.

This feeding disorder has been referred to in the early literature as maternal deprivation, deprivation dwarfism and psychosocial deprivation. The growth failure and developmental delay of these infants were considered a consequence of a continuum of neglect and/or maltreatment of the child leading to insecure attachment to the caregiver.

## Epidemiology

It is difficult to assess how commonly this feeding disorder occurs. However, there appears to be an increased prevalence of cases in the lower socioeconomic classes, as noted by Chatoor and colleagues (1997).

## Etiology

Much has been written about mothers whose infants fail to thrive and appear to have a disorder of reciprocity. They are frequently described as suffering from character disorder, affective illness, alcohol abuse and drug abuse. Early research suggested that the highest risk exists when the mother's needs take precedence over those of the infant, and that difficulties of these mothers in nurturing their infants stem from the unmet needs of the mothers during their own childhood.

Family problems and distressed marital relationships have been reported in a number of noncontrolled and controlled studies of failure to thrive. In addition, socially adverse living conditions, poverty and unemployment are reported to be more prevalent in these families of infants with failure to thrive.

Between 45 to 93% of the infants with failure to thrive are insecurely attached. Mothers of infants with failure to thrive are more likely to be classified as insecurely attached to their own parents, as measured by the Adult Attachment Interview (Main and Goldwyn, 1991).

The growth failure of these infants with poor caregiver–infant reciprocity appears to be a critical manifestation of a failed relationship between a mother and her infant during the first year of life, when the foundation for mutual engagement and attachment is usually laid. A transgenerational pattern of insecure attachment appears to be at the root of the mother's difficulty to engage with her infant and leads to a lack of emotional and physical nurturance of the infant.

## Diagnosis

Most of these infants are not brought for pediatric well-baby care but present to the emergency department because of an acute illness, when their poor nutritional state draws the attention of pediatricians. Because of their severe failure to thrive, these infants frequently require hospitalization. During the hospitalization, the psychiatric consultant is usually called in to assist in the diagnosis and treatment of the infant's growth and developmental problems. The evaluation should include an assessment of the infant's feeding, developmental and health history, including any changes in the infant's behavior during the hospitalization. In addition, the mother's pregnancy, delivery, family situation and social support need to be thoroughly explored. A mental status examination of the mother should be performed to rule out severe psychiatric illness, particularly whether she suffers from depression or is abusing alcohol or drugs.

Many of these mothers are elusive and avoidant of any contact with professionals. Consequently, the observation of

mother–infant interactions may have to be obtained indirectly, through the report of other professionals who admitted the infant to the hospital.

Infants with feeding disorders of poor mother–infant reciprocity characteristically feed poorly, avoid eye contact and are weak in the first few days of hospitalization. When picked up, they might scissor their legs and hold up their arms in a surrender posture to balance their heads, which seem too heavy for their little weak bodies. They usually do not cuddle like healthy well-fed infants, rather they keep their legs drawn up or appear hypotonic, like rag dolls. However, these infants appear to blossom under the tender care of a primary care nurse who engages with them during feeding and plays with them. They become increasingly responsive, begin to smile, feed hungrily and gain weight. These striking changes in behavior of these young infants when they are fed and attended to by a nurturing caretaker are characteristic of a feeding disorder of poor mother–infant reciprocity and differentiate these infants from infants with organic problems that have resulted in growth failure and developmental delays.

### Course and Natural History

Because of an inconsistent definition of failure to thrive, it is not clear whether all of these infants suffered from a feeding disorder of poor mother–infant reciprocity. In general, nonorganic failure to thrive during infancy has been associated with later cognitive and behavioral problems. Hufton and Oates (1977) reported that of 21 children who had been diagnosed with nonorganic failure to thrive during infancy, at the age of 6 years, half of the children had abnormal personalities and two-thirds had a delayed reading age.

### Treatment

Various treatment approaches have been proposed, ranging from home-based interventions to hospitalization in severe cases. Because of the complexity of the issues involved in the etiology of nonorganic failure to thrive, most psychiatrists and researchers suggest that multiple and case-specific interventions may be required. An outpatient approach appears to be safe in cases of mild neglect when there is no evidence of deprivational behavior on the part of the mother, the infant is older than 12 months, and the parents have a support system and have sought medical care for previous sickness. Immediate hospitalization of young infants with neglectful failure to thrive is indicated if it is associated with non-accidental trauma; if the degree of failure to thrive is considered severe; if there is serious hygiene neglect; if the mother appears severely disturbed, abusing drugs or alcohol; if the mother lives in a chaotic lifestyle and appears overwhelmed with stresses; or if the mother–infant interaction appears angry and uncaring.

During the hospitalization it is most important to assign a primary care nurse who can be warm and nurturing to woo the infant into a mutual relationship. Improvement of the infant's health and affective availability can then be used to engage the mother with her infant and in the treatment process. Recovery from growth failure does not indicate that the parent–child relationship is adequate. The mother's ability to engage her infant and to participate in the treatment process has to be at the core of the treatment plan. The degree of parental awareness and cooperation is predictive of outcome for failure to thrive.

Because these mothers frequently present with a variety of psychological and social disturbances, their problems need to be explored while nutritional, emotional and developmental rehabilitation goes on with the infant. It is important to look for and identify any positive behavior a mother shows toward her

infant and to use it as a building block to bolster her competence and interest in her infant. Nurturance of the mother is the first critical step in the treatment to facilitate her potential to nurture her infant. Moreover, the family can serve as a stress-buffering or stress-producing system. The hospitalization of the infant provides a critical time to assess whether the infant needs to be placed in alternative care. In some situations of severe neglect or associated abuse, the case needs to be reported to protective services, which at times can be instrumental in mobilizing the family or in finding foster care.

Discharge from the hospital is a critical time when all services need to be in place to ensure appropriate follow-through of the treatment plan for these vulnerable infants. For some infants, daycare in a nurturing environment will give the mother an opportunity to pursue some of her own interests and needs as well as to make the time with her infant more special and enjoyable. Visits by a home care nurse or regular treatment sessions in the home by a social worker are some of the alternatives to consider because many of these mothers struggle with coming to therapy in an office setting. Because of the complexity of the problems involved in the etiology of this feeding disorder, a flexible multidisciplinary approach that is coordinated by the primary therapist is usually most effective.

## Infantile Anorexia

### Diagnostic Criteria

- A. Refusal to eat adequate amounts of food for at least 1 month.
- B. Onset of the food refusal under 3 years of age, most commonly during the transition to spoon- and self-feeding.
- C. Does not communicate hunger signals, lacks interest in food, but shows strong interest in exploration and/or interaction with caregiver.
- D. Shows significant growth deficiency.
- E. The food refusal did not follow a traumatic event.
- F. The food refusal is not due to an underlying medical illness.

### Epidemiology

A study from Sweden reported that 1 to 2% of infants younger than 1 year of age had severe feeding problems associated with refusal to eat or vomiting, resulting in poor weight gain. At 4 years, 71% of those with food refusal were reported by their parents as still having feeding problems (Dahl and Sundelin, 1992). The disorder seems to be equally as common among boys and girls of all racial backgrounds and appears most commonly in the middle and upper middle class.

### Etiology

Chatoor and colleagues (2000) tested a transactional model for the understanding of infantile anorexia by which certain characteristics of the infant combine with certain vulnerabilities in the mother to bring out negative responses and conflict in their interactions. They also found that infants with infantile anorexia were rated higher by their mothers on temperament difficulty, irregularity of feeding and sleeping patterns, negativity, dependence and unstoppable behaviors than were healthy eaters. The mothers of children with infantile anorexia were found to demonstrate more attachment insecurity to their own parents. The mothers' attachment insecurity frequently stemmed from extremes of pa-

rental discipline in the form of parental over control or emotional unavailability while they were growing up. The infants' temperament characteristics, their mothers' insecure attachment to their own parents, and the mothers' drive to be thin themselves correlated significantly with mother–infant conflict during feeding.

It is helpful to look at infantile anorexia from a developmental perspective. Between 9 and 18 months of age, the general developmental task of separation and individuation takes on special significance in the feeding relationship. Issues of autonomy versus dependency must be worked out in the dyad, particularly during the transition to self-feeding. If the mother is able to read the infant's signals correctly and responds contingently, the infant will learn to differentiate physiological feelings of hunger and fullness from emotional experiences such as anger, frustration, or the wish for attention. In this case, the infant's food intake will be internally regulated through physiological cues of hunger and satiety. On the other hand, if the mother is insecure in how to interpret the infant's cues and responds in a noncontingent way, the infant will learn to associate feeding with negative or positive emotional experiences. Consequently, infants who are irregular and whose cues are difficult to read, and mothers who are insecure in how to interpret their infants' cues and respond in an inconsistent and noncontingent way, will develop conflict during feeding, and the infant will fail to develop internal regulation of eating.

## Diagnosis

Infants with this feeding disorder are usually referred for a psychiatric evaluation due to food refusal and growth failure. The infants' food refusal usually becomes of concern between 6 months and 3 years, most commonly between 9 and 18 months of age, during the transition to spoon- and self-feeding. However, some parents report that even during the first few months of life, these infants were easily distracted by external stimuli and became disinterested in feeding. Then, the mothers were able to compensate for the infants' poor feeding by feeding them more frequently. However, by the end of the first year when infants are transitioned to spoon- and self-feeding, these infants take only a few bites and want to get out of the high chair to play. Most parents report that these infants hardly show any signals of hunger and seem more interested in exploring and playing than eating. Usually, the parents become increasingly worried about their infants' poor food intake and try to increase their infants' eating by coaxing, distracting, offering different food, feeding during play, feeding at night, threatening and even force-feeding their infants. However, most parents report that these methods worked only temporarily, if at all, and that their infants continued to eat poorly in spite of all their efforts.

The diagnostic evaluation of this feeding disorder should include the infant's feeding, developmental and health history, and the observation of mother and infant during feeding. In addition to the infant's history, the mother's perception of her infant's temperament, her family situation, her childhood background, and her own eating habits and attitude toward limit setting need to be explored.

## Course and Natural History

Initially, infants with this feeding disorder fail to gain adequate weight. After several weeks or months of poor food intake, their linear growth slows down and they develop chronic malnutrition. In most cases their heads continue to grow at a normal rate. As the children grow older, their bodies appear small and thin, but

their head size and brain development appear to progress at a normal rate.

## Treatment

The psychotherapeutic intervention is based on the developmental psychopathological model of infantile anorexia as outlined in the section on etiology. The major goal of the intervention is to “facilitate internal regulation of eating” by the infant. The intervention consists of three components:

1. Assess and then explain the infant's special temperamental characteristics and developmental conflicts to the mother to help her understand the lack of expected hunger cues and the infant's struggle for control during the feeding situation.
2. Explore the mother's upbringing and the effect it has had on the parenting of her infant to help the mother understand her conflicts and difficulties in regard to limit setting.
3. Explain the concept of internal versus external regulation of eating. Help the mother to develop mealtime routines that facilitate the infant's awareness of hunger, leading to internal regulation of eating, improved food intake and growth. In addition, coach the parents to set limits to the infant's behaviors that interfere with eating. These feeding guidelines include:
  - a. Schedule meals and snacks at regular 3- to 4-hour intervals and do not allow the infant to snack or drink from the bottle or breast in between.
  - b. Limit meal duration to 30 minutes.
  - c. Praise the infant for self-feeding but stay emotionally neutral whether the infant eats little or a lot.
  - d. Do not use distracting toys or television during feedings.
  - e. Eliminate desserts or sweets as a reward at the end of the meal; rather integrate them into regular meals and snacks.
  - f. Put the infant in “time-out” for inappropriate behaviors during feeding (e.g., throwing the spoon or food, climbing out of the high chair).

These three steps in the treatment are best accomplished in three sessions lasting 2 to 3 hours each and grouped close together within a 2- to 3-week period. The intensity of this brief intervention facilitates a close therapeutic alliance between the therapist and the mother and gives the mother the opportunity to experience the support she needs to make major changes in her interactions with her infant.

Giving the mother the choice as to who in the family (or anyone else) should be included in the therapeutic process, and at what point, is part of putting the mother in control. Because many of these mothers have felt helpless as children and ineffective as parents, the empowerment of the mother is critical to the success of the treatment.

## Sensory Food Aversions

### Diagnostic Criteria

- A. Consistently refuses to eat specific foods with specific tastes, textures, and/or smells.
- B. Onset of the food refusal during the introduction of a different type of food (different milk, different baby food, or different table food).
- C. Eats without difficulty when offered preferred foods.
- D. The food refusal has resulted in specific nutritional deficiencies and/or delay in oral motor development.

## Epidemiology

Sensory food aversions are a common problem among toddlers. A survey of 1523 parents of toddlers ranging in age from 12 to 36 months found that 20% of the parents indicated that their toddlers were eating only a few types of food “often” or “always”, and 6% of the same parents were indicating that they worried “often” or “always” that their children were not eating enough to grow.

## Etiology

Several studies indicate that genetic predisposition as well as environment affect toddlers’ food preferences, though empirical studies have not explored the origins of selective food refusal in infants and toddlers. Some individuals avoid particular foods because they find their taste and/or odor too aversive. Parents with extreme taste sensitivities may offer a restricted range of foods to their children and model eating only certain foods that they like. Limited exposure to a variety of foods may enhance the toddlers’ food selectivity.

## Diagnosis

Sensory food aversions occur along a spectrum of severity. Some children refuse to eat only a few types of food, making it possible for the parents to accommodate the child’s food preferences. Others may refuse most foods, disrupt family meals and cause serious parental concern about the children’s nutrition. The diagnosis of a feeding disorder should only be made if the food selectivity results in nutritional deficiencies, and/or has led to oral motor delay.

Sensory food aversions become apparent when infants are introduced to a different milk, to baby food, or to table food with a variety of tastes and textures. Usually, when foods that are aversive to the infant are placed in the infant’s mouth, the infant’s reactions range from grimacing to gagging, vomiting, or spitting out the food. After an initial aversive reaction, the infants usually refuse to continue eating that particular food, becoming distressed if forced to do so, and may generalize their reluctance to eat one food to other foods with similar characteristics.

If infants refuse many foods or whole food groups, their limited diet may lead to specific nutritional deficiencies, and they will experience delay in their oral motor development due to lack of practice with chewing. In addition, the children’s refusal to eat a variety of foods frequently leads to family conflict at mealtime, and puts a strain on the child and the family in social situations outside the home.

The evaluation of infants and young children with sensory food aversions should address how many foods the child consistently refuses and how many foods he/she usually accepts. A nutritional assessment needs to look not only at the anthropometric measures of the child to rule out acute and/or chronic malnutrition, but needs to address whether the child may lack adequate intake of vitamins, zinc, iron and/or protein. In addition, an oral motor assessment needs to determine whether the child has fallen behind in this area of development. Delayed oral motor development will limit the kind of foods the child should be offered in order to prevent choking, and may be associated with a delay in speech development. In addition, the parents’ food preferences during childhood and adulthood should be explored to assess whether the parents may be limited in the variety of foods they offer their child. Additional, nonfood hypersensitivities should also be explored.

## Course and Natural History

No longitudinal data are available outlining the course of this feeding disorder. Sensory food aversions begin to show in about 10% of toddlers between 12 and 18 months of age, but then increase to 20% and stay around that frequency until 3 years of age. Older children with sensory food aversions may experience social anxiety when their peers become aware that they eat only certain foods, and some children avoid social situations that include eating.

## Treatment

In young infants (4–7 months of age), a few repeated exposures to new foods enhance the infants’ acceptance not only of that food but also of other similar foods. However, this changes in the second year of life, when the acceptance of new foods only increased significantly after 10 or more exposures to those same foods. It appears that novel flavors become more preferred after repeated pairing with high caloric carbohydrates versus low caloric carbohydrates.

It is useful to introduce a variety of foods during the first year of life when infants in general are less discriminating in their food preferences. However, if infants show strong aversive reactions (e.g., gagging or vomiting) early on when offered a certain food, it is advisable to give up on that particular food and not offer it again. If the infant shows a less severe reaction (e.g., grimaces or wants to spit out a new food) it is also best to stop offering the new food during that feeding, but introduce it again after a few days in a small amount and paired with some other food that the infant likes, increasing the amounts of the new food very gradually until the infant appears comfortable with it.

For toddlers, the challenge remains how to keep them interested in trying new foods after they have had aversive experiences with some foods. Coercive techniques, for example, threatening children to sit at the table until they finish eating everything on their plate or depriving them of certain privileges, have a significant negative effect. On the other hand, toddlers are very responsive to modeling by their parents. Toddlers are more willing to try a new food if they can observe their parents eating it without being offered. If they ask for their parents’ food, it is best to give them only a small amount while saying that they can have more if they like the food. If the parents stay neutral as to whether the toddler likes the food or not, toddlers remain neutral as well and do not appear to become scared of trying new foods. However, once children fear to try new foods, their diet becomes more and more limited and, by 3 years of age, most young children are not swayed by what their parents eat. Some young children like to imitate their peers and may be willing to eat new foods in a preschool setting; however, others become anxious in social situations and try to avoid eating with others.

## Post Traumatic Feeding Disorder

### Diagnostic Criteria

- A. Food refusal follows a traumatic event or repeated traumatic insults to the oropharynx or gastrointestinal tract (e.g., choking, severe vomiting, reflux, insertion of nasogastric or endotracheal tubes, suctioning) that trigger intense distress in the infant.

- B. Consistent refusal to eat manifests in one of the following ways:
1. Refuses to drink from the bottle, but may accept food offered by spoon (although consistently refuses to drink from the bottle when awake, may drink from the bottle when sleepy or asleep).
  2. Refuses solid food, but may accept the bottle.
  3. Refuses all oral feedings.
- C. Reminders of the traumatic event(s) cause distress as manifested by one or more of the following:
1. Shows anticipatory distress when positioned for feeding.
  2. Shows intense resistance when approached with bottle or food.
  3. Shows intense resistance to swallow food placed in the infant's mouth.
- D. The food refusal poses an acute or long-term threat to the child's nutrition.

### Epidemiology

Although no studies on the prevalence of this disorder are available, it appears that the occurrence of this feeding disorder has been increasing because of the growing number of infants with complex medical problems who survive.

### Etiology

Although it is difficult to say what the inner experience of a young infant might be, the affective and behavioral expressions of infants provide a window to their inner life. In a study of infants diagnosed with post traumatic feeding disorder, also including a control group of healthy eaters and a group of anorectic infants matched by age, sex, race and socioeconomic background, conflict in mother–infant interactions during feeding was present in both feeding-disordered groups. However, only those subjects with a post traumatic feeding disorder demonstrated intense preoral and intraoral feeding resistance. They appeared distressed, cried and pushed the food away in anticipation of being fed, and kept solid food in their cheeks or spat it out if the mothers were able to place any food in their mouths. The mothers usually reported that these defensive behaviors started abruptly after the infant experienced severe vomiting, gagging, or choking or underwent invasive manipulation of the oropharynx (e.g., insertion of feeding and endotracheal tubes or vigorous suctioning).

### Diagnosis and Differential Diagnosis

This feeding disorder is characterized by the infant's consistent refusal either to drink from the bottle or to eat any solid foods, and in most severe cases, by the infant's refusal to eat at all. Depending on the mode of feeding that the infants appear to associate with the traumatic event(s), some refuse to eat solids, but will continue to drink from the bottle, whereas others may refuse to drink from the bottle, but are willing to eat solids. Some infants may put baby food in their mouths, but then spit out any food that has any little lumps in it. Most infants get stuck in these food patterns and may lose weight or lack certain nutrients because of their limited diet.

Reminders of the traumatic event(s) (e.g., the bottle, the bib, or the high chair) may cause intense distress for some infants, whereby they become fearful when they are positioned for feedings and/or presented with feeding utensils and food. They resist being fed by crying, arching and refusing to open their mouths. If food is placed in their mouths, they intensely resist swallowing.

They may gag or vomit, let the food drop out, actively spit the food out, or store the food in their cheeks and spit it out later. The fear of eating seems to override any awareness of hunger. Therefore, infants who refuse all foods, including liquids and solids, require acute intervention due to dehydration and starvation.

In addition to a thorough history about the onset of the infant's food refusal and the medical and developmental history, the observation of the infant and mother during feeding is critical for understanding this feeding disorder and differentiating it from infantile anorexia and from sensory food aversions. It is helpful to ask the mother to bring a variety of foods, including those that the infant refuses and those that he or she accepts. Infants with a post traumatic feeding disorder characteristically appear engaged and comfortable with their mothers as long as the feared food is out of sight. Some infants begin to show distress when they are placed in the high chair and they struggle to get away. In less severe cases, the infant might allow the food to go into the mouth but then spit it out and show distress only when urged to swallow. This anticipatory fear of food differentiates infants with a post traumatic feeding disorder from anorectic infants, whose food refusal appears random and related to issues of control in the relationship with the mothers. Toddlers with sensory aversions to certain types of food might also show distress when urged to eat these foods. However, their mothers do not remember a traumatic event that seemed to trigger the food refusal behaviors.

### Course and Natural History

Most infants seem to get locked into their food refusal patterns. The more anxiously the parents react to the infant's food refusal, the more anxious the infants appear to become, with the parent and the infant feeding off each other's anxiety. Individual case studies indicate that some of these infants depend for years on gastrostomy feedings to survive. Others may live on milk and puréed food until school age, when the social embarrassment of their eating behavior urges the parents to seek help.

### Treatment

Because of the complexity of many of these cases, a multidisciplinary team (consisting of a pediatrician or gastroenterologist, a psychiatrist or psychologist, a social worker, an occupational therapist or hearing and speech specialist, a nutritionist and a specially trained nurse to serve as team coordinators) is best equipped to meet all the needs of these infants and their parents.

Before any psychiatric treatment can be successfully initiated, the medical and nutritional needs of the infant need to be addressed. In severe cases of total food refusal, it is important to act quickly to maintain the infant's hydration. The medical and psychiatric team members must work together to assess whether temporary nasogastric tube feedings are indicated or whether plans for a gastrostomy should be made. Unfortunately, the repeated insertion of nasogastric feeding tubes can intensify a post traumatic feeding disorder, and an infant in a labile medical condition can take months if not years to recover.

The psychiatric treatment of this feeding disorder involves a desensitization of the infant to overcome the anticipatory anxiety about eating and return to internal regulation of eating in response to hunger and satiety. It is most important to help the parents understand the dynamics of a post traumatic feeding disorder so that they can recognize the infant's anticipatory anxiety and become active participants in the treatment. After identification of triggers of anticipatory anxiety (e.g., the sight of the high chair, the bottle, or certain types of food), a desensitization by gradual

exposure can be initiated or a more rapid desensitization through more intensive behavioral techniques can be implemented.

With both techniques, it is important to have a professional assess the infant’s oral motor coordination because many infants who refuse to eat for extended periods fall behind in their oral motor development due to lack of practice. The rapid introduction of table food to a child who has delayed oral motor skills may lead to choking, thereby creating a setback to the desensitization process.

During the desensitization process, the infant has to be reinforced for swallowing the food. This behavioral manipulation of the infant’s eating frequently leads to external regulation of eating in response to the reinforcers. Once the infant has become comfortable with eating, it is important to phase out these external reinforcers to allow the infant to regain internal regulation of eating in response to hunger and fullness. This can be a difficult transition because many infants gain control over their parent’s emotions by eating or not eating. The techniques described under infantile anorexia – the implementation of the feeding guidelines contained in step 3 – can be helpful in making this transition.

As summarized in Figure 29.1, each of these five feeding disorders presents with specific symptom patterns and characteristic mother–infant interactions, which help to diagnose and differentiate the various feeding disorders. The correct diagnosis is critical because a treatment that is helpful for one feeding disorder may be ineffective or even worsen another feeding disorder. For example, infants with infantile anorexia become more aware of their hunger cues and feed better if fed only every

4 hours without being offered food or liquids in between meals. However, an infant with post traumatic feeding disorder who is afraid of eating will not accept food regardless of how long he or she has been kept without feeding. On the other hand, behavioral techniques that help extinguish fear-based food refusal in a post traumatic feeding disorder further distract an infant with infantile anorexia and further interfere with the awareness of hunger.

## Rumination Disorder

### Definition

Rumination disorder is characterized by the repeated regurgitation and rechewing of food occurring for at least one month with prior normal functioning. As in the case of feeding disorder of infancy and early childhood, these behaviors cannot be the result of a medical condition affecting the gastrointestinal tract. Similarly, this diagnosis is not made in the presence of anorexia nervosa or bulimia nervosa.

### Epidemiology and Etiology

Rumination disorder appears to be uncommon, occurring more often in boys than in girls and also in individuals with mental retardation.

Several authors have attributed rumination to an unsatisfactory mother–infant relationship, (including neglect or lack of stimulation, and sometimes to stressful life situations of the

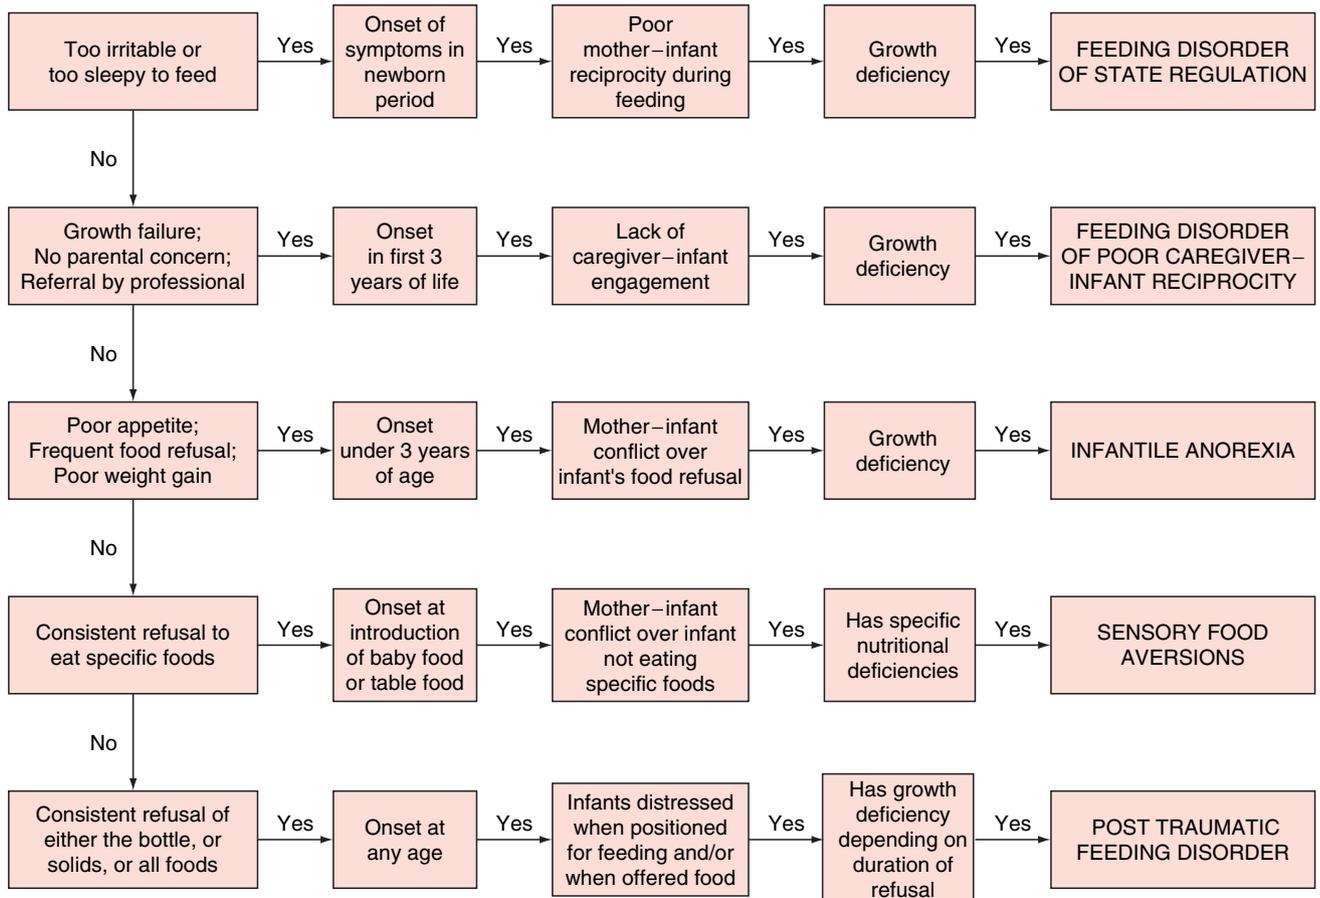

Figure 29.1 Diagnostic decision tree for differential diagnosis of feeding disorders of infancy or early childhood.

parent. Others have considered rumination a learned behavior that is maintained by special attention by the caregivers to the child's rumination and, consequently, the rumination has to be unlearned by counter conditioning. Rumination can be seen along a continuum: a patient may have gastrointestinal disease, such as hiatal hernia or reflux, and little psychiatric illness in the mother–infant relationship at one end of the spectrum; or the converse, a patient might have no reflux and severe psychiatric illness in the mother–infant relationship at the other end of the spectrum. Reflux or a temporary illness associated with vomiting frequently precedes the rumination. At some point, the infant seems to learn to initiate vomiting and turn it into rumination to achieve self-regulation. It appears that in circumstances in which the infant fails to elicit or loses either caring attention or tension-relieving responses from the caretaker, the infant resorts to rumination as a means of self-soothing and relief of tension.

## Diagnosis

Most frequently, infants who ruminate come to the attention of professionals because of “frequent vomiting” and weight loss. Some infants ruminate primarily during the transition to sleep when left alone, and their ruminatory activity might not be readily observed. However, these infants are frequently found in a puddle of vomitus, which should raise suspicion of rumination. Other infants can be observed to posture with the back arched, to put the thumb or whole hand into the mouth, or to suck on the tongue rhythmically to initiate the regurgitation of food. Most of the regurgitated food is initially vomited, but gradually the infant appears to learn to hold more of the food in the mouth to rechew and reswallow. “Experienced” ruminators appear to be able to bring up food through repeated tongue movements. They learn to rechew and reswallow the food without losing any of it. Their rumination can be inferred only from the movements of their cheeks and foul oral odor because of the frequent regurgitation.

In addition to taking a thorough medical history, it is important to explore the onset of vomiting and the social context under which the symptoms developed. An acute medical illness or a stressor in the parents' life is frequently associated with the onset of vomiting.

When exploring the stressors in the mother–infant relationship, one needs to be careful neither to alienate the mother nor to add additional stress to the relationship. It is best to observe the infant in various situations with the mother, with other caretakers and alone in the crib during the transition to sleep. These observations will help in understanding the severity of the rumination, and whether it is situational or pervasive. In addition to assessing the rumination in the infant, the mother–infant relationship and the mother's life circumstances need to be evaluated because the mother's ability to soothe and to stimulate her infant is critical for successful intervention.

## Course and Natural History

The onset of rumination is frequently in the first year of life except in individuals with developmental delays, in whom the disorder may occur during later years. Rumination has also been reported to occur in adults with normal intelligence and in association with bulimia nervosa. In some infants and children, the disorder is believed to remit, however, electrolyte imbalance, weight loss, dehydration and death have been reported to result from rumination, and rumination should always be taken seriously.

## Treatment

Diverse theories of etiology have resulted in various proposed methods of treatment. Besides surgical intervention to prevent reflux and the early use of mechanical restraints, treatment has been primarily behavioral or psychodynamic or a combination of both.

On the basis of the assumption that rumination is a learned habit reinforced by increased attention for regurgitation, unlearning by counter conditioning has been suggested. Some authors have used electric shock after other methods had failed. A number of alternative procedures of punishment, such as aversive taste stimuli (lemon juice or hot sauce), have been developed. There are difficulties in the use of aversive taste stimuli as punishment. Frequently, the infants are out of reach of the caretakers when they ruminate; consequently, the use of lemon juice or hot sauce is inconsistent, and this delays learning. Some infants appear to become adapted to these aversive taste stimuli. These authors suggest scolding the infant by shouting “No”, placing the infant down, and leaving the room for 2 minutes immediately on initiation of rumination by the infant. If the infant is not ruminating on the caretaker's return, he or she is to be picked up, washed and played with as a reward.

There may be two behavioral causes of rumination: 1) reward learning through increased attention for regurgitation, and 2) social deprivation. Whereas punishment with time-out may be necessary for the first type, holding the child for 10 to 15 minutes before, during and after meals is the treatment of choice for the second type. A psychodynamic approach based on the assumption that rumination results from a disturbance in the mother–infant relationship has been advocated. Mothers of ruminating infants are frequently found to be overwhelmed by their personal lives, which make them unavailable or tense in their relationship with their infants. Psychotherapy for the mother and environmental changes that produce enhanced mothering have been proposed.

After an understanding of the mother's situation has been gained, treatment is best individualized by use of a combination of psychodynamic and behavioral interventions to enhance the mother–infant relationship in general, and to address the symptom of rumination in particular.

## Pica

### Definition

Pica refers to behaviorally and culturally inappropriate eating of nonnutritional substances for at least 4 weeks. It is most often associated with poverty related nutritional deficiencies and mental retardation.

### Epidemiology

Pica is a common, but frequently missed problem. The onset of pica is usually during the toddler age between 12 and 24 months. Because infants commonly mouth objects, it is difficult to make the diagnosis in young infants. Estimates of the prevalence of pica among institutionalized mentally retarded individuals range from 10 to 33%.

Children with pica are more susceptible to malnutrition, anemia, diarrhea or constipation, and worm infestation. It has been noted that pica is highest in a group of children hospitalized for accidental poisoning and that more than 60% of mothers with children with pica have pica themselves.

## Etiology

Organic, psychodynamic, socioeconomic and cultural factors have been implicated in the cause of this disorder. Some authors have suggested that inadequate dietary intake of iron and calcium leading to abnormal cravings may induce pica. Other authors have implicated psychosocial stress, maternal deprivation, parental neglect and abuse, and disorganized and impoverished family situations in the etiology of pica. In certain population groups, cultural acceptance of pica has been considered an important factor in the etiology of this disorder as well.

Most helpful clinically is a multifactorial etiology, whereby constitutional, developmental, familial, socioeconomic and cultural factors interact with each other. Children who engage in pica often experience frequent separations from one or both parents followed by replacement of rapidly changing, inadequate caretakers who seemed to encourage oral gratification in response to the child's distress. These children show a high degree of other oral activities (e.g., thumb-sucking or nail-biting) and may be seeking gratification caused by the lack of parental availability and nurture.

## Diagnosis

Because mouthing of objects is still common in toddlers between 1 and 2 years, the diagnosis of pica should be made only if the behavior is persistent and inappropriate for the child's developmental level. The diagnosis of pica should be explored in children with accidental poisoning, with lead intoxication, or with worm infestation. Young children with signs of malnutrition or iron deficiency should also be considered for the diagnosis of pica.

The assessment should include the history of the child's development in general, and feeding in particular. Special attention should be given to other oral activities that the child may use for self-soothing and relief of tension. In addition, the home environment and the parents' relationship with each other and with the child need to be explored to assess the parents' availability to nurture and supervise the child. Above all, mother and child should be observed during a meal and during play to gain a better understanding of their relationship and how the symptoms of pica can be understood in the context of that relationship.

If the diagnosis of pica is established, it is critical that the child undergo a thorough physical examination to rule out any of the complications associated with this disorder, such as nutritional deficiencies (especially iron deficiency), lead poisoning, intestinal infections (toxoplasmosis or intestinal parasites), or gastrointestinal bezoars.

## Course and Natural History

In many instances, the disorder is believed to be self-limited and to remit spontaneously after a few months. However, there may be a developmental impact of the disorder in some children. For example, younger children may be somewhat retarded in the use of their speech and show conflicts about their dependency needs and aggressive feelings. Adolescents may evidence some degree of depression, borderline personality disorders, other forms of

disturbed oral activities and the use of tobacco, alcohol, or drugs. There may be a strong relationship between pica in childhood and symptoms of bulimia nervosa in adolescence.

## Treatment

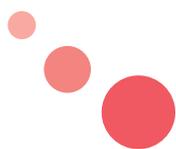

In treating pica, one must consider the various factors that appear to contribute to the development of pica as well as its complications. It is important to treat the child medically while addressing the psychosocial needs of the child's family as well. The mothers need to be made aware of the dangers of pica and should be enlisted in providing a childproof environment. This might include removing lead from paint in old substandard housing units or instituting anthelmintic therapy for family pets. A psychoeducational treatment approach that, in addition to teaching the mothers the dangers of pica, would also provide social support to help them become more available to their children is preferable.

## Comparison of DSM-IV/ICD-10 Diagnostic Criteria

In contrast to DSM-IV-TR, which allows the diagnosis of pica to be made in the presence of other mental disorders if it is sufficiently severe to warrant independent clinical attention, the ICD-10 Diagnostic Criteria for Research for Pica exclude this diagnosis in the presence of any other mental disorder (except mental retardation). ICD-10 does not have a separate category for rumination disorder. Instead it includes this DSM-IV-TR category within its definition of Feeding Disorder of Infancy and Childhood which combines rumination with the persistent failure to eat adequately.

# Childhood Disorders: Tic Disorders

## Phenomenology and Diagnostic Criteria

The cardinal features of Tourette's disorder and the other tic disorders are motor and vocal tics. Motor tics are usually brief, rapid and stereotyped movements, but can also be slower, more rhythmic, or even dystonic in nature. Simple motor tics are movements of individual muscle groups and include brief movements such as eye blinking, head shaking and shoulder shrugging. Complex motor tics involve multiple muscle groups, such as a simultaneous eye deviation, head turn and shoulder shrug. Some complex tics appear more purposeful, such as stereotyped hopping, touching, rubbing, or obscene gestures (copropraxia). Vocal tics are usually brief, staccato-like sounds, but can also be words or phrases. Simple vocal tics, often caused by the forceful movement of air through the nose and mouth, include sniffing, throat clearing, grunting, or barking-type sounds. Complex vocal tics usually include words, phrases, or the repetition of one's own words (palilalia) or the words of others (echolalia). Coprolalia (repetition of obscene phrases), often incorrectly considered essential for the diagnosis of Tourette's disorder, is an uncommon symptom with only 2 to 6% of Tourette's disorder cases so affected.

Tics most often begin early in childhood, wax and wane in severity, and change in character and quality over time. Tics are exacerbated by excitement and tension, and can attenuate during periods of focused, productive activity and sleep. Tics are involuntary, yet because they are briefly suppressible or can be triggered by environmental stimuli, they may appear as volitional acts. Patients describe tension developing if a tic is resisted, which only subsides by completion of the tic. In some individuals, tics are preceded or provoked by a thought or physical sensation referred to as a premonitory urge.

## Diagnostic Criteria for the Tic Disorders

There are four diagnostic categories included in the tic disorders section of the *Diagnostic and Statistical Manual of Mental Disorders: Fourth Edition (DSM-IV)* (American Psychiatric Association, 1994): 1) Tourette's disorder; 2) chronic motor or vocal tic disorder (CT); 3) transient tic disorder; and 4) tic disorder not otherwise specified, which is a residual category for tic disorders not meeting the duration or age criteria of the other categories. In general, diagnostic decisions are based on whether both motor and phonic tics are present, duration of time affected with tics, age at onset, lack of another medical cause for the tics, and the presence of impairment.

## DSM-IV-TR Criteria 307.23

### Tourette's Disorder

- A. Both multiple motor and one or more vocal tics have been present at some time during the illness, although not necessarily concurrently. (A **tic** is a sudden, rapid, recurrent, nonrhythmic, stereotyped motor movement or vocalization.)
- B. The tics occur many times a day (usually in bouts) nearly every day or intermittently throughout a period of more than 1 year, and during this period there was never a tic-free period of more than three consecutive months.
- C. The disturbance causes marked distress or significant impairment in social, occupational, or other important areas of functioning.
- D. The onset is before age 18 years.
- E. The disturbance is not due to the direct physiological effects of a substance (e.g., stimulants) or a general medical condition (e.g., Huntington's disease or postviral encephalitis).

## Epidemiology

### Incidence and Prevalence

Tic disorders appear to be common (>1:100), whereas Tourette's disorder is less common (5:10000). In general, tic disorders occur more frequently in children than adults. People with mild tic disorders are much more common than those with severe, complex symptoms. Also people with tic disorders may present for clinical attention with tics, but tics may not end up as the focus of clinical attention as comorbid conditions are often more impairing than the tics themselves. Given these realities, the numbers of adults with persistent and severely impairing tics that warrant tic-suppressing medication is probably very small and may still be considered rare. More common are those adults with mild to moderate Tourette's disorder who come to clinical attention not only because of tics, but also because of comorbid psychiatric

**DSM-IV-TR Criteria 307.22****Chronic Motor or Vocal Tic Disorder**

- A. Single or multiple motor or vocal tics (i.e., sudden, rapid, recurrent, nonrhythmic, stereotyped motor movements or vocalizations), but not both, have been present at some time during the illness.
- B. The tics occur many times a day nearly every day or intermittently throughout a period of more than 1 year, and during this period there was never a tic-free period of more than three consecutive months.
- C. The disturbance causes marked distress or significant impairment in social, occupational, or other important areas of functioning.
- D. The onset is before age 18 years.
- E. The disturbance is not due to the direct physiological effects of a substance (e.g., stimulants) or a general medical condition (e.g., Huntington's disease or postviral encephalitis).
- F. Criteria have never been met for Tourette's disorder.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

**DSM-IV-TR Criteria 307.21****Transient Tic Disorder**

- A. Single or multiple motor and/or vocal tics (i.e., sudden, rapid, recurrent, nonrhythmic, stereotyped motor movements or vocalizations).
- B. The tics occur many times a day, nearly every day for at least 4 weeks, but for no longer than 12 consecutive months.
- C. The disturbance causes marked distress or significant impairment in social, occupational, or other important areas of functioning.
- D. The onset is before age 18 years.
- E. The disturbance is not due to the direct physiological effects of a substance (e.g., stimulants) or a general medical condition (e.g., Huntington's disease or postviral encephalitis).
- F. Criteria have never been met for Tourette's disorder or chronic motor or vocal tic disorder.

*Specify if:*

**Single episode or recurrent.**

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

disorders. Perhaps most common are those adults with mild tics, with and without comorbid symptoms that do not come to clinical attention at all. A similar pattern is seen in children, with fewer

children presenting with severe tics warranting tic suppression than children with mild to moderate tics and comorbid psychiatric disorders. Perhaps the most common are those children with transient tics that are not impairing and without comorbid conditions who may never come to clinical attention.

**Frequently Cooccurring Symptoms or Disorders**

Cooccurring problems can be more disabling than tics and are often the reason people with tics come to clinical attention. Difficulties with mood, impulse control, obsessive–compulsive behaviors, anxiety, attention and learning problems, and conduct problems are common. In some patients, these problems reach diagnosable proportions, but in many others, they are less severe and do not fulfill diagnostic criteria. The most frequent cooccurring disorders are attention-deficit/hyperactivity disorder (ADHD; 50–60%) and obsessive–compulsive disorder (OCD; 30–70%). The exact relationship of these problems to Tourette's disorder is controversial.

**Attention-deficit/Hyperactivity Disorder**

Upward of 50% of clinically ascertained children and adolescents with Tourette's disorder may be affected with problems of attention, concentration, activity level, or impulse. In community-based epidemiological samples of subjects with Tourette's disorder, the estimated frequency of ADHD is lower (8–41%) than in clinic populations (Apter *et al.*, 1993). In the epidemiological study with the lowest prevalence estimate of ADHD in Tourette's disorder (8%), subjects were 16 to 17 years of age, and the assessment of ADHD focused on current affected status (point prevalence), not lifetime diagnosis (Apter *et al.*, 1993). Even though the point prevalence of ADHD was more than twice that seen in the general population, factors such as the age of the sample and examination for current status probably led to an underestimate of ADHD in Tourette's disorder.

**Obsessive–Compulsive Symptoms**

Obsessions and compulsions are stereotyped, persistent, and intrusive thoughts and behaviors that are experienced as senseless. Because these thoughts and behaviors can be common in the general population, persons are considered “disordered” only when the obsessions or compulsions become severe, disabling, or time-consuming. Obsessions that are commonly seen in OCD include fears of contamination, fears of harm coming to oneself or others, scrupulosity, fear of losing control of one's impulses, counting, fear of losing things, fear of being unable to remember, or experiencing images of terrible things happening. Compulsions commonly seen in OCD include repeated or stereotyped washing and grooming rituals; repeated checking of locks, switches, or doors; and repetition of other senseless rituals.

Differences in clinical phenomenology have been noted in studies of obsessions and compulsions in patients with Tourette's disorder compared with patients with OCD (without Tourette's disorder). Patients with Tourette's disorder have greater concern with physical symmetry, evenness, and exactness, which are often described as “just right” phenomena and concerns with impulse control. In contrast, patients with OCD have more frequent concerns regarding contamination and more cleaning and grooming rituals than do patients with Tourette's disorder. Also, the absolute number of independent concerns appears to be greater in patients with Tourette's disorder than in patients with OCD. Patients with OCD more often have a single concern around which their symptoms coalesce, such as contamination.

In contrast, patients with Tourette's disorder may have multiple concerns, such as symmetry, violent or sexual images or urges, worries about losing control, or counting. Some investigators have argued that the obsessions and compulsions in Tourette's disorders are more sensory–motor in character, whereas those in OCD are more cognitive and affective.

### Relationship of the Commonly Cooccurring Symptoms and Conditions with Tourette's Disorder

Some studies support a broad Tourette's disorder phenotype that include commonly cooccurring comorbid conditions, whereas others identify a more circumscribed phenotype and define Tourette's disorder consistent with DSM-IV diagnosis – impairing multiple motor and vocal tics of 1-year duration. The outcome of this controversy has implications for treatment, but also for the definition of what Tourette's disorder is. For example, for people with Tourette's disorder and multiple comorbid conditions a simple moniker – Tourette's disorder – can simplify a very complex situation. For example, some parents have noted that it is difficult for them to conceptualize their child as having Tourette's disorder, OCD, ADHD, major depressive disorder and a learning disorder and prefer to use Tourette's disorder as a way to simplify the complexity in their own minds and in the minds of others. On the other hand people with Tourette's disorder but without multiple comorbidities may not be appropriately understood or treated if it is assumed that the Tourette's disorder label means tics plus a variety of other psychiatric disorders.

For clinical purposes we recommend that clinicians use a narrow conceptualization of Tourette's disorder and describe other problems as they may or may not occur. In this way each individual will carry diagnoses or problems that can be specifically described and appropriately addressed.

In the available research studies there is general agreement that chronic vocal or motor tics are a milder form of Tourette's disorder and that some forms of OCD are an alternative expression of the Tourette's disorder genetic diathesis. ADHD is very common in clinically ascertained subjects with Tourette's disorder, but may not be as uniformly present in community samples of people with Tourette's disorder. Within the literature, there are two major hypotheses regarding the relationship of Tourette's disorder to cooccurring disorders:

- 1) The putative Tourette's disorder gene is responsible for Tourette's disorder, CT, OCD and some forms of ADHD in Tourette's disorder probands and their families. Other disorders that commonly cooccur in Tourette's disorder subjects are not associated with Tourette's disorder and are not part of the Tourette's disorder phenotype. The cooccurrence of these other disorders with Tourette's disorder reflects either ascertainment bias in the sample or the development of disorders secondary to living with Tourette's disorder.
- 2) The putative Tourette's disorder gene is responsible for Tourette's disorder and the frequently associated psychiatric and behavioral problems seen in Tourette's disorder subjects.

## Etiology

### Genetics

Comparison of the concordance rates for Tourette's disorder in monozygotic and dizygotic twins identifies Tourette's disorder as

an inherited condition. The twin studies, however, are unable to identify a particular mode of genetic transmission or to identify the breadth of the clinical phenotype. To answer these questions, other research methods are required. Segregation analyses of family study data have been used to identify the pattern of genetic transmission and alternative phenotypes of the Tourette's disorder genetic diathesis. Linkage studies of Tourette's disorder based on the assumption of Tourette's disorder as an autosomal dominant condition have been undertaken but to date have not been successful. Candidate gene studies based on the neurotransmitter hypotheses of the etiology of Tourette's disorder have also not been successful in identifying the Tourette's disorder gene(s). Recently, a large federally funded sibpairs study of Tourette's disorder has published encouraging results.

### Twin Studies

Evidence from twin studies suggests an important role for both genetic and nongenetic factors in the development of Tourette's disorder. Two large twin studies have shown high concordance rates in monozygotic twins for Tourette's disorder (both twins have Tourette's disorder) and for tic disorders (one twin has Tourette's disorder, the other has tics but not Tourette's disorder). In both of the studies, the concordance rate for Tourette's disorder in monozygotic twins was more than 50%. When the concordance rates were calculated for the presence of any tic disorder, they approached 100%. By comparing the concordance rates of monozygotic twins with dizygotic twins, one can separate the role of genetic factors from other environmental factors. In the one study in which such a comparison was done, the concordance rate for Tourette's disorder in monozygotic twins was significantly higher than the concordance rate in dizygotic twins (Price *et al.*, 1985), further suggesting a powerful role for genetics in Tourette's disorder.

### Pathophysiology

In Tourette's disorder, the complex clinical presentation suggests several neuroanatomical sites of disease as well as neurochemical substrates including the basal ganglia and their interconnections with the frontal cortex and limbic system. Abnormalities in these structures could readily cause the wide variety of motor, sensory–motor, cognitive and affective symptoms seen in patients with Tourette's disorder. The complex phenotypic presentation seen in Tourette's disorder could also be produced by a neurochemical abnormality at various locations within this circuitry. Reports of group A beta-hemolytic streptococcus-related antineuronal antibodies being associated with the development or exacerbation of tics and OCD suggest a role for infectious agents and autoimmune processes in the etiology of these complex disorders.

## Anatomical and Biological Abnormalities

### Neuroanatomical Abnormalities in Tourette's Disorder

Increasingly sophisticated imaging methods, such as volumetric magnetic resonance imaging (MRI) and functional neuroimaging, have identified subtle abnormalities in the basal ganglia and its interconnections with cortical and limbic regions of the brain.

Two volumetric magnetic resonance studies identified the absence of the usual left–right asymmetry in the basal ganglia, leading to speculation of hypoplasia or atrophy of the left basal ganglia in Tourette's disorder. Areas associated with tic suppression may reflect brain areas involved in central nervous system disinhibition and ultimately tic symptoms. Functional neuroimaging

studies, such as single-photon emission computed tomography, have identified decreased blood flow to the basal ganglia, specifically the left lenticular region. Positron emission tomography identified similar decrements of glucose use in the basal ganglia. Areas associated with increased functioning in Tourette's disorder include the midbrain, lateral premotor and supplemental motor cortexes and areas associated with sensorimotor, executive and paralimbic functioning. Areas associated with decreased functioning include the circuitry involving the caudate and thalamus, and their interconnections with the cortical and limbic areas.

### Neurochemical Abnormalities

A number of neurochemical abnormalities have been proposed in Tourette's disorder, in large part on the basis of responsiveness of symptoms to specific pharmacological agents. Tic suppression with dopamine blockers such as haloperidol and beta-adrenergic agonists such as clonidine have implicated the dopamine–acetylcholine and adrenergic systems, respectively. The serotonin system has been implicated because of the association of Tourette's disorder with OCD and the positive therapeutic effect of serotonin reuptake inhibitors in OCD.

### Other Biological Causes

In several reports the development of tics as well as obsessive–compulsive symptoms in children and adolescents has been associated in time with group A beta-hemolytic streptococcal infection. The underlying mechanism is proposed to be similar to that involved in the development of Sydenham's chorea, in which antibodies developed in the course of infection cross-react with basal ganglia tissues, resulting in the characteristic choreiform movement disorder of Sydenham's. Case reports have described subjects with the abrupt onset or exacerbation in symptoms occurring in parallel with antibody increases and with MRI changes in caudate size. These cases have been given the acronym PANDAS for Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcal Infection. These preliminary findings link the development of a movement disorder and psychiatric symptoms to an infectious agent and autoimmune processes, and suggest new and alternative treatments including the potential for vaccines for Tourette's disorder and OCD, though the possibility of chance association is high given that tics, obsessive–compulsive symptoms and streptococcal infections are common events in childhood.

### Environmental Causes of Tourette's Disorder

To date, studies have not identified any specific factors that cause Tourette's disorder, yet it is increasingly clear that environmental factors have an impact on tic severity and, perhaps, even on the types of symptoms expressed. Clinical wisdom suggests that tic severity increases in response to stressful (e.g., examinations) or exciting life experiences (e.g., amusement parks). It is also not uncommon for persons with Tourette's disorder to be able to identify a particular environmental stimulus that initiated either a bout of symptoms or a new tic symptom.

Environmental factors associated with increases in symptom severity can occur early in development, including prenatal (intrauterine) development. In a study comparing groups of Tourette's disorder subjects with severe versus mild tics, protracted vomiting by a subject's mother during her pregnancy with the subject was a risk factor for increased tic severity (Leckman *et al.*, 1990). Because of the male preponderance of Tourette's disorder, it has been postulated that intrauterine exposure to androgenic hormones may be a factor in the development of tics and in

tic severity. An open-label study of flutamide, an antiandrogenic hormone, identified significant but transient tic reduction in adult men, suggesting at least a partial role for sex hormones in tic severity (Peterson *et al.*, 1994). Family-genetic and twin studies have also been useful for identifying factors associated with tic severity and have found an association between birth weight and tic severity suggesting that differences in intrauterine environment may be associated with tic severity.

### Psychosocial Aspects of Tourette's Disorder

Although psychosocial issues do not play a large etiological role in the development of tic disorders they do play a major role in adaptation and impairment and are often the focus of treatment and rehabilitative efforts. Clinical work that involves the family, friends, school and workplace is often the bedrock of treatment in a patient with Tourette's disorder.

### Children

For children with Tourette's disorder, the onset of symptoms occurs early in development and directly affects family life and relationships with peers and schoolmates. The diagnostic label of Tourette's disorder can be helpful for understanding the nature of a youngster's problems and can communicate the need to protect the youngster from excessive adversity. The diagnostic label can, however, be a problem. There is a tension between protecting a child with Tourette's disorder from adversity while ensuring that the child encounters and masters life's challenges. With too much protection, a child may run the risk of not developing a strong and complex identity adequate for the rigors of adult life. Support from parents for mastering the challenges of development is key to long-term functioning of children with Tourette's disorder.

### Young Adults

The transition to adulthood is difficult enough for most young people, but young adults with Tourette's disorder have a particular challenge. The transition to adulthood often occurs when an important component of their early experience and identity (i.e., Tourette's disorder) begins to show some improvement. Young adults most vulnerable during this transition are those who, as a result of their Tourette's disorder, did not develop the foundations of an adult identity as a child. These adults often face the rigors of adult life without the necessary skills to manage, but also without the presence of tic symptoms of sufficient severity to explain their impairment.

### Adults

Today's adult with Tourette's disorder belongs to a different cohort than today's child with Tourette's disorder. Most adults with Tourette's disorder were not diagnosed in childhood. They did not have the "protection" of the diagnosis and often experienced significant confusion, isolation and discrimination. Some adults with Tourette's disorder have significant anger, resentment and distrust related to their early life experiences including ineffective treatments, which can have an impact on current functioning. Many adults who appear to function well in spite of their Tourette's disorder may be doing so at an emotional cost.

## Diagnosis

### Clinical Presentation

Before the 1980s, only people with the most severe and clinically obvious tics were diagnosed with Tourette's disorder. The

majority of these patients were adults who pursued care and were correctly diagnosed only when their tic symptoms were disabling and when classic symptoms such as coprolalia were present. Adults with milder tics generally did not pursue care and may have been stigmatized without the awareness of the cause of their movements. Children with tics were not identified at all or were identified as having other behavioral or psychiatric difficulties. Increasingly, as medical professionals and the public became more knowledgeable about tic disorders, psychiatrists began to see children at younger ages and with milder symptoms. Today, psychiatrists sometimes become involved even when the tics themselves are not obvious or even disabling. In today's clinical practice, the challenge is often not the treatment of the tics but identification of cooccurring and often more disabling psychiatric, behavioral, family and school problems.

More than half of families who finally pursue expert consultation find out about tic disorders from news articles or television. Many parents describe as their worst fear that their child's mild tic disorder is the beginning of a permanent neuropsychiatric disorder with a deteriorating course. Other children are identified during evaluation for other problems, such as ADHD. When the diagnosis of Tourette's disorder is made as part of an evaluation for other problems, it can be particularly difficult for the family and the patient to cope with the additional and unexpected diagnosis. Clearly, at the time of the evaluation, the patient and family are often frightened and require considerable psychological support.

Some children with tics, who present directly to a neurologist or a psychiatrist for an evaluation, may have a parent who has been diagnosed with a tic disorder. In this context, children can present early in the course of their disorder, often before a clear diagnosis can be made. The parents of these children were often diagnosed with tics late in their life or experienced significant duress from their symptoms and want their child to have a better experience.

## Assessment

### Tic Severity

Clinical assessment of the tic disorders begins with identification of the specific movements and sounds. It is also important to identify the severity of and impairment caused by the tics. A number of structured and semistructured instruments are available for the identification of tics and the rating of tic. Knowledge of the basic clinical parameters of tics and the course of illness dictates the evaluation. Questioning patients and their families about the presence of simple and complex movements in muscle groups from head to toe is a good beginning. Because vocal tics usually follow the development of motor tics, questions about the presence of simple sounds is next. Inquiring about the presence of complex vocal tics completes the tic inventory. It is helpful to elucidate other aspects of tic severity, such as the absolute number of tics; the frequency, forcefulness and intrusiveness of the symptoms; the ability of the patient successfully to suppress the tics; and how noticeable the tics are to others. It is also important to know whether premonitory sensory or cognitive experiences are a component of specific tics because these intrusive experiences may disrupt functioning more than the tics themselves. Although the waxing and waning nature of the tics and the replacement of one tic with another do not directly affect severity, identifying the characteristic course of illness is important for diagnostic confidence.

Last, it is important to assess the impairment due to the tics themselves. Whereas tic severity is frequently correlated with overall impairment, it is not uncommon to identify patients in whom tic severity and impairment are not correlated. Patients who experience more impairment than their tic symptoms apparently warrant a particular clinical challenge. A number of clinical features of tics are associated with impairment:

- Large, disruptive, or painful motor movements;
- Vocalizations that call attention to the patient;
- Premonitory sensations or cognitions that intrude into consciousness;
- Tics that are socially unacceptable.

### Associated Cooccurring Conditions

Whereas tic severity and impairment are often correlated, many patients with mild tics are most impaired by the comorbid conditions ADHD, OCD and Learning Disorders. An adequate assessment of these conditions is part of any comprehensive evaluation. The assessment of tic-related obsessive-compulsive symptoms, for example, touching, tapping, rubbing, "evening up", repeating actions, stereotypical self-mutilation, staring, echolalia and palilalia, although often omitted from the traditional psychiatric and neurological review of symptoms, should always be part of the routine evaluation of patients with tics, OCD, or ADHD.

### Psychosocial Issues

Psychosocial issues can play a role in tic severity and in overall adaptation and impairment. Assessment of family, peer and school support for the youngster (adequate protection) along with assessment for the presence of opportunities to be intellectually, physically and socially challenged is important. The balance between protection and challenge in children is critical for long-term development. An environment that is too protective decreases opportunities for building skills. An environment that is too challenging can lead to frustration, anger and maladaptive coping.

### Physical Examination Findings

Tic assessment requires a careful evaluation of observable tic symptoms. Interestingly, the absence of tic symptoms during an evaluation, in spite of the parent's or patient's report, is not uncommon and should not necessarily lead to clinical doubt. Occasionally, an additional clinical observer (e.g. nurse or medical student) may identify tics more readily than the psychiatrist conducting the evaluation. Other than the observation of tics in the interview, there are no pathognomonic physical examination findings. Patients with Tourette's disorder have been noted to have nonfocal and nonspecific subtle neurological findings ("soft" signs). If tic suppression with neuroleptic agents is considered, a more structured method of documenting the complex movements that are part of the pretreatment baseline evaluation is useful for following the progression of the disease and for subsequent assessment for neuroleptic-induced movements.

## Differential Diagnosis

### Differential Diagnosis of Tics

Tics have many characteristics that differentiate them from the other movement disorders. Perhaps most important to "ruling in"

### DSM-IV-TR Criteria

Simple, rapid movements  
 Myoclonus  
 Chorea  
 Seizures  
 Simple, sustained movements  
 Dystonia  
 Athetosis  
 Complex or sustained movements  
 Mannerisms  
 Stereotypies  
 Restless legs  
 Seizures

Jankovic J (1992) Diagnosis and classification of tics and Tourette syndrome. *Adv Neurol* 58, 7–14. Reprinted with permission from Lipincott William & Wilkins.

tics as a diagnostic possibility is the childhood history of simple motor tics in the face. Other movement disorders do not have a similar pattern of movement onset or location. There are atypical presentations of tic disorders that may resemble other movement disorders, but these would be unusual and would probably require a consultation with a movement disorders expert.

Movement disorders such as chorea and dystonia are continuous movements and can be distinguished from tics, which are intermittent. Paroxysmal dyskinesias, although episodic, are more often characterized by choreiform and dystonic movements, which are different from tics. Myoclonic movements and exaggerated startle responses are also intermittent movements but are usually large-muscle movements that occur in response to a patient-specific stimulus. Complex tics can be more difficult to differentiate from other complex movements such as mannerisms, gestures, or stereotypies. In a person with clear-cut motor tics, it may be difficult to differentiate a complex motor tic from a “camouflaged” tic (making a simple tic appear to be a purposeful action, e.g., an upward hand movement that the person turns into a hair smoothing gesture), mannerism, gesture, or stereotypy. Mannerisms or gestures are often not impairing; stereotypies tend to occur exclusively in children and adults with developmental disabilities and mental retardation (Jankovic, 1992).

It is also possible to have a tic disorder and another movement disorder. For example, tic movements can cooccur with dystonia. Similarly, it is not uncommon in tertiary referral centers to see developmentally disabled children and adults with both tics and stereotypies.

### Course and Natural History

In Tourette’s disorder, tic symptoms usually begin in childhood; mean age at onset is 7 years. Motor tics of the eyes and face are the most common and earliest presenting symptoms. In many patients, the motor tics remain isolated in the face. When motor tics do progress, there is a tendency for additional tics to present sequentially from the head and face to the neck, shoulders, trunk and extremities. Vocal tics tend to follow the development of motor tics. Complex tics of both types tend to follow the development of simple tics. Longitudinal studies suggest that tic severity is greatest in most patients during the latency and early teenage years. Most patients experience a decline in tic severity as they get older and only a small percentage of patients (10%) experience a severe or deteriorating course.

**Table 30.1 Goals of Treatment**

Educate the patient and family about tic disorders.  
 Define the cooccurring disorders.  
 Create a hierarchy of the clinically impairing conditions.  
 Treat the impairing conditions using somatic, psychological and rehabilitative approaches.  
 Aid in creating a supportive yet challenging psychosocial milieu.

Obsessive–compulsive symptoms in persons with Tourette’s disorder generally begin somewhat later than ADHD and tics and may actually progress differentially from tic symptoms. Tic symptoms tend to improve into adulthood; obsessive–compulsive symptoms may actually increase in severity. Long-term studies of the course of obsessive–compulsive symptoms in persons with Tourette’s disorder have not been made. The course of ADHD symptoms is similar in persons with and without Tourette’s disorder.

## Standard Approaches to Treatment

### Educate the Patient and Family

The initiation of treatment can be a delicate process, given the difficulties patients and their families experience before finding appropriate care. Most families are frightened about their child’s having a neuropsychiatric disorder and envision a grim prognosis. After the evaluation is completed, often in the first session, general education of the patient and family about the course of the tic disorder is essential (Table 30.1). Most patients and families are relieved to hear that the majority of persons with tics have consistent improvement in tic severity as they move through their teenage years and into adulthood. They are also pleased to hear that tic symptoms are not inherently impairing.

### Identify Cooccurring Disorders

Identifying whether ADHD, LD and OCD are present is especially important because they are often the more common impairing conditions in these children. One of the major pitfalls of treatment of patients with Tourette’s disorder is to pursue tic suppression to the exclusion of the treatment of other cooccurring conditions that are present and possibly more impairing.

### Create a Hierarchy of the Clinically Impairing Conditions

Most psychiatrists, as part of their formulation, create some clinical hierarchy; yet in Tourette’s disorder, with the multitude of often complex problems, it is essential that a conscious effort be made to formulate, organize and create hierarchies for treatment. For example children with moderate tics and separation anxiety with school refusal should be considered for a treatment with selective serotonin reuptake inhibitor (SSRI) for their separation anxiety rather than neuroleptics for tic suppression (The Research Unit on Pediatric Psychopharmacology Anxiety Study Group, 2001). It is possible with successful treatment of the anxiety disorder that patient may also experience a reduction in tic severity also.

### Treat the Impairing Conditions

#### Tic Suppression: Pharmacological

The goal of pharmacological treatment is the reduction of tic severity, not necessarily the elimination of tics. Haloperidol has

been used effectively to suppress motor and phonic tics for more than 30 years. Since that time, a number of other neuroleptic agents have also been identified as useful in tic suppression, including fluphenazine and pimozide. In Europe, the substituted benzamides, sulpiride and tiapride, and the nonneuroleptic tetrabenazine have also been shown to be useful. As new neuroleptic agents become available, clinical trials for tic suppression invariably occur. Preliminary results with risperidone have been mixed, whereas trials with clozapine are more uniformly negative. The major drawback with neuroleptic agents is the frequent and significant side effects, which often preclude continued use of the medication.

### Haloperidol

Haloperidol is a high-potency neuroleptic that preferentially blocks dopamine  $D_2$  receptors. Historically, haloperidol has been the most frequently used medication for tic suppression. It is effective in a clear majority of patients, although relatively few patients are willing to tolerate the side effects to obtain the tic-suppressing benefits. Neuroleptics are often effective at low doses, and low doses minimize side effects. For haloperidol, doses in the range of 0.5 to 2.0 mg/day are usually adequate. Starting dosages are low (0.25–0.5 mg/day), with small increases in dose (0.25–0.5 mg/day) every 5 to 7 days. Most often the medication is given at bedtime, but with low doses, some patients may require twice-a-day dosing for good tic control.

Side effects with all neuroleptics are common and include sedation, acute dystonic reactions, extrapyramidal symptoms including akathisia, weight gain, cognitive dulling and the common anticholinergic side effects. There have also been reports of subtle, difficult to recognize side effects with neuroleptics, including clinical depression, separation anxiety, panic attacks and school avoidance.

Dosage reduction is the most prudent response to side effects, although the addition of medications such as benztropine for the extrapyramidal symptoms can be useful. Dosage reduction in those children with Tourette's disorder who have been administered neuroleptics long term may be complicated by withdrawal dyskinesias and significant tic worsening or rebound. Withdrawal dyskinesias are choreoathetoid movements of the orofacial region, trunk and extremities that appear after neuroleptic discontinuation or dosage reduction and tend to resolve in 1 to 3 months. Tic worsening even above pretreatment baseline level (i.e., rebound) can last up to 1 to 3 months after discontinuation or dosage reduction. Tardive dyskinesia, which is similar in character to withdrawal dyskinesia, most often develops during the course of treatment or is "unmasked" with dosage reductions. Rarely have cases of tardive dyskinesia been reported to occur in patients with Tourette's disorder.

### Fluphenazine

Whereas fluphenazine has never undergone controlled trials, clinical experience suggests that it has somewhat fewer side effects than haloperidol. Fluphenazine has both dopamine  $D_1$  and  $D_2$  receptor-blocking activity, and the side effect profile is similar to that of haloperidol. Fluphenazine is slightly less potent than haloperidol so that starting doses are somewhat higher (0.5–1 mg/day), as are treatment doses (3–5 mg/day).

### Pimozide

Pimozide is a potent and specific blocker of dopamine  $D_2$  receptors. Its side-effect profile is generally similar to that of the other neuroleptics, although it has fewer sedative and extrapyramidal

side effects than haloperidol. In contrast to either haloperidol or fluphenazine, pimozide has calcium channel blocking properties that affect cardiac conduction, as evidenced by changes in the electrocardiogram. The coadministration of other medications that affect cardiac conduction, such as the tricyclic antidepressants (TCAs), is generally contraindicated. Baseline and follow-up electrocardiograms are important for adequate management of patients.

Beginning treatment with a dose of 1 mg/day is prudent, although with pimozide's long half-life, every-other-day dosing can be used to decrease the effective daily dose. Increases of up to 1 mg/day can occur every 5 to 7 days until symptoms are controlled. Most patients experience clinical benefit with few side effects with doses of 1 to 4 mg/day. Higher doses can be associated with more side effects. In a comparison of pimozide, haloperidol and no drug in patients with Tourette's disorder and ADHD, pimozide at 1 to 4 mg/day was useful in decreasing tics and improving some aspects of cognition that are commonly impaired in ADHD (Sallee and Rock 1994). The potential to have impact on both Tourette's disorder and ADHD symptoms with a single drug is a clear advantage that pimozide may have over other neuroleptics.

### Atypical Neuroleptics

The atypical neuroleptics appear to have replaced the standard neuroleptics as the mainstay of treatment for the psychotic disorders. Given the potentially lower risk for tardive dyskinesia with these agents, their efficacy has been assessed for tic suppression in patients with Tourette's disorder. To date there are only small controlled or open trials to guide the clinician in the use of these agents. Clozapine does not appear to be effective as a tic-suppressing agent and its hematological side effects preclude its use. Risperidone has been effective in reducing tic symptoms severity in one controlled trial (Dion *et al.*, 2002) and may have the added benefit of augmenting SSRIs in treating tic-related OCD.

Olanzapine in low doses does not appear to have the same tic-suppressing power as the typical neuroleptics which may be related to olanzapine's relatively weak dopamine  $D_2$  blocking activity. Side effects, especially weight gain, have dampened the enthusiasm for the atypicals risperidone, olanzapine and quetiapine. In one of the larger placebo-controlled trials ( $N = 56$ ) of the new neuroleptics, ziprasidone was found to be effective in reducing tic symptoms. The mean dose was low  $28 \pm 10$  mg/day. There were few side effects including a low incidence of weight gain (Gilbert *et al.*, 2000).

### Clonidine and Guanfacine

Whereas controlled trials have shown that some patients benefit with symptom reduction, the overall effect of clonidine for tic suppression and ADHD is more modest than that achieved with the "gold standards" (haloperidol and the stimulants, respectively) for these conditions (Goetz, 1993). Given clonidine's mild side-effect profile, it is often the first drug used for tic suppression, especially in those children with Tourette's disorder and ADHD. Treatment is initiated at 0.025 mg/day and increased in increments of 0.025 to 0.05 mg/day every 3 to 5 days or as side effects (sedation) allow. Usual effective treatment doses are in the range of 0.1 to 0.3 mg/day and are given in divided doses (4–6 hours apart). Higher doses are associated with side effects, primarily sedation, and are not necessarily more effective. The onset of action is slower for tic suppression (3–6 weeks) than for ADHD symptoms. Side effects, in addition to

sedation, include irritability, headaches, decreased salivation, and hypotension and dizziness at higher doses. Interestingly, owing to clonidine's short half-life, some patients experience mild withdrawal symptoms between doses. More severe rebound in autonomic activity and tics can occur if the medication is discontinued abruptly. Some patients find that clonidine in the transdermal patch form provides a more stable clinical effect and avoids multiple doses each day. Children are usually stabilized on oral doses before they are switched to the patch. A rash at the site of the patch is a common, but manageable, complication of treatment.

Guanfacine is an alpha-2-adrenergic agonist that potentially offers greater benefit than clonidine because of differences in site of action, side effects and duration of action. In nonhuman primates, guanfacine appears to bind preferentially with alpha-2-adrenergic receptors in prefrontal cortical regions associated with attentional and organizational functions. Guanfacine's long half-life offers the advantage of twice-a-day dosing, which is more convenient than the multiple dosing required with clonidine. In a randomized, placebo-controlled trial ( $N = 31$ ) of children with tics and ADHD, guanfacine in doses up to 0.3 mg/day had an average 31% reduction in tic severity compared with no reduction on placebo. Clinically the effect on tics is less than would be expected on neuroleptics (Scahill *et al.*, 2001).

### Benzodiazepines

Benzodiazepines can be useful in decreasing comorbid anxiety in patients with Tourette's disorder. In addition, clonazepam appears also to be useful in selected patients for tic reduction. Often, doses of 3 to 6 mg/day may be necessary for tic reduction. Because sedation is a significant side effect at these dosages, an extended titration phase of 3 to 6 months may be necessary. Similarly, a slow taper is required to avoid withdrawal symptoms.

### Pergolide

Agonist activity on presynaptic dopamine neurons results in decrease dopamine release and may therefore result in decreased tic severity in people with Tourette's disorder. To exploit this finding a number of small open trials of dopamine agonists and a small controlled trial of pergolide ( $N = 24$ ) have been conducted. Pergolide, a mixed  $D_1$ - $D_2$ - $D_3$  dopamine agonist often used for restless leg syndrome, was found to be superior to placebo in reducing tic severity and was associated with few adverse events (Gilbert *et al.*, 2000). Doses used were low as higher doses may be associated with dopamine agonist effects postsynaptically.

### Baclofen

Baclofen, a muscle relaxant, is GABA-B receptor agonist that acts presynaptically to inhibit the release of excitatory amino acids such as glutamate. In a small placebo controlled crossover trial ( $N = 10$ ) baclofen 20 mg t.i.d. was not found to be effective in reducing tic severity but did appear to have an effect on tic-related impairment (Singer *et al.*, 2001).

### Infection and Autoimmune-based Treatments

Several treatment studies have been undertaken based on the hypothesis that some forms of Tourette's disorder or OCD may be related to streptococcal infection. Based on the beneficial effects of penicillin prophylaxis in preventing recurrences of rheumatic fever, a similar strategy was employed in subjects meeting criteria for PANDAS (Garvey *et al.*, 1999). The study was limited

by a number of flaws and although the concept of prophylaxis is compelling, special design considerations will be required in future studies.

After small open trials with the immunomodulatory treatments such as plasma exchange or intravenous immunoglobulin (IVIG), a larger trial comparing these methods to sham IVIG was undertaken. Children meeting criteria for PANDAS ( $N = 30$ ) were randomly assigned (1:1:1) to treatment with plasma exchange (five single-volume exchanges over 2 weeks), IVIG (1 g/kg daily on two consecutive days), or placebo (saline solution given in the same manner as IVIG) and subjects were reported as doing well at 1 year (Lougee *et al.*, 2000). Although this study is encouraging there are a number of methodological problems including lack of a placebo control for plasma exchange and inclusion of uncontrolled subjects in outcome analysis after the first month. These findings do support ongoing investigation of these treatment methods but given the cost, risk and highly experimental nature of these treatments it is recommended that patients obtain these treatments only in the context of ongoing clinical investigations of these treatments at major medical research centers (for further information, see <http://intramural.nimh.nih.gov/research/pdn/web.htm>).

### Tic Suppression: Nonpharmacological

The behavioral technique shown to be most effective is habit reversal training. For Tourette's disorder, habit reversal training is the use of a competing muscle contraction or behavioral response that opposes the tic movement. This method is usually combined with relaxation training, self-monitoring, awareness training and positive reinforcement. In the few published studies of habit reversal training, there were marked overall reductions in tic frequency. Treatment averaged 20 training sessions during an 8- to 11-month period. Marked tic reduction was noted at 3 to 4 months. Interestingly, urges or sensations experienced before the tic movements also decreased with behavioral treatment (Azrin and Peterson, 1990).

### Psychosocial Treatments

There are no published systematic studies of psychosocial interventions for patients with Tourette's disorder. Most treatment efforts are based on a combination of traditional psychosocial interventions and clinical judgment.

### Education

Perhaps the most useful psychosocial and educational intervention is to make the patient aware of the Tourette Syndrome Association, both national and local chapters. This and other self-help groups can be useful as a source of support and education for patients, families and psychiatrists.

### Therapy

Individual psychotherapy can be useful for support, development of awareness, or addressing personal and interpersonal problems more effectively. Family therapy can be useful when families have problems adjusting, functioning and communicating. Although most families do well, some families have difficulties understanding the involuntary nature of tics and may punish their children for their tics, even after diagnosis and education. Alternatively, some families have more behavior difficulties with their children after diagnosis than before. Many parents of children with Tourette's disorder inadvertently lower general behavior expectations because of confusion about what behaviors are

and are not tics, or because of the parents' desire not to add any additional stress to the youngster's life. Also, with confusion in the field regarding the scope of problems in Tourette's disorder, some parents see all maladaptive behaviors as involuntary and do not hold their children responsible for their behaviors. For children with Tourette's disorder to do well, they need support from their family to develop effective self-control in areas not affected by Tourette's disorder so that optimal adaptation can occur.

In newly diagnosed adults, psychotherapy oriented toward adequate adjustment to the diagnosis is important but not always easy. Adult patients frequently experience a mixture of relief to be finally diagnosed, with anger and resentment related to their past experiences with discrimination or inadequate medical care. Severely affected adults may also need psychotherapy to deal with the psychological and psychosocial difficulties related to having a chronic illness.

### Other Psychosocial Interventions

For children, active intervention at school is essential to create a supportive yet challenging academic and social environment. Efforts to educate teachers, principals and other students can result in increased awareness of Tourette's disorder and tolerance for the child's symptoms.

Many young adults are finding Tourette's disorder support and social groups important for interpersonal contact and continued adult development. Efforts to keep people with Tourette's disorder working are important, as are rehabilitation efforts for those who are not working. Finding housing and obtaining disability or public assistance may be necessary for the most disabled patients with Tourette's disorder.

### Genetic Counseling

One question commonly asked by young adults with Tourette's disorder is their risk for having a child with Tourette's disorder. Given the fact that many who present for clinical attention with Tourette's disorder have comorbid conditions, genetic counseling of people with Tourette's syndrome should include not only the risk for Tourette's disorder but also the risk for other neuropsychiatric problems such as ADHD or OCD that may be part of the young person's history. In addition, because the base rate of neuropsychiatric disorders is high, it is not uncommon for spouses of people with Tourette's disorder to have a neuropsychiatric disorder. In providing counseling to these couples it is important that genetic counseling be conducted not just about Tourette syndrome, but about the other conditions that occur as part of the young couple's history.

## Treatment of Cooccurring Psychiatric Disorders in Tourette's Disorder

### Treatment of Attention-deficit/Hyperactivity Disorder

#### Nonpharmacological Approaches

The nonpharmacological approaches to ADHD in Tourette's disorder are similar to approaches in children without Tourette's disorder. The presence both at home and at school of a structured environment, consistent behavioral management, and a generally positive, rewarding atmosphere can produce significant improvement in ADHD symptoms. Increasingly, there are specific

programs for children with ADHD that go beyond basic positive programming and include more intensive and specific behavioral approaches.

### Pharmacological Treatments

The two major difficulties in the treatment of ADHD in Tourette's disorder are the risk of side effects from the stimulants and desipramine, arguably the most potent treatment agents for ADHD and the lack of adequate alternatives.

### Stimulants

In the early 1970s, a number of reports of induction or exacerbation of tics by stimulant medications raised concerns about the role of stimulants as a cause of Tourette's disorder. At that time, the concern was that stimulants could be causing tics *de novo* or that increases in tic severity would endure even if stimulant medications were discontinued. Concurrent with these reports, other authors noted that tic induction or exacerbation was relatively infrequent and that the beneficial effects in some patients with Tourette's disorder outweighed any negative impact on tic severity.

As a result, stimulants have been used infrequently for ADHD in Tourette's disorder. However, results of short-term and long-term double-blind, placebo-controlled trials with stimulants in Tourette's disorder are positive and support a role for stimulants in some patients with Tourette's disorder plus ADHD. Increasingly, psychiatrists are cautiously, and with fully informed consent, using stimulant medication in selected children and adolescents with Tourette's disorder and ADHD. In the patient in whom tics are increased by stimulants, combined treatment with stimulants and tic-suppressing agents can be used.

More recently, in a large ( $N = 136$ ) multicenter double-blind, placebo-controlled trial, children with ADHD and a chronic tic disorder were randomly assigned to clonidine alone, methylphenidate alone, clonidine plus methylphenidate or placebo for the treatment of their ADHD. The results suggest that the active treatments were superior to placebo, with the combination treatment being the most effective. With respect to worsening of tic severity the percentage of children with worsening of tics was similar in each of the medication conditions including placebo. For methylphenidate, 20% reported tic increases compared with 26% on clonidine alone and 22% on placebo. Interestingly tic severity lessened in all active treatment groups even in the methylphenidate group. Other side effects were predictable with sedation commonly associated with clonidine treatment (The Tourette Syndrome Study Group, 2002). Given the controversy regarding the coadministration of clonidine and methylphenidate it is important to note the absence of cardiac toxicity in children on combined medication.

Given the above, informed consent prior to initiating stimulant medication should include information regarding the risks for new onset of tics or tic exacerbations. In Table 30.2 is a listing of topics that might be useful to address during informed consent. This listing is not intended to be a comprehensive or exhaustive.

### Desipramine

Desipramine is a TCA with prominent noradrenergic activity that has been noted to improve attention and concentration in children and adolescents with ADHD and Tourette's disorder plus ADHD. Symptom improvement is often significant with lower doses than needed for depression. Side effects are generally limited. The cardiac side effects of increased heart rate and elevation in blood pressure are usually not clinically significant; however, reports

**Table 30.2 Informed Consent for Stimulants**

- Parent education about the complexity of presentation and relevant information about ADHD and tics.
- Tics go up and down, usually tics increase with excitement and stress and go down with calm, focused activity. Such changes will likely continue to occur while on stimulants.
- Predictable exacerbation each year – starting and ending school, winter holidays, vacations, parties, etc.
- Over the lifetime tics tend to decrease in mid to late teens.
- Risk of stimulants for tic exacerbation
  - Controlled trials demonstrate that tics go up, go down, or stay the same with stimulant treatment. In approximately 20% of children tics will increase regardless of treatment medication or placebo. There is no clear association as previously thought.
  - Longer-term studies suggest that when tics do appear to increase on stimulants there is a reasonable chance they are reversible with discontinuation of stimulant medication.
  - It is possible that there is greater risk in younger children than teens.
- Parents have to understand the following: “If you are willing, you need to understand that your kid’s tics may go up and not come down with medication treatment. Or if there are no tics now that tics may start and continue. This is very unfortunate it could be related to medication but it might have been his time for his tics either to begin or worsen”.
- Doctors should understand the following: Do not start if parents are not really prepared. It is better for parents to make a risk–benefits decision after gaining knowledge, experience and perspective while under your care.

of sudden death in children and adolescents taking desipramine have resulted in marked reductions nationally in the use of desipramine in children and adolescents.

### Nortriptyline

Given the concern about the cardiac effects of desipramine, TCAs such as nortriptyline have been used for the treatment of ADHD. The only available report, a chart review, assessed the effect of nortriptyline in children and adolescents with Tourette’s disorder plus ADHD. The majority of subjects experienced moderate to marked improvement in both ADHD and tics (Wilens *et al.*, 1993). Although the concern regarding sudden death is less with nortriptyline than with desipramine, it is prudent to obtain baseline and follow-up electrocardiograms.

### Clonidine and Guanfacine

Data supporting the efficacy of these agents has been limited to open trial or small controlled trials. In the largest trial to date subjects ( $N = 34$ ; mean age of 10.4 years) were randomly assigned to 8 weeks of guanfacine or placebo. Guanfacine was superior to placebo (37 versus 8%) in reduction of the total score on the teacher-rated ADHD Rating Scale and significant differences were also observed in omission and commission errors on a continuous performance test (Scahill *et al.*, 2001).

### Selective Noradrenergic Reuptake Inhibitors (SNRIs)

One SNRI has recently been approved for the treatment of ADHD in children and one is under FDA review for major depression. Atomoxetine has been demonstrated to be effective and approved for use in children and adults with ADHD. Given its mechanism of action it is possible that atomoxetine could improve ADHD symptoms without exacerbating tic symptoms. Studies are currently underway. Similarly reboxetine, which has an indication in Europe for depression, may be useful for ADHD in people with tics disorders.

### Treatment of Obsessive–Compulsive Disorder

#### Nonpharmacological Approaches

The positive role of cognitive–behavioral treatments of OCD is well established in adults. Most reports of nonpharmacological treatment of OCD in children and adolescents are case studies. Only one report has a sufficient sample size and a protocol-driven, cognitive–behavioral treatment regimen to begin to establish the possible role of such treatment in children and adolescents with OCD. There are no specific reports of cognitive–behavioral treatment or other nonpharmacological treatments of OCD in adults or children with Tourette’s disorder. Given the success of cognitive–behavioral treatment in OCD, it is likely that patients with Tourette’s disorder and OCD will also be able to benefit from cognitive–behavioral treatment.

#### Pharmacological Treatments

The number of agents available for the treatment of OCD in patients with and without Tourette’s disorder is increasing. Currently available agents include the TCA clomipramine and the specific serotonin reuptake inhibitors fluoxetine, sertraline, paroxetine, fluvoxamine and citalopram. Even though only a few of these agents have a specific indication for OCD (clomipramine and fluvoxamine), others may be effective in OCD given their serotonergic activity. The choice of agent depends on the side-effect profile, the potential drug interactions and the psychiatrist’s familiarity with the drug.

With the exception of clomipramine, all of the available agents have mild and somewhat similar side-effect profiles. Drug interaction issues must be taken into account, especially in children with complex presentations or multiple medical conditions given the increased possibility of multiple drug regimens. The reports of elevated TCA levels in patients receiving TCA and fluoxetine are good examples of unforeseen drug interactions with the specific serotonin reuptake inhibitors.

Increasingly, augmentation strategies are pursued in patients with OCD and with Tourette’s disorder plus OCD, when clinical symptoms remain after initial treatment. A number of strategies have been used, including augmentation with lithium, neuroleptics, buspirone, clonazepam, liothyronine sodium (T3) and fenfluramine. Although positive outcomes of these strategies have been reported in open trials, only neuroleptic augmentation has shown to be of any benefit in controlled trials. Interestingly, controlled trials of haloperidol combined with specific serotonin reuptake inhibitors in patients with Tourette’s disorder and OCD demonstrated improvement in both tic and OCD symptoms.

## Treatment-refractory Cases

Strategies for approaching two types of treatment-refractory symptoms are discussed here: 1) patients who are truly treatment-refractory with severe and impairing symptoms of Tourette's disorder and OCD, despite conventional and heroic treatments, and 2) patients, often children, who are clinically complex and enigmatic, and whose impairment is disproportionately greater than their tic, obsessive-compulsive, or ADHD symptoms would suggest.

## Treatment-refractory Tics

Perhaps the most important "treatment" in patients with severe incapacitating tics is a full clinical reevaluation to assess the adequacy of previous evaluations and treatment efforts. It is not uncommon for treatment-refractory patients to have had inadequate evaluations and treatment trials.

Two alternative treatment strategies are available for truly treatment-refractory tics. When a single tic or a few tics are refractory and impairing, the injection of botulinum toxin into the specific muscle group can be helpful. This strategy is most useful for painful, dystonic tics. Treatment has a long duration of action, but the effect does decrease in 2 to 4 months, and repeated injections may be necessary. Specific side effects are few, other than weakness in the affected muscle. Some patients reported the loss of the premonitory sensation with their botulinum toxin treatment. For the psychiatrist, it is essential to work with a neurologist experienced in using botulinum toxin.

There have been reports in the literature and the media concerning the use of neurosurgical approaches for the treatment of refractory tics. To date, the optimal size and location of the surgical treatment lesions are not known. There are no well-controlled trials, although some data are available from patients with OCD and tics who were treated for OCD. In these patients, the impact on tic severity was mixed. Because these approaches are particularly controversial, it is important, before considering neurosurgical approaches, to complete a detailed and exhaustive reevaluation to determine whether all other treatment options are exhausted. It is also important that patients who pursue neurosurgical approaches consider centers of clinical excellence where controlled treatment trials are ongoing.

## Treatment-refractory Obsessive-Compulsive Disorder

A similarly thorough and exhaustive reevaluation is critical for patients with Tourette's disorder plus OCD who present as treatment-refractory. Diagnostic reevaluation focuses on whether other psychiatric disorders are present and disabling and whether the current hierarchy of clinical disability considers all conditions.

Pharmacological reevaluation is especially critical because there are an increasing number of new medications and potential medication combinations. Rather than repeated change from one antiobsessional agent to another, consideration can be given to augmentation strategies, because they take less time than changing agents and may offer synergistic benefits. Low-dose neuroleptic augmentation is the best first choice; controlled trials support the use of low-dose neuroleptics for augmentation of serotonin reuptake inhibitors in OCD. Lithium and T3 are proven, effective augmenters of antidepressants for depression, yet neither is proven effective in OCD. Because of the frequent overlap of OCD and major depression, lithium or T3 augmentation may be the next best choice.

Treatment-refractory or malignant OCD has been the psychiatric disorder most frequently treated with neurosurgical interventions in the modern era. Whereas it is a major treatment intervention, the surgical approaches are somewhat better defined, and the outcome in severe cases is often positive. Also, medical centers are available that specialize in the presurgical work-up and the neurosurgical procedure.

## Clinically Complex Patients

Clinically complex patients may be severely impaired without having severe tic or OCD symptoms. The clinically complex patient is often a diagnostic dilemma with additional diagnoses complicating the clinical picture. In addition, patients can become clinically complex when otherwise straightforward treatments are a challenge to implement.

## Diagnosis

In clinically complex patients, the diagnostic challenge is not an accurate assessment of tics, ADHD, obsessive-compulsive symptoms, or LDs, although this is important. In clinically complex patients, the diagnostic goal is to identify what other conditions or factors may be present that make the current treatment approaches difficult.

From a strictly diagnostic point of view, it is the additional psychiatric conditions beyond Tourette's disorder, OCD, ADHD and LDs that often escape clinical observation and result in diagnostic dilemmas and treatment failures.

## Treatment Implementation

Clinical problems occur when the treating psychiatrist does not have access to critical information or is not in control of the treatment process. Traditionally, psychiatrists develop a relationship with the patient and the other major figures in the patient's life. Given the current clinical climate, a comprehensive level of involvement can be overwhelming and enormously time-consuming for the psychiatrist. Because it is increasingly difficult for the psychiatrist to be as involved as necessary, problems with poorly coordinated team efforts and the psychiatrist's lack of awareness of important clinical issues can have a negative impact on the treatment of a patient.

Psychiatrists who work with children and adolescents may wish to consider changes in their treatment approaches to these patients. Experience in tertiary care centers suggests that expanded time with the parents is a critically important and efficient approach to care. Psychiatrists who form a treatment partnership with families, respecting and addressing their concerns, educating them about Tourette's disorder, training them to evaluate and manage complex behaviors, and empowering them to be an effective advocate for their child, are providing good care. In working directly with families, the collection of important information regarding the family's and patient's functioning is direct and regular, and often small interventions can produce changes in family functioning that have a positive ripple effect throughout the life of the child.

## Pharmacological Treatment Dilemmas

It is often difficult to obtain accurate information regarding side effects and treatment response in child patients. Parents, children and psychiatrists, in spite of a good collaborative effort, may have different understandings of the target symptoms, side-effect profile, and what constitutes a positive clinical response. This ambiguity makes any but the most robust clinical responses difficult

to observe. Again, experience at tertiary referral centers suggests that the lack of a clinical response to medication in complex patients may often be related to inadequate monitoring of medicine effects and inadequate treatment trials.

Clinically complex patients may not have a robust response to a single medication but may require multiple medication trials to identify which medications offer the most benefit, and in which combination. Sequential treatment trials are difficult for all involved, especially children and families, who are often looking for a single powerful intervention. With the added complexity of treatment, there is the added risk of confusion and the need for an excellent psychiatrist–patient–family relationship. In those cases in which the relationship is not optimal, it is possible that a patient may not have the maximal clinical benefit of pharmacological interventions.

With increasing numbers of available psychotropic medications, psychiatrists become increasingly less experienced with the range of clinical effects and side effects in individual medications. In clinically complex patients, the prescription of unfamiliar medications may be necessary but may add to the risk that a trial will be discontinued prematurely because of doubt about a side effect. In addition, unusual side effects, such as the apathy or disinhibition syndromes seen with some patients receiving the specific serotonin reuptake inhibitors, may go unnoticed and add to clinical morbidity.

Whereas pharmacological interventions offer great promise, clinical experience suggests that excellent diagnostic skills, good relationships with the patient and family, time, and a keen eye for effects and side effects are necessary for benefits to be realized. Less intensive efforts may make patients appear more complex than necessary.

### Comparison of DSM-IV/ICD-10 Diagnostic Criteria

The ICD-10 and DSM-IV-TR criteria sets for the tic disorders are almost identical.

# Childhood Disorders: Elimination Disorders and Childhood Anxiety Disorders

## Enuresis

### Definition

Functional enuresis is usually defined as the intentional or involuntary passage of urine into bed or clothes in the absence of any identified physical abnormality in children older than 4 years of age. It is often associated with psychiatric disorder and enuretic children are frequently referred to mental health services for treatment.

### Course and Natural History

The acquisition of urinary continence at night is the end stage of a fairly consistent developmental sequence. Bowel control during sleep marks the beginning of this process and is followed by bowel control during waking hours, bladder control during the day, and finally night-time bladder control. Most children achieve this final stage by the age of 36 months. With increasing age, the likelihood of spontaneous recovery from enuresis decreases. The chronic nature of the condition is further shown in the study by Rutter and colleagues (1973), in which only 1.5% of 5-year-old bed-wetters became dry during the next 2 years.

### Enuresis (Not Due to a Medical Condition)

**This disorder is characterized by the repeated voiding of urine into clothes or bed at the age of 5 (chronologically or developmentally) or older for a period of at least twice weekly over three months. Enuresis reflects a significant emotional distress or impairment in social, academic or other important areas of functioning.** Enuresis may be either diurnal (during waking hours) or nocturnal (during night-time sleep) or a combination of both.

Nocturnal enuresis is as common in boys as girls until the age of 5 years, but by age 11 years, boys outnumber girls 2:1. Not until the age of 8 years do boys achieve the same levels of night-time continence that are seen in girls by the age of 5 years, probably due to slower physiological maturation in boys. In addition, the increased incidence of secondary enuresis (occurring after an initial 1-year period of acquired continence) in boys further affects the sex ratio seen in later childhood. Daytime enuresis occurs more commonly in girls and is associated with higher rates of psychiatric disturbance.

### Etiology and Pathophysiology

Possible biological factors include a structural pathological condition or infection of the urinary tract (or both), low functional bladder capacity, abnormal antidiuretic hormone secretion, abnormal depth of sleep, genetic predisposition and developmental

delay. Evidence has also been found for sympathetic hyperactivity and delayed organ maturation as seen by delay in ossification.

Obstructive lesions of the urinary outflow tract, which can cause urinary tract infection (UTI) as well as enuresis, have been thought to be important, with a high prevalence of such abnormalities seen in enuretic children referred to urologic clinics. This degree of association is not seen at less specialized pediatric centers, however, and most studies linking urinary outflow obstruction to enuresis are methodologically flawed (Shaffer *et al.*, 1979). Structural causes for enuresis should be considered the exception rather than the rule.

UTI has been found to occur frequently in children, especially girls and a large proportion (85%) of them have been shown to have nocturnal enuresis. Also, in 10% of bedwetting girls, urinalysis results show evidence of bacterial infection. The consensus is that as treating the infection rarely stops the bedwetting, UTI is probably a result rather than a cause of enuresis.

The concept that children with enuresis have low functional bladder capacities has been widely promoted. Shaffer and colleagues (1984) found a functional bladder capacity one standard deviation lower than expected in 55% of a sample of enuretic children in school clinics. Although low functional capacity may predispose the child to enuresis, successful behavioral treatment does not appear to increase that capacity, rather the sensation of a full (small) bladder promotes waking to pass urine so that enuresis does not occur. Reduction of nocturnal secretion of antidiuretic hormone (ADH) has been described in a small number of children with enuresis, causing excessive amounts of dilute urine to be produced during the night and overwhelming bladder capacity. Several mechanisms are associated with enuresis, including increased nocturnal urine volume, small nocturnal functional bladder capacity, increased spontaneous bladder contractions, and the inability to arouse to the stimulus of a large and/or contracting bladder. This may identify two main groups of children with enuresis: those who demonstrate nocturnal spontaneous bladder contractions (detrusor dependent enuresis) and those with nocturnal polyuria (volume dependent enuresis).

Approximately 70% of children with nocturnal enuresis have a first-degree relative who also has or has had nocturnal enuresis. Twin studies have shown greater monozygotic (68%) than dizygotic (36%) concordance. An association between enuresis and early delays in motor, language and social development has been noted in both prospective community samples and a large retrospective study of clinical subjects (Steinhausen and Gobel, 1989). Genetic factors are probably the most important in the etiology of nocturnal enuresis but somatic and psychosocial

environmental factors have a major modulatory effect. Most commonly, nocturnal enuresis is inherited via an autosomal dominant mode of transmission with high penetrance (90%). However, a third of all cases are sporadic. Four gene loci associated with nocturnal enuresis have been identified but the existence of others is presumed (locus heterogeneity). Other psychosocial correlates described include delayed toilet training, low socioeconomic class, stress events and other child psychiatric disorders. Stress events seem to be more clearly associated with secondary enuresis. Reported events include the birth of a younger, early hospitalizations and head injury (Chadwick, 1985).

Psychiatric disorder occurs more frequently in enuretic children than in other children, although no specific types have been identified (Mikkelsen and Rapoport, 1980). The relative frequency of disorder ranges from two to six times that in the general population and is more frequent in girls, in children who also have diurnal enuresis and in children with secondary enuresis.

There is little evidence that enuresis is a symptom of underlying disorder because psychotherapy is ineffective in reducing enuresis, anxiolytic drugs have no antienuretic effect, tricyclic antidepressants exert their therapeutic effect independent of the child's mood, and purely symptomatic therapies, such as the bell and pad, are equally effective in disturbed and nondisturbed children. A further explanation for the association is that enuresis, a distressing and stigmatizing affliction, may cause the psychiatric disorder. However, although some studies have shown that enuretic children who undergo treatment become happier and have greater self-esteem, other studies show that psychiatric symptoms do not appear to lessen in children who are successful with a night alarm. A final possibility is that enuresis

and psychiatric disorder are both the result of joint etiological factors such as low socioeconomic status, institutional care, large sibships, parental delinquency, and early and repeated disruptions of maternal care. Shared biological factors may also be important in that delayed motor, speech and pubertal development, already shown to be associated with enuresis, have proven to be more frequent in disturbed enuretic children than in those without psychiatric disorder.

## Diagnosis and Differential Diagnosis

The presence or absence of conditions often seen in association with enuresis should be assessed and ruled out as appropriate (Figure 31.1). Other causes of nocturnal incontinence should be excluded, for example, those leading to polyuria (diabetes mellitus, renal disease, diabetes insipidus) and, rarely, nocturnal epilepsy.

## Assessment

### History

Information on the frequency, periodicity and duration of symptoms is needed to make the diagnosis and distinguish functional enuresis from sporadic seizure-associated enuresis. If there is diurnal enuresis, an additional treatment plan is required. A family history of enuresis increases the likelihood of a diagnosis of functional enuresis and may explain a later age at which children are presented for treatment. Projective identification by the affected parent—whereby the parent does not separate feelings about himself having the diagnosis and the current experience of the affected child—may further hinder treatment. For subjects

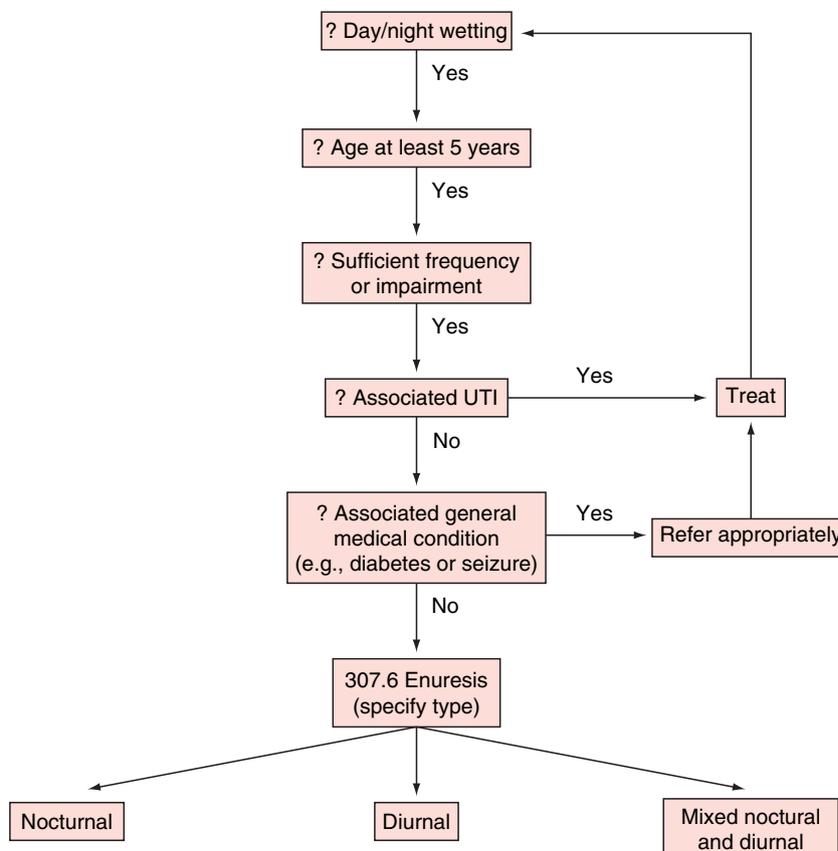

Figure 31.1 Diagnostic decision tree for enuresis.

with secondary enuresis, precipitating factors should be elicited, although such efforts often represent an attempt to assign meaning after the event.

Questions that are useful in obtaining information for treatment planning include “Why is this a problem?” and “Why does this need treatment now?” because these factors may influence the choice of treatment (is a rapid effect needed?) or point to other pressures or restrictions on therapy. It is important to inquire about previous management strategies used at home, for example, fluid restriction, nightlifting (getting the child out of bed to take to the toilet in an often semi-asleep state), rewards and punishments. Parents often come with the assertion that they have tried everything and that nothing has helped. Examining the reasons for failure of simple strategies is useful for ensuring that more sophisticated treatments do not befall the same fate. There is little evidence that fluid restriction is useful, although nightlifting may be beneficial for the large number of children who never reach professional attention. Rewards are usually material and are given only for unreasonably high performance levels, with the delay between action and reward being too long. Physical punishment and verbal chastisements, ineffective at best, may well maintain the enuresis. Punishment is often too harsh and tends to be applied inconsistently depending on parental mood. If specific treatments have been prescribed, either behavioral or pharmacological, it is important to discover the reasons they may have failed.

## Mental Status Examination

The child’s views and any misconceptions that he or she may have about the enuresis, its causes and its treatment should be fully explored. Asking the child for three wishes may help determine whether the enuresis is a concern to the child. This may unmask marked embarrassment or guilt from behind a facade of denial about the problem and can be educational for parents who believe their children could stop wetting “if only they wanted to or tried harder”. Pictures drawn by the child that describe how the child views himself or herself when enuresis is a problem and when it is not appropriate for younger children and can graphically illustrate the misery experienced by children with enuresis.

## Physical Examination

All children should have a routine physical examination, with particular emphasis placed on detection of congenital malformations indicative of urogenital abnormalities. A midstream specimen of urine should be examined for the presence of infection. Radiological or further medical investigation is indicated only in the presence of infected urine, enuresis with symptoms suggestive of recurrent UTI (frequency, urgency and dysuria), or polyuria.

## Treatment

Practical management for nocturnal enuresis is presented in Table 31.1.

**Table 31.1 Practical Management of Nocturnal Enuresis**

Stage 1	Assessment
	Obtain history: frequency, periodicity and duration of wetting. Why is this a problem? Why now? Mental status: views and misconceptions (parent and child). Discover reasons for previous failure or failures. Perform routine physical examination (any minor congenital abnormalities?). Midstream specimen of urine must be obtained. Radiology and further physical investigation is needed only if symptoms or evidence of urinary tract infection (dysuria and frequency or positive culture results) or polyuria.
Stage 2	Advice
	Education that enuresis is common and not deliberate. Aim to reduce punitive behavior. Transmit optimism: however, anticipate disappointment at no instant cure. Preview the stepwise recovery and warn of the possibility of relapse.
Stage 3	Baseline
	Use star chart. Focus on positive achievements (be creative). Examine the effect of simple interventions (e.g., lifting)
Stage 4	Night Alarm
	First-line management unless important to obtain rapid short-term effect. Demonstrate night alarm equipment in the office. Telephone follow-up within a few days of commencing therapy. Or <b>Drug Therapy</b>
	If rapid suppression of wetting is needed (e.g., before vacation or camp, to defuse aggressive or hostile situation between child and parents and siblings). When family has proved incapable of using the equipment. After failure or multiple relapses. Medication of choice: DDAVP (Desmopressin) 20–40 µg at night

The overall goals of treatment can depend on the reason for referral. Commonly, the child is brought to the physician before some planned activity, for example, a family vacation or a trip to camp, and the need is for a rapid (e.g., pharmacological) short-term therapy. A gradual behavioral approach would not likely meet with much approval even though it may offer a chance for a permanent cessation of wetting.

### Standard Treatment

About 10% of children have a reduction in the number of wet nights after a single visit to a clinician in which the only intervention was the recording of baseline wetting frequency and simple reassurance. Such reassurance should make clear that enuresis is a biological condition that is made worse by stress and that may be associated in a noncausal way with other psychiatric disorders. Younger children can be told that their problem is shared by many others of the same age. The excellent prognosis for patients who comply with therapy should be stressed. Recording the frequency of enuresis can be achieved by using a simple star chart. This is most effective if performed by the child, who records each dry night with a star. The completed chart is then shown to the parents on a daily basis, and they can provide appropriate praise and reinforcement.

### Waking and Fluid Restriction

Although systematic studies have failed to show any effect of these interventions with enuretic inpatients, it may be that these strategies work for the majority of enuretic children who are not referred for treatment.

### Surgery

Based on the premise that enuresis is causally associated with outflow tract obstruction, various surgical procedures have been advocated, for example, urethral dilatation, meatotomy, cystoplasty and bladder neck repair. This cannot be supported because, in addition to the dubious concept of outflow tract obstruction per se, the surgery does not alter the urodynamics of the bladder. Reported positive treatment effects are slight (no controlled studies exist), and there remains a significant potential for adverse effects (urinary incontinence, epididymitis and aspermia).

### Pharmacotherapy

Although it has been repeatedly demonstrated that temporary suppression rather than cure of enuresis is the usual outcome of drug therapy, it remains the most widely prescribed treatment in the USA. Four classes of drugs have principally been employed: synthetic antidiuretic hormones, tricyclic antidepressants, stimulants and anticholinergic agents.

**Synthetic Antidiuretic Hormone** A number of randomized double-blind placebo-controlled trials (RCT) have shown that the synthetic vasopeptide DDAVP (desmopressin) is effective in enuresis. The drug is usually administered intranasally, although oral preparations of equal efficacy have been developed (equivalent oral dose is 10 times the intranasal dose). Almost 50% of children are able to stop wetting completely with a single nightly dose of 20 to 40 µg of DDAVP given intranasally. A further 40% are afforded a significant reduction in the frequency of enuresis with this treatment. As with tricyclic antidepressants, however, when treatment is stopped, the vast majority of individuals relapse. Side effects of this medication include nasal pain and con-

gestion, headache, nausea and abdominal pain. Serious problems of water intoxication, hyponatremia and seizures are rare. It is important to be aware that intranasal absorption is reduced when the patient has a cold or allergic rhinitis. The mode of action of desmopressin is unknown. It may reduce the production of night-time urine to an amount less than the (low) functional volume of the enuretic bladder, thereby eliminating the urge to micturate. With regard to identifying those most likely to respond to DDAVP treatment, it has been found that those most likely to be permanently dry are infrequent wetting older children who respond to lower dose (20 µg) desmopressin.

**Tricyclic Antidepressants** The short-term effectiveness of imipramine and other related antidepressants has also been demonstrated via many RCTs. Imipramine reduces the frequency of enuresis in about 85% of bed-wetters and eliminates enuresis in about 30% of these individuals. Night-time doses of 1 to 2.5 mg/kg are usually effective and a therapeutic effect is usually evident in the first week of treatment. Relapse after withdrawal of medication is almost inevitable, so that 3 months after the cessation of tricyclic antidepressants, nearly all patients will again have enuresis at pretreatment levels. Side effects are common and include dry mouth, dizziness, postural hypotension, headache and constipation. Toxicity after accidental ingestion or overdose is a serious consideration, causing cardiac effects, including arrhythmias and conduction defects, convulsions, hallucinations and ataxia. Concern has been expressed about the possibility of sudden death (presumably caused by arrhythmia) in children taking tricyclic drugs. The mode of action for tricyclic antidepressants is unclear, although one observation is that tricyclic agents seem to increase functional bladder volumes possibly resulting from noradrenergic reuptake inhibition.

**Stimulant Medication** Sympathomimetic stimulants such as dexamphetamine have been used to reduce the depth of sleep in children with enuresis; but because there is no evidence that enuresis is related to abnormally deep sleep, their lack of effectiveness in stopping bed-wetting is no surprise. Used in combination with behavioral therapy, there is some evidence that stimulants can accentuate the learning of nocturnal continence.

**Anticholinergic Drugs** Drugs such as propantheline, oxybutynin and terodiline can reduce the frequency of voiding in individuals with neurogenic bladders, reduce urgency and increase functional bladder capacity. There is no evidence, however, that these anticholinergic drugs are effective in bed-wetting, although they may have a role in diurnal enuresis. Side effects are frequent and include dry mouth, blurred vision, headache, nausea and constipation.

### Psychosocial Treatments

The night alarm was first used in children with enuresis in the 1930s. This system used two electrodes separated by a device (e.g., bedding) connected to an alarm. When the child wet the bed, the urine completed the electrical circuit, sounded the alarm and the child awoke. All current night alarm systems are merely refinements on this original design. A vibrating pad beneath the pillow can be used instead of a bell or buzzer, or the electrodes can be incorporated into a single unit or can be miniaturized so that they can be attached to night (or day) clothing. With treatment, full cessation of enuresis can be expected in 80% of cases. Reported cure rates (defined as a minimum of

14 consecutive dry nights) have ranged from 50 to 100%. The main problem with this form of enuretic treatment, however, is that cure is usually achieved only within the second month of treatment. This factor may influence clinicians to prescribe pharmacological treatments that, although more immediately gratifying, do not offer any real prospect of cure. It has been suggested that adjuvant therapy with methamphetamine or desmopressin will reduce the amount of time before continence is achieved. Using a louder auditory stimulus or using the body-worn alarm may also improve the speed of treatment response. Factors associated with delayed acquisition of continence include failure of the child to wake with the alarm, maternal anxiety and a disturbed home environment, although no influence has been seen regarding the age of the child or the initial wetting frequency.

A further consequence of the delayed response to a night alarm is premature termination occurring in as many as 48% of cases and is more common in families that have made little previous effort to treat the problem, in families that are negative or intolerant of bed-wetting, and in children who have other behavioral problems. Compliance-reducing factors also include failure to understand or follow the instructions, failure of the child to awaken, and frequent false alarms. The only reported side effect of treatment with the night alarm is “buzzer ulcers” caused by the child lying in a pool of ionized urine. This problem has been eliminated with modern transistorized alarms that do not employ a continuous, relatively high voltage across the electrodes to detect enuresis.

Relapse after successful treatment, if it occurs, will usually take place within the first 6 months after cessation of treatment. It is reported that approximately one-third of children relapse; however, no clear predictors of relapse have been identified.

Table 31.2 presents various remedies for night alarm problems.

### Ultrasonic Bladder Volume Alarm

Although the traditional enuresis alarm has good potential for a permanent cure, the child is mostly wet during treatment. Furthermore, the moisture alarm requires that the child make the somewhat remote association between the alarm event and a full bladder after the bladder has emptied. In an exploratory study (Pretlow, 1999), a new approach to treating nocturnal enuresis was investigated using a miniature bladder volume measurement instrument during sleep. In this, an alarm sounded when bladder volume reached 80% of the typical enuretic volume. Two groups were studied. Group 1 used the night-time device alone; group 2, in addition, had supplementary daytime bladder retention training (aiming to increase functional capacity). In groups 1 and 2 the mean dryness rate before study initiation versus during the study was 32.9 and 9.3% versus 88.7 and 82.1%, respectively. Night-time bladder capacity increased 69% in group 1 and 78% in group 2, while the cure rate was 55% (mean treatment period 10.5 months) and 60% (mean treatment period 7.2 months), respectively.

### Acupuncture

The efficacy of traditional Chinese acupuncture has been studied (Serel *et al.*, 2001) in a small ( $n = 50$ ) clinical sample. It was reported that within 6 months, 86% of patients were completely dry and a further 10% of patients were dry on at least 80% of

**Table 31.2 Problem Solving for the Night Alarm If...**

Bell “does not work”	Check position, connections and batteries. If using separating sheet, check that it is porous. Check that child is not turning off equipment. Place alarm out of easy reach.
Child does not wake	Make alarm louder. Parent should wake child.
Child does not become dry	Ensure compliance. Ensure that child responds promptly. Use adjuvant DDAVP or dextroamphetamine. Ensure that child has robe (e.g., change own bed-sheets) after alarm.
False alarms	Ensure that separating sheet is big enough, not soiled and will insulate. Use thicker nightclothes.
Relapse	Repeat treatment. Consider over learning after response to re-treatment.

nights. Relapse rates appeared better than with psychopharmacologic agents.

### Summary

There were approximately 22 randomized trials conducted between 1985 and 1997 involving 1100 children treated pharmacologically or behaviorally for primary nocturnal enuresis. The quality of many of these trials is poor with very few trials comparing drugs with each other, or drugs with alarms or other behavioral interventions, and few having adequate follow-up periods. Desmopressin and tricyclics appeared equally effective while on treatment, but this effect was not sustained after treatment stopped. It is clear that further comparisons between drug and behavioral treatments are needed, and should include relapse rates after treatment is finished.

### Assessment and Management of Diurnal Enuresis

Daytime enuresis, although it can occur together with night-time enuresis, has a different pattern of associations and responds to different methods of treatment. It is much more likely to be associated with urinary tract abnormalities and to be comorbid with other psychiatric disorders. As a result, a more detailed and focused medical and psychiatric evaluation is indicated. Urine should be checked repeatedly for infection, and the threshold for ordering ultrasonographical visualization of the urological system should be low. The history may make it apparent that the daytime wetting is situation specific. For example, school-based enuresis in a child who is too timid to ask to use the bathroom could be alleviated by the teacher’s tactfully reminding the child to go to the bathroom at regular intervals.

Observation of children with diurnal enuresis has established that they do experience an urge to pass urine before micturition but that either this urge is ignored or the warning comes too late to be of any use because of an “irritable bladder”. Therefore, treatment strategies are based on establishing a pattern of toileting before the times that diurnal enuresis is likely to occur (usually between 12 noon and 5 pm) and using positive reinforcement to promote regular use of the bathroom.

Portable systems that can be worn on the body and use a sensor in the underwear as well as an alarm that can be worn on the wrist have been developed. Studies have shown no significant differences between the wetness alarm and the simple timed alarm. The easiest therapeutic alternative, therefore, is to buy the child a digital watch with a countdown alarm timer.

Unlike nocturnal enuresis, drug treatment with tricyclic antidepressants such as imipramine is ineffective, whereas the use of anticholinergic agents such as oxybutynin and terodiline shows a therapeutic impact on the frequency of daytime enuresis.

## Encopresis

### Definition

Encopresis is usually defined as the intentional or involuntary passage of stool into inappropriate places in the absence of any identified physical abnormality in children older than 4 years. It may not be attributable to a medical condition and must occur at least monthly for a period of three months. The distinction is drawn between encopresis with constipation (retention with overflow based on history or physical examination) and encopresis without constipation. Other classification schemes include making a primary–secondary distinction (based on having a 1-year period of continence) or soiling with fluid or normal feces.

### Course and Natural History

Less than one-third of children in the USA have completed toilet training by the age of 2 years with a mean age of 27.7 months. Bowel control is usually achieved before bladder control.

The age cutoff for “normality” is set at 4 years, the age at which 95% of children have acquired fecal continence (Stein and Susser, 1967). As with urinary continence, girls achieve bowel control earlier than boys.

### Epidemiology

The overall prevalence of encopresis in 7- and 8-year-old children has been shown to be 1.5%, with boys (2.3%) affected more commonly than girls (0.7%). There was a steadily rising likelihood of continence with increasing age, until by age 16 years the reported prevalence was almost zero. Rutter and coworkers (1970) reported a rate of 1% in 10- to 12-year-old children, with a strong (5 : 1) male/female ratio. Retrospective study of clinic-referred encopretic children has shown that 40% of cases are primary (true failure to gain control), with a mean age of 6.7 years, and 60% of cases are secondary, with a mean age of 8 years (Levine, 1975). Eighty percent of patients were constipated, with no difference in this feature seen between primary and secondary subtypes.

### Etiology and Pathophysiology

Within the first year of life, children can show a tendency toward constipation, with concordance for constipation being six times

### Clinical Vignette 1

John, an 8-year-old boy, was the sixth child in a sibship. He was brought by his mother for treatment of nocturnal enuresis which was occurring on average five times a week, with no particular pattern. Two of his elder brothers had also wet the bed until the age of 10 and 13 years, respectively, as had his biological father who was no longer living with the family. The mother had become exasperated with John's wetting and had begun punishing him by forcing him to wash his bedclothes by hand every morning before school. His brothers made fun of him, and peers at school avoided him because he frequently came to school still smelling of stale urine. He was not allowed to have anything to drink after 6 pm, and a star chart was currently being used without much success. No praise was given for the two dry nights per week because his mother was convinced that this meant the enuresis was deliberate. John drew a picture describing the terror and anxiety of having a wet night. His three wishes were to stop wetting, to get a Nintendo machine of his own and to find a real dinosaur fossil.

The initial management included an explanation of the condition, microbiological analysis of a midstream specimen of urine and instructions on baseline recording using the star chart. Overt punishments were eliminated, although John was expected to help change his sheets, and effort was expended in trying to help his mother praise him for the dry nights he was able to achieve. After a 2-week baseline period, urinalysis results came back negative and the frequency of enuresis remained at four to five nights per week. John and his mother were instructed in the use of a night alarm and were telephoned 2 days later to check on any problems. It appeared that John was not waking with the buzzer, and they were instructed to place the alarm unit on an old cookie tin to amplify the sound. Dry nights were recorded on John's chart, with verbal praise after each one.

An initial target of three dry nights per week was set, with the promise of a trip to the movies for John and the two brothers who shared a bedroom with him. This was achieved the first week, although it took a further 6 weeks before he went a full week without a wet bed. After 2 weeks of continence, the restriction on night-time fluids was relaxed without incident. Six months later he remained dry, and school and home relationships were markedly improved.

more frequent in monozygotic than in dizygotic twins. Fecal retention and reduced stool frequency between 12 and 24 months of age can predict later encopresis. Encopretic children with constipation and overflow are found to have rectal and colonic distention, massive impaction with hard feces and a number of specific abnormalities of anorectal physiology. These abnormalities, which may be primary or secondary to constipation, include elevated anal resting tone, decreased anorectal motility and weakness of the internal anal sphincter, and dysfunction of the external anal sphincter. Encopresis may occur after an acute episode of constipation following illness or a change in diet. In addition to the pain caused by attempts to pass an extremely hard stool, a number of specific painful perianal conditions such as

anal fissure can lead to stool withholding and later fecal soiling. Stressful events such as the birth of a sibling or attending a new school have been associated with up to 25% of cases of secondary encopresis. In nonretentive encopresis, the main theories center on faulty toilet training. Stress during the training period, coercive toileting leading to anxiety and “pot phobia”, and failure to learn or to have been taught the appropriate behavior have all been implicated. True fecal urgency, which may have a physiological or pathological basis, may also be important in a small proportion of cases (Woodmansey, 1967).

### Diagnosis and Differential Diagnosis

The main efforts during the diagnostic process are to establish the presence or absence of constipation and, to a lesser extent, distinguish continuous (primary) from discontinuous (secondary) soiling (Figure 31.2). Taylor and Hersov (1994) listed three types of identifiable encopresis in children: 1) it is known that the child can control defecation, but she or he chooses to defecate in inappropriate places; 2) there is true failure to gain bowel control, and the child is unaware of or unable to control soiling; and 3) soiling is due to excessively fluid feces, whether from constipation and overflow, physical disease, or anxiety. In practice, there is frequently overlap among types or progression from one to another. Unlike enuresis, fecal soiling rarely occurs at night or during sleep, and if present, is indicative of a poor prognosis. Soiling due to anal masturbation has been reported, although this causes staining of the sheets rather than full stools in the bedclothes.

### Phenomenology

In the first group, in which bowel control has been established, the stool may be soft or normal (but different from fluid-type feces seen in overflow). Soiling due to acute stress events (e.g.,

the birth of a sibling, a change of school, or parental separation) is usually brief once the stress has abated, given a stable home environment and sensible management. In more severe pathological family situations, including punitive management or frank physical or sexual abuse (Boon, 1991), the feces may be deposited in places deliberately to cause anger or irritation, or there may be associated smearing of feces on furniture and walls. Other covert aggressive antisocial acts may be evident, with considerable denial by the child of the magnitude or seriousness of the problem.

In the second group, in which there is failure to learn bowel control, a nonfluid stool is deposited fairly randomly in clothes, at home and at school. There may be conditions such as mental retardation or specific developmental delay, spina bifida, or cerebral palsy that impair the ability to recognize the need to defecate and the appropriate skills needed to defer this function until a socially appropriate time and location. In the absence of low IQ or pathological physical condition, patients have been reported as having associated enuresis, academic skills problems and antisocial behavior. They present to pediatricians primarily and are usually younger (age 4–6 years) than other encopretic individuals. It is thought that this type of soiling is considerably more common in socially disadvantaged, disorganized families because of stressful, faulty or inconsistent training.

In the third group, excessively fluid feces are passed, which may result from conditions that cause true diarrhea (e.g., ulcerative colitis) or, much more frequently, from constipation with overflow causing spurious diarrhea. A history of retention, either willful or in response to pain, is prominent in the early days of this form of encopresis, although later it may be less apparent because of fecal overflow. Behavior such as squatting on the heels to prevent defecation or marked anxiety about the prospect of

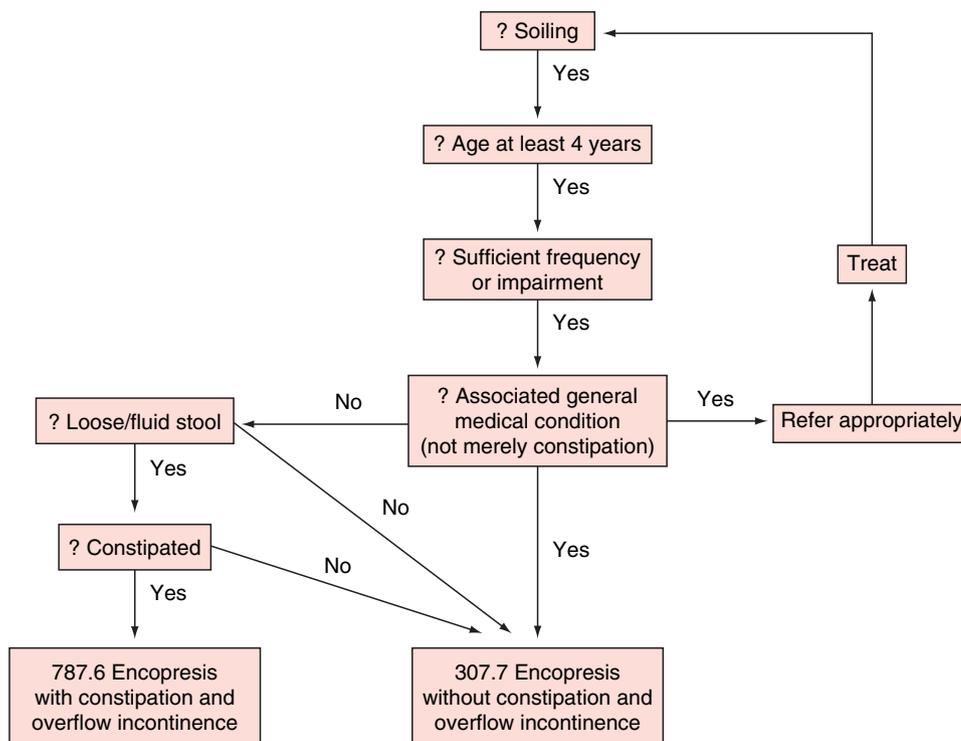

Figure 31.2 Diagnostic decision for encopresis.

using the toilet (although rarely amounting to true phobic avoidance) may be described.

### Issues and Further Assessment

The comprehensive assessment process should include a medical evaluation, psychiatric and family interviews, and a systematic behavioral recording.

The medical evaluation comprises a history, review of systems, physical examination, and appropriate hematological and radiological tests. Although the vast majority of patients with encopresis are medically normal, a small proportion have pathological features of etiological significance. Physical causes of encopresis without retention include inflammatory bowel disease (e.g., ulcerative colitis, Crohn's disease), central nervous system disorders, sensory disorders of the anorectal region or pelvic floor muscles (e.g., spina bifida, cerebral palsy). Organic causes of encopresis with retention include Hirschsprung's disease (aganglionosis in intermuscular and submucous plexuses of the large bowel extending proximally from the anus), neurogenic megacolon, hypothyroidism, hypercalcemia, chronic codeine or laxative usage, anorectal stenosis and fissure. It should also be remembered that these conditions rarely have their first presentation with encopresis alone.

The physical assessment should include an abdominal and rectal examination, although a plain abdominal radiograph is the most reliable way to determine the presence of fecal impaction. Anorectal manometry should be considered in the investigation of children with severe constipation and chronic soiling, especially those in whom Hirschsprung's disease is suspected.

Psychiatric and family interviews should include a developmental history and a behavioral history of encopresis (antecedents, behavior and consequences). Specific areas of stress, acute or chronic, affecting the child or family, or both, should be discovered. Associated psychopathological conditions are more commonly found in the older child, in secondary encopresis, and when soiling occurs not only in clothes. Anxiety surrounding toileting may indicate pot phobia, coercive toileting, or a history of painful defecation. A history should be obtained of the parents' previous attempts at treatment together with previously prescribed therapy so that reasons for previous failure can be identified and anticipated in future treatment planning.

### Treatment

Practical management for encopresis is presented in Table 31.3.

#### Standard Treatment

The principal approach to treatment is predicated on the results of the evaluation and the clinical category assigned. This differentiates between the need to establish a regular toileting procedure in patients in whom there has been a failure to learn this social behavior and the need to address a psychiatric disorder, parent-child relationship difficulties, or other stresses in the child who exhibits loss of this previously acquired skill in association with these factors. In both cases, analysis of the soiling behavior may identify reinforcing factors important in maintaining dysfunction. Detection of significant constipation will, in addition, provide an indication for adjuvant laxative therapy.

#### Behavioral Treatments

Behavioral therapy is the mainstay of treatment for encopresis. In the younger child who has been toilet trained, this focuses on practical elimination skills, for example, visiting the toilet after

**Table 31.3 Practical Management of Encopresis**

Stage 1	Assessment
	Whether primary or secondary. Is there physical cause? Presence or absence of constipation. Presence or absence of acute stress. Presence or absence of psychiatric disorder including phobic symptoms or smearing. ABC (antecedents, behavior, consequences) of encopresis including secondary gain. Discover reasons for previous failure or failures.
Stage 2	Advice
	Education regarding diet, constipation and toileting. Aim to reduce punitive or coercive behavior. Transmit optimism; however, anticipate disappointment at no instant cure. Preview the stepwise recovery and warn of the possibility of relapse.
Stage 3	Toileting
	Baseline observation using star chart. Focus on positive achievements, e.g., toileting, rather than soiling. High-fiber diet (try bran in soup, milk shakes). Toilet after meals, 15 min maximum. Check that adequately rising intra-abdominal pressure is present. Graded exposure scheme if "pot phobic" with
	Laxatives
	Indicated if physical examination or abdominal radiograph shows fecal loading. Medication of choice: Senokot syrup (senna) up to 10 mL b.i.d., lactulose syrup up to 30 mL (20 mg) b.i.d. Dosage will be reduced over time; titrate with bowel frequency.
	Enemas
	Microenema (e.g., bisacodyl, 30 mL) if the bowel is excessively loaded with rock-like feces.
Stage 4	Biofeedback
	Consider after relapse or failure to respond to toileting or laxatives.

each meal, staying there for a maximum of 15 minutes, using muscles to increase intra-abdominal pressure and cleaning oneself adequately afterward. Parents or caretakers, or both, need to be educated in making the toilet a pleasant place to visit and should stay with the younger child, giving encouragement and praise for appropriate effort. Small children whose legs may

dangle above the floor should be provided with a step against which to brace when straining. Initially, a warm bath before using the toilet may relax the anxious child and make it easier to pass stool. Systematic recording of positive toileting behavior, not necessarily being clean (depending on the level of baseline behavior), should be performed with a personal star chart. For the child with severe anxiety about sitting on the toilet, a graded exposure scheme may be indicated.

### Role of the Family in Treatment

Removing the child's and family's attention from the encopresis alone and focusing onto noticing, recording and rewarding positive behavior often defuses tension and hostility and provides the opportunity for therapeutic improvement. Identifying and eliminating sources of secondary gain, whereby soiling is reinforced by parental (or other individuals') actions and attention, even if negative or punitive, make positive efforts more fruitful. Some investigators advocate mild punishment techniques, such as requiring the child to clean his or her own clothes after soiling, although care must be taken to prevent this from becoming too punitive. In certain settings, particularly school, attempts are made to prevent soiling by extremely frequent toileting that, although keeping the child clean, does not promote and may even hinder the acquisition of a regular bowel habit. Formal therapy, either individual or family based, is indicated in only a minority of patients with an associated psychiatric disorder, marked behavioral disturbance, or clear remediable family or social stresses.

### Physical Treatments

In patients with retention leading to constipation and overflow, medical management is nearly always required, although it is usually with oral laxatives or microenemas alone. The use of more intrusive and invasive colonic and rectal washout or surgical disimpaction procedures is nearly always the result of the clinician's impatience rather than true clinical need.

Uncontrolled studies of combined treatment with behavioral therapy and laxatives reported marked improvement in symptoms (not cure) in approximately 70 to 80% of patients. A more recent controlled randomized trial (Nolan *et al.*, 1991) comparing behavioral therapy in retentive primary encopresis with and without laxatives showed that at 12-month follow-up, 51% of the combined treatment (laxative plus behavioral therapy) group had achieved remission (at least one 4-week period with no soiling episodes), compared with 36% of the behavioral therapy only group ( $P = 0.08$ ). Partial remission (soiling no more than once a week) was achieved in 63% of patients with combined therapy versus 43% with behavioral therapy alone ( $P = 0.02$ ). Patients receiving laxatives achieved remission significantly sooner, and the difference in the Kaplan–Meier remission curves was most striking in the first 30 weeks of follow-up ( $P = 0.012$ ). When patients who were not compliant with the toileting program were removed from the analysis, however, the advantage of combined therapy was not significant. These results must also be viewed in light of a 50% spontaneous remission rate at 2 years reported in some studies.

### Biofeedback Therapy

The finding that some children with treatment-resistant retentive encopresis involuntarily contract the muscles of the pelvic floor and the external anal sphincter, effectively impeding passage of stool, has led to efforts to use biofeedback in this instance. It

has similarly been reported that as few as six sessions of biofeedback therapy can lead to a significant reduction in symptom frequency for as many as 86% of previously treatment-resistant patients (Loening-Baucke, 1995). It is possible, however, that biofeedback is principally of benefit to nonretentive chronic soilers (van Ginkel *et al.*, 2000).

## Other Disorders Specific to Children and Adolescents

### Separation Anxiety Disorder

#### Definition

Separation anxiety disorder is typified by developmentally inappropriate and excessive anxiety concerning separation from home or attachment figures. This diagnosis is included within the child and adolescent disorders because, although adults may have separation problems/symptoms, a diagnosis of separation anxiety disorder is not made in adulthood. The onset of this disorder, therefore, must be prior to the age of 18 years. Symptoms (a minimum of three) must be present for at least four weeks and cause significant distress or impairment in social or academic functioning. Excessive and developmentally inappropriate levels of anxiety are manifested by the following behaviors:

- Fears and worry about losing, or about harm befalling significant attachment figures.
- Recurrent and intense distress when leaving home or attachment figures.
- Reluctance or refusal to attend school.
- Excessive worry about separation from an attachment figure through getting lost or kidnapped.
- Inability to feel comfortable being alone without the presence of attachment figures or other adults.
- Difficulty in sleeping without being in the presence of an attachment figure.
- Frequent anxiety dreams about separation.
- Repeated complaints of symptom such as nausea, vomiting, stomach aches, headaches, prior to threatened separation from an attachment figure.

The diagnosis of early onset separation anxiety disorder is made when symptoms appear prior to the age of six years.

#### Natural History and Course

The community prevalence of SAD is generally estimated to be around 4% in children and young adolescents; it decreases in prevalence from childhood through adolescence. Amongst clinically referred subjects (aged 5–18 years) with anxiety disorders, separation anxiety disorder was found to be the most frequently occurring disorder, with a lifetime prevalence of 44.7%. The age of onset has been reported to be 4 to 7 years, with earlier onset being associated with clinical status and comorbidity (Biederman *et al.*, 1997). Separation anxiety, particularly in younger samples, is found more frequently in girls than boys: a ratio as high as 2.5:1. In a 3- to 4-year prospective study (Last *et al.*, 1996) of subjects with anxiety disorders, 29% of children had separation anxiety disorder (21% had SAD as their primary diagnosis) at baseline. On follow-up, 92% of children previously diagnosed with SAD no longer had symptoms that met full criteria for SAD,

although 25% had developed a new disorder, most frequently a depressive disorder. Finding that 50% of adult panic patients had experienced separation anxiety during childhood, it has been hypothesized that separation anxiety may be a childhood precursor to adult panic disorder and agoraphobia.

### Etiology and Pathophysiology

Sensitivity to suffocation cues, important in the carbon dioxide (CO<sub>2</sub>) challenge paradigm in panic disorder and respiratory response, may differentiate children with anxiety disorder, and separation anxiety in particular, from children without an anxiety disorder. Inhalation of air containing raised CO<sub>2</sub> concentration results in increased catecholamine release throughout the body and perceived anxiety. This response appears mediated via the locus coeruleus, a group of norepinephrine-containing neurons originating in the pons and projecting to all major brain areas. The locus coeruleus forms part of the reticular activating system (RAS) and functions to regulate noradrenergic tone and activity. Hypothalamic and thalamic nuclei also play a role in the perception of and response to external threats. They act by transmitting arousal information from the RAS to limbic and cortical areas involved in sensory integration and perception. The thalamus is thought to have a role in the perception of anxiety, whereas the hypothalamic nuclei mediate the response by the neuroendocrine system. Urinary cortisol has been shown to be raised (indicative of HPA overactivity) in infants aged 1 year who demonstrated extreme distress when separated from their primary attachment figure.

Separation anxiety, when developmentally appropriate, is seen via attachment theory as an adaptive response that infants use to enhance proximity to their caregivers. In this, when the infant has adequate proximity to the caregiver in a given context, attachment behaviors (separation anxiety symptoms) subside and are replaced by alternate behaviors. On the basis of their response to various experimental paradigms, infants can be categorized into having different types of attachment. Although the nosology of attachment has varied, the most frequently described type of pathological attachment is known as “insecure attachment”. Excessive distress on separation evinced by insecurely attached infants appears to be the earliest manifestation of separation anxiety disorder, but this pattern is not specific, in that it can be the precursor of other types of anxiety (e.g., social phobia/avoidant disorder, panic disorder) in childhood and adolescence.

### Diagnosis and Differential Diagnosis

The assessment strategy will depend upon the child's age, symptom profile, the sources of available information and the purpose of the assessment. As discussed above, separation anxiety is normal at some ages and is maximal around 14 months of age. The most prevalent symptoms in young children (aged 5–8 years) are worry about losing or about possible harm to an attachment figure, and reluctance or refusal to go to school. Children aged 9 to 12 years most frequently reported recurrent excessive distress when separated from home or attachment figures, whereas adolescents (aged 13–16 years) had physical symptoms on school days. More symptoms were reported with decreasing age.

The usual unstructured clinical interview can, in view of its poor reliability and variable symptom coverage, be supplemented by standardized diagnostic interviews such as the Diagnostic Interview Schedule for Children (DISC) or the Anxiety

Disorder Interview Schedule (ADIS) which have shown acceptable test–retest reliability and validity. In addition, there are a large number of self-report questionnaires that can assess children's fears and anxieties, either to detect anxiety disorders in community samples or to distinguish between different anxiety disorders in clinically referred children. The most useful of these are the Multidimensional Anxiety Scale for Children (MASC) (March *et al.*, 1997) and the Screen for Child Anxiety Related Emotional Disorders (SCARED) (Birmaher *et al.*, 1997). These have been shown to have good test–retest reliability, internal consistency and can differentiate not only anxious children from nonanxious children but also distinguish specific anxiety disorders from each other. Particularly with younger children, there is value to direct observation of the child either in determining the diagnosis or in behavioral analysis.

Other issues in assessment of separation anxiety include: the relative value of information from differing methodologies, how to integrate information from separate informants, and also the cultural validity of most measures of anxiety. Differential diagnoses to consider include generalized anxiety disorder (GAD), where the anxiety is more free-floating, less situation-specific and occurs independent of separation from the primary attachment figure. Children with social phobia will display a fear of social situations where they may be the object of public scrutiny. This anxiety may be ameliorated by the presence of a familiar person but will not occur exclusively when the attachment figure is absent, as with separation anxiety.

School refusal has long been associated with separation anxiety disorder, though this relationship holds mainly for younger children when school nonattendance is most closely linked to fear of separation, whereas in adolescents fear of school and social-evaluative situations is more typical. It is important in the assessment of school nonattendance, a frequent impairment associated with SAD, to distinguish anxiety-related school refusal from conduct disorder–related truancy. Typically the school-refusing child will stay at home or with parents, whereas the truanting child will go off with peers. In the presence of school refusal, a useful approach (Kearney and Silverman, 1999) is to attempt to categorize the behavior as fulfilling one of the four following functions:

1. Avoidance of stimuli provoking specific fearfulness or anxiety (e.g., separation).
2. Escape from aversive social or evaluative situations (e.g., social phobia).
3. Attention-getting behavior (e.g., physical complaints/tantrums).
4. Positive tangible reinforcement (e.g., parental collusion).

### Treatment

Following a good behavioral and functional analysis, the most frequently employed clinical approach to the treatment of separation anxiety and school refusal is behavioral. The principles of systematic desensitization to feared objects or situations will be employed, gradually increasing the amount of separation that can be tolerated in a graduated fashion. Systematic desensitization usually has three components. First, a response, incompatible with anxiety (relaxation techniques), is taught. The second component is the collaborative construction of a hierarchy of feared situations. These will range from the very mild (producing mild disquiet) to the most anxiety provoking (avoided at all costs!). It is important to include a great deal of specificity in

describing these situations including the duration spent in the feared situation, the degree to which others are involved, and the distance from home/attachment figure. After ranking these feared situations, the final component of treatment is the regular progression of exposure to feared situations whilst employing anxiety management techniques. It is important that the child is allowed to exercise some control over the speed with which new settings are experienced. The avoidance of reinforcement of unwanted behaviors and the promotion of fear-coping strategies is similarly important.

In the particular example of school refusal associated with separation anxiety, it is important to encourage an early return to school so that secondary impairments (academic failure and social isolation) are minimized. Generally, if the period of absence has been less than 2 months then return is very often successful.

In older subjects, cognitive approaches may be more successful than the primary behavior strategies usually employed with younger children. Cognitive approaches postulate that the child's maladaptive thoughts, beliefs and attitudes (schema) cause or maintain the experience of anxiety. Treatment consists of identifying negative self-statements ("I can't ever do this") or external beliefs ("If I'm not there my Mom won't be able to cope"), and replacing them with more adaptive beliefs.

Pharmacological treatment studies of separation anxiety similarly have tended to focus on samples with school refusal behavior and various diagnostic status and/or comorbidity. Early studies used imipramine or clomipramine with varying success. Considering safety and efficacy, the SSRIs appear to be the first-line treatment for separation anxiety disorder, but more studies are needed to confirm preliminary results. Tricyclic antidepressants and benzodiazepines may be considered when the child has not responded to SSRIs or when adverse effects have exceeded benefits. There is some evidence that treatments can be additive or synergistic. Alternatively, when combining drug and psychosocial treatments, a lower dose of one or both may be possible, with a resultant decrease in expense, inconvenience, or adverse events. Drug effects are often seen sooner than those due to exposure-based therapy, though it is hoped that the slower to emerge benefits of therapy may be more long lasting.

## Selective Mutism

### Definition

The essential feature of selective mutism is the persistent failure for at least one month (but not limited to the first month after the start of school) to speak in specific social situations where speaking is expected, despite speaking in other situations (most commonly in the home). Children with this disorder become impaired in social and educational settings. Selective mutism must not be diagnosed when there is a lack of knowledge or comfort speaking, for example, when a child is an immigrant.

### Epidemiology

Previously referred to as **elective mutism**, in DSM-IV-TR the condition was renamed **selective mutism**, so as to be less judgmental. The prevalence is usually reported as 0.6 to seven per 1000, with higher incidence in females rather than males. When subjects failing to speak in the first few weeks of school (a DSM-IV-TR requirement) are excluded, rates do not exceed two per

1000. Onset is usually in the preschool years, but the peak age of presentation and diagnosis is between 6 and 8 years. A high incidence of insidious onset of refusal to speak with anyone except family members is reported. The other typical picture is one of acute onset of mutism on starting school.

### Etiology

Three basic theories have been proposed to explain the etiology of selective mutism: children who are negative, oppositional and controlling; traumatized children; and children who have severe anxiety, chiefly social phobia. Although early psychodynamic theorists described an enmeshed relationship between mother and child, the father being distant and ineffectual, and a conflicted relationship between the parents, the only two controlled studies of selective mutism did not find family functioning worse compared with the families of other emotionally disturbed children (Kolvin and Fundudis, 1981; Wilkins, 1985). Associated features include a history of delayed speech and articulation problems, and possibly increased incidence of enuresis and/or encopresis. There may be a family history of general shyness, or of elevated levels of anxiety in the parents.

### Assessment

Prior to making a diagnosis of selective mutism, a comprehensive evaluation should be conducted to rule out other explanations for mutism and to assess important comorbid factors. For obvious reasons, the parental interview will form the mainstay of evaluation but, as discussed below, direct observation (and interview if it is possible) of the child can afford important diagnostic information important to obtain information of the nature of the onset (insidious or sudden), any uncharacteristic features (i.e., not talking to family members, abrupt cessation of speech in one setting, absence of communication in all settings) suggestive of other neurological or psychiatric disorders (e.g., pervasive developmental disorders, acquired aphasia), and any history of neurological insult/injury, developmental delays, or atypical language and/or speech. The assessment should also include the degree to which nonverbal communication or non-face-to-face communication is possible, the presence of anxiety symptoms in areas other than speaking, social and behavioral inhibition, medical history including ear infections and hearing deficiencies. Parents will be able to give information on where and to whom the child will speak, the child's speech and language complexity at home, articulation problems, use of nonverbal communication (e.g., gestures), any history of speech and language delays, and the possible importance of bilingualism (where primary language is not English). It can be useful to have the parents provide an audiotape of the child speaking at home. The child evaluation can assess the presence of anxiety and social inhibition (willingness to communicate through gesture or drawing). Physical examination of oral sensory and motor ability may provide evidence of neurological problems (i.e., drooling, asymmetry, orofacial weakness, abnormal gag reflex, impaired sucking or swallowing). Specialist audiometry (pure tone and speech stimuli as well as tympanometry and acoustic reflex testing) may provide evidence of hearing and/or middle ear problems that can have a significant effect on speech and language development. Cognitive abilities may be difficult to assess, but the performance section of the WISC-R or Raven's Progressive Matrices as well as the Peabody Picture Vocabulary Test may be useful in the nonverbal child.

## Treatment

Treatment has long been regarded as difficult and the prognosis poor. Approaches have included behavioral therapy, family therapy, speech therapy and, more recently, pharmacological agents. Unfortunately most published studies are single case reports, with very few controlled studies.

Behavioral treatment focuses on mutism as a means of getting attention and/or escaping from anxiety. A controlled study (Calhoun and Koenig, 1973) of eight subjects with random assignment to treatment (teacher and peer reinforcement of verbal behavior) or control showed significant increases in mean number of vocalizations after 5 weeks of treatment. These gains were not, however, maintained at 12-month follow-up. Other techniques have included graded exposure, shaping and modeling. The goal of a treatment program should be to decrease the anxiety associated with speaking whilst encouraging the child to interact verbally.

Regarding pharmacotherapy, the use of SSRI medication in cases of selective mutism with associated anxiety (principally social phobia) has promise. An open trial of 21 children using a mean dose of 28.1 mg/day of fluoxetine showed improvement in 76% of cases (Dummit *et al.*, 1996). A placebo-controlled double-blind study showed mixed results, though both groups remained highly symptomatic. More chronic (>14 weeks) treatment was recommended (Black and Uhde, 1994).

## Comparison of DSM-IV/ICD-10 Diagnostic Criteria

In contrast to DSM-IV-TR which establishes a minimum duration of 3 months for encopresis, the ICD-10 Diagnostic Criteria for Research has set a minimum duration of 6 months. In ICD-10, this disorder is referred to as “Nonorganic Encopresis”.

For enuresis, the ICD-10 Diagnostic Criteria for Research have a different frequency threshold: at least twice a month in children aged under 7 years and at least once a month in children aged 7 years or more. In contrast, DSM-IV-TR requires either a frequency of twice a week for at least three consecutive months (regardless of age) or else the presence of clinically significant distress or impairment. Furthermore, ICD-10 includes a very strict exclusion criterion, preventing a diagnosis of enuresis to be made if there is any evidence of another mental disorder. In ICD-10, this disorder is referred to as “nonorganic enuresis”.

For separation anxiety disorder, the DSM-IV-TR and ICD-10 symptom items are almost identical. The ICD-10 Diagnostic Criteria for Research are narrower in that the age of onset must be before the age of six years and the diagnosis cannot be made if the presentation is “part of a broader disturbance of emotions, conduct, or personality”. The DSM-IV-TR criteria and ICD-10 Diagnostic Criteria for Research for selective mutism are almost identical. In ICD-10, the disorder is referred to as “elective mutism”.

This chapter reviews dementia, delirium, amnesic and other cognitive disorders. Traditionally, these conditions have been classified as organic brain disorders to distinguish them from such diseases as schizophrenia, mania and major depressive disorder, the so-called functional disorders. With the publication of the DSM-IV, the distinction between functional and organic disorders was eliminated. Significant research into the neurobiological aspects of psychiatric disorders and the utilization of sophisticated neurodiagnostic tests such as positron emission tomographic scanning in individuals with schizophrenia led to the inescapable conclusion that every psychiatric condition has a biological component. Thus the term functional became obsolete and even misleading.

The conditions formerly called organic are classified in DSM-IV into three groupings: 1) delirium, dementia, and amnesic and other cognitive disorders; 2) mental disorders due to a general medical condition; and 3) substance-related disorders (American Psychiatric Association, 1994). Delirium, dementia and amnesic disorders are classified as cognitive because they feature impairment in such parameters as memory, language, or attention as a cardinal symptom. Each of these three major cognitive disorders is subdivided into categories that ascribe the etiology of the disorder to a general medical condition, the persisting effects of a substance, or multiple etiologies. A "not otherwise specified" category is included for each disorder (American Psychiatric Association, 1994).

In the case of delirium, the primary disturbance is in the level of consciousness with associated impairments in orientation, memory, judgment and attention. Dementia features cognitive deficits in memory, language and intellect. The amnesic disorder is characterized by impairment in memory in the absence of clouded consciousness or other noteworthy cognitive dysfunction. In general, the cognitive disorders should represent a decline from a previous higher level of function, of either acute (delirium) or insidious (dementia) onset, and should interfere with the patient's social or occupational functioning (American Psychiatric Association, 1994).

## Dementia, Delirium and Other Cognitive Disorders

### Dementia

Dementia is defined in DSM-IV as a series of disorders characterized by the development of multiple cognitive deficits (including memory impairment) that are due to the direct physiological effects of a general medical condition, the persisting effects of

a substance, or multiple etiologies (e.g., the combined effects of a metabolic and a degenerative disorder) (American Psychiatric Association, 1994). The disorders constituting the dementias share a common symptom presentation and are identified and classified on the basis of etiology. The cognitive deficits exhibited in these disorders must be of significant severity to interfere with either occupational functioning or the individual's usual social activities or relationships. In addition, the observed deficits must represent a decline from a higher level of function and not be the consequence of a delirium. A delirium can be superimposed on a dementia, however, and both can be diagnosed if the dementia is observed when the delirium is not in evidence. Dementia typically is chronic and occurs in the presence of a clear sensorium. If clouding of consciousness occurs, the diagnosis of delirium should be considered. The DSM-IV classification of dementia is reviewed in Table 32.1.

### Epidemiology

The prevalence of dementias is not precisely known. Estimates vary depending on the age range of the population studied and whether the individuals sampled were in the general community, acute care facilities, or long-term nursing institutions. A review of 47 surveys of dementia conducted between 1934 and 1985 indicated that the prevalence of dementia increased exponentially by age, doubling every 5 years up to age 95 years, and that this condition was equally distributed among men and women, with Alzheimer's dementia (AD) much more common in women (Slaby and Erle, 1993). A National Institute of Mental Health Multisite Epidemiological Catchment Area study revealed a 6-month prevalence rate for mild dementia of 11.5 to 18.4% for persons older than 65 years living in the community (Kallmann, 1989). The rate for severe dementia was higher for the institutionalized elderly: 15% of the elderly in retirement communities, 30% of nursing home residents and 54% of the elderly in state hospitals (Cummings and Benson, 1983).

Studies suggest that the fastest growing segment of the US population consists of persons older than the age of 85 years, 15% of whom are demented (Henderson, 1990). Half of the US population currently lives to the age of 75 years and one quarter lives to the age of 85 (Berg *et al.*, 1994). A study of 2000 consecutive admissions to a general medical hospital revealed that 9% were demented and, among those, 41% were also delirious on admission (Erkinjuntii *et al.*, 1986). The cost of providing care for demented patients exceeds \$100 billion annually (about 10% of all health care expenditures), and the average cost to families in 1990 was \$18 000 a year (Berg *et al.*, 1994).

**Table 32.1 DSM-IV Classification of Dementia**

Dementia of the Alzheimer type
Early onset vs. late onset
Uncomplicated
With delirium
With delusions
With depressed mood
Vascular dementia
Uncomplicated
With delirium
With delusions
With depressed mood
Dementia due to head trauma
Dementia due to Parkinson's disease
Dementia due to HIV disease
Dementia due to Huntington's disease
Dementia due to Pick's disease
Dementia due to Creutzfeldt–Jakob disease
Dementia due to other general medical conditions (e.g., neurosyphilis, normal-pressure hydrocephalus)
Substance-induced persisting dementia
Dementia due to multiple etiologies
Dementia not otherwise specified

## Clinical Features

Essential to the diagnosis of dementia is the presence of cognitive deficits that include memory impairment and at least one of the following abnormalities of cognition: aphasia, agnosia, apraxia, or a disturbance in executive function (American Psychiatric Association, 1994). Memory function is divided into three compartments that can easily be evaluated during a mental status examination. These are immediate recall (primary memory), recent (secondary) memory and remote (tertiary) memory. Primary memory is characterized by a limited capacity, rapid accessibility and a duration of seconds to a minute (Karp, 1984). The anatomic site of destruction of primary memory is the reticular activating system, and the principal activity of the primary memory is the registration of new information. Primary memory is generally tested by asking the individual to repeat immediately a series of numbers in the order given. For instance, if the examiner mentions the numbers 1–2–3, the patient should be able to repeat them in the same order. This loss of ability to register new information accounts in part for the confusion and frustration the demented patient feels when confronted with unexpected changes in daily routine. Secondary memory has a much larger capacity than primary memory, a duration of minutes to years, and relatively slow accessibility. The anatomic site of dysfunction for secondary memory is the limbic system, and individuals with a lesion in this area may have little difficulty repeating digits immediately, but show rapid decay of these new memories. In minutes, the patient with limbic involvement may be totally unable to recall the digits or even remember that a test has been administered (Karp, 1984). Thus, secondary memory represents the retention and recall of information that has been previously registered by primary memory. Clinically, secondary memory is tested by having the individual repeat three objects after

having been distracted (usually by the examiner's continuation of the Mental Status Examination) for 3 to 5 minutes. Like primary memory, secondary recall is often impaired in dementia. Often if the examiner gives the demented patient a clue (such as "one of the objects you missed was a color"), the patient correctly identifies the object. If this occurs the memory testing should be scored as "three out of three with a cue", which is considered to be a slight impairment. Giving clues to the demented patient with a primary memory loss is pointless, because the memories were never registered. Wernicke–Korsakoff syndrome is an example of a condition in which primary memory may be intact while secondary recall is impaired.

Tertiary (remote) memory has a capacity that is probably unlimited, and such memories are often permanently retained. Access to tertiary memories is slow, and the anatomical dysfunction in tertiary memory loss is in the association cortex (Karp, 1984). In the early stages of dementia, tertiary memory is generally intact. It is tested by instructing the individual to remember personal information or past material. The personal significance of the information often influences the patient's ability to remember it. For example, a woman who worked for many years as a seamstress might remember many details related to that occupation, but could not recall the names of past presidents or three large cities in the USA. Thus, a patient's inability to remember highly significant past material is an ominous finding. Collateral data from informants is essential in the proper assessment of memory function. In summary, primary and secondary memories are most likely to be impaired in dementia, with tertiary memory often spared until late in the course of the disease.

In addition to defects in memory, patients with dementia often exhibit impairments in language, recognition, object naming and motor skills. Aphasia is an abnormality of language that often occurs in vascular dementias involving the dominant hemisphere. Because this hemisphere controls verbal, written and sign language, these patients may have significant problems interacting with people in their environment. Patients with dementia and aphasia may exhibit paucity of speech, poor articulation and a telegraphic pattern of speech (nonfluent, Broca's aphasia). This form of aphasia generally involves the middle cerebral artery with resultant paresis of the right arm and lower face. Despite faulty communication skills, patients having dementia with nonfluent aphasia have normal comprehension and awareness of their language impairment. As a result, such patients often present with significant depression, anxiety and frustration.

By contrast, patients having dementia with fluent (Wernicke's) aphasia may be quite verbose and articulate, but much of the language is nonsensical and rife with such paraphasias as neologisms and clang (rhyming) associations. Whereas nonfluent aphasias are usually associated with discrete lesions, fluent aphasia can result from such diffuse conditions as dementia of the Alzheimer type. More commonly, fluent aphasias occur in conjunction with vascular dementia secondary to temporal or parietal lobe CVA. Because the demented patients with fluent aphasia have impaired comprehension, they may seem apathetic and unconcerned with their language deficits if they are, in fact, aware of them at all. They do not generally display the emotional distress of patients with dementia and nonfluent aphasia (Table 32.2).

Patients with dementia may also lose their ability to recognize. Agnosia is a feature of a dominant hemisphere lesion and involves altered perception in which, despite normal sensations, intellect and language, the patient cannot recognize objects. This

**Table 32.2** Classification of Aphasias

Type	Language	Comprehension	Motor
Wernicke's (receptive)	Impaired Articulate Paraphasias	Impaired	Normal
Broca's (expressive)	Nonfluent Sparse Telegraphic Inarticulate	Intact	Right hemiparesis
Global	Nonfluent Mute	Impaired	Variable right hemiplegia

is in contrast to aphasia in which the patient with dementia may not be able to name objects, but can recognize them. The type of agnosia depends on the area of the sensory cortex that is involved. Some demented patients with severe visual agnosia cannot name objects presented, match them to samples, or point to objects named by the examiner. Other patients may present with auditory agnosia and be unable to localize or distinguish such sounds as the ringing of a telephone. A minority of demented patients may exhibit astereognosis, inability to identify an object by palpation. Demented patients may also lose their ability to carry out selected motor activities despite intact motor abilities, sensory function and comprehension of the assigned task (apraxia). Affected patients cannot perform such activities as brushing their teeth, chewing food, or waving good-bye when asked to do so.

The two most common forms of apraxia in demented patients are ideational and gait apraxia. Ideational apraxia is the inability to perform motor activities that require sequential steps and results from a lesion involving both frontal lobes or the complete cerebrum. Gait apraxia, often seen in such conditions as normal-pressure hydrocephalus, is the inability to perform various motions of ambulation. It also results from conditions that diffusely affect the cerebrum. Impairment of executive function is the ability to think abstractly, plan, initiate and end complex behavior. On Mental Status Examination, patients with dementia display problems coping with new tasks. Such activities as subtracting serial sevens may be impaired.

Obviously, aphasia, agnosia, apraxia and impairment of executive function can seriously impede the ability of the demented patients to interact with their environment. An appropriate mental status examination of the patient with suspected dementia should include screening for the presence of these abnormalities.

### Associated Features and Behavior

In addition to the diagnostic features already mentioned, patients with dementia display other identifying features that often prove problematic. Poor insight and poor judgment are common in dementia and often cause patients to engage in potentially dangerous activities or make unrealistic and grandiose plans for the future. Visual-spatial functioning may be impaired, and if patients have the ability to construct a plan and carry it out, suicide attempts can occur. More common is unintentional self-harm resulting from carelessness, undue familiarity with strangers, and disregard for the accepted rules of conduct.

Emotional lability, as seen in pseudobulbar palsy after cerebral injury, can be particularly frustrating for caregivers, as are occasional psychotic features such as delusions and hallucinations. Changes in their environment and daily routine can be particularly distressing for demented patients, and their frustration can be manifested by violent behavior.

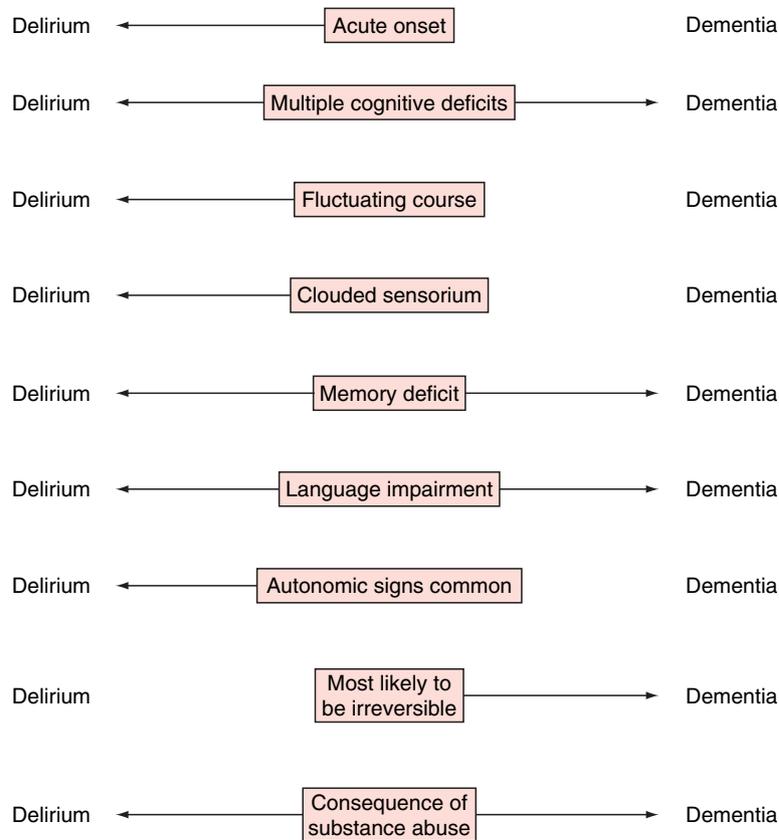

### Course

The course of a particular dementia is influenced by its etiology. Although historically the dementias have been considered progressive and irreversible, there is, in fact, significant variation in the course of individual dementias. The disorder can be progressive, static, or remitting (American Psychiatric Association, 1994). In addition to the etiology, factors that influence the course of the dementia include: 1) the time span between the onset and the initiation of prescribed treatment, 2) the degree of reversibility of the particular dementia, 3) the presence of comorbid psychiatric disorders, and 4) the level of psychosocial support. The previous distinction between treatable and untreatable dementias has been replaced by the concepts of reversible, irreversible and arrestable dementias. Most reversible cases of dementia are associated with shorter duration of symptoms, mild cognitive impairment and superimposed delirium. Specifically, the dementias caused by drugs, depression and metabolic disorders are most likely to be reversible. Other conditions such as normal pressure hydrocephalus, subdural hematomas and tertiary syphilis are more commonly arrestable.

Although potentially reversible dementias should be aggressively investigated, in reality, only 8% of dementias are partially reversible and about 3% fully reversible (Kaufman, 1990b). There is some evidence to suggest that early treatment of demented patients, particularly those with Alzheimer's type, with such agents as donepezil, which acts as an inhibitor of acetylcholinesterase, and galanthamine may slow the rate of progression of the dementia.

### Differential Diagnosis

Memory impairment occurs in a variety of conditions including delirium, amnesic disorders and depression (American Psychiatric Association, 1994). In delirium, the onset of altered memory is acute and the pattern typically fluctuates (waxing and waning) with increased proclivity for confusion during the night. Delirium is more likely to feature autonomic hyperactivity and alterations in level of consciousness. In some cases a dementia can have a superimposed delirium (Figure 32.1).

**Figure 32.1** Differentiation of delirium and dementia.

Patients with major depressive disorder often complain of lapses in memory and judgment, poor concentration and seemingly diminished intellectual capacity. Often these symptoms are mistakenly diagnosed as dementia, especially in elderly patients. A thorough medical history and mental status examination focusing on such symptoms as hopelessness, crying episodes and unrealistic guilt, in conjunction with a family history of depression, can be diagnostically beneficial. The term **pseudodementia** has been used to denote cognitive impairment secondary to a functional psychiatric disorder, most commonly depression (Korvath *et al.*, 1989). In comparison with demented patients, those with depressive pseudodementia exhibit better insight regarding their cognitive dysfunction, are more likely to give “I don’t know” answers, and may exhibit neurovegetative signs of depression. Pharmacological treatment of the depression should improve the cognitive dysfunction as well. Because of the rapid onset of their antidepressant action, the use of psychostimulants (methylphenidate, dextroamphetamine) to differentiate between dementia and pseudodementia has been advocated by some authors (Frierson *et al.*, 1991). Some authors have proposed abandonment of the term pseudodementia, suggesting that most patients so diagnosed have both genuine dementia and a superimposed affective disorder (Figure 32.2).

An amnesic disorder also presents with a significant memory deficit, but without the other associated features such as aphasia, agnosia and apraxia. If cognitive impairment occurs only in the context of drug use, substance intoxication or substance withdrawal is the appropriate diagnosis. Although mental retardation implies below average intellect and subsequent impairment in other areas of function, the onset is before 18 years

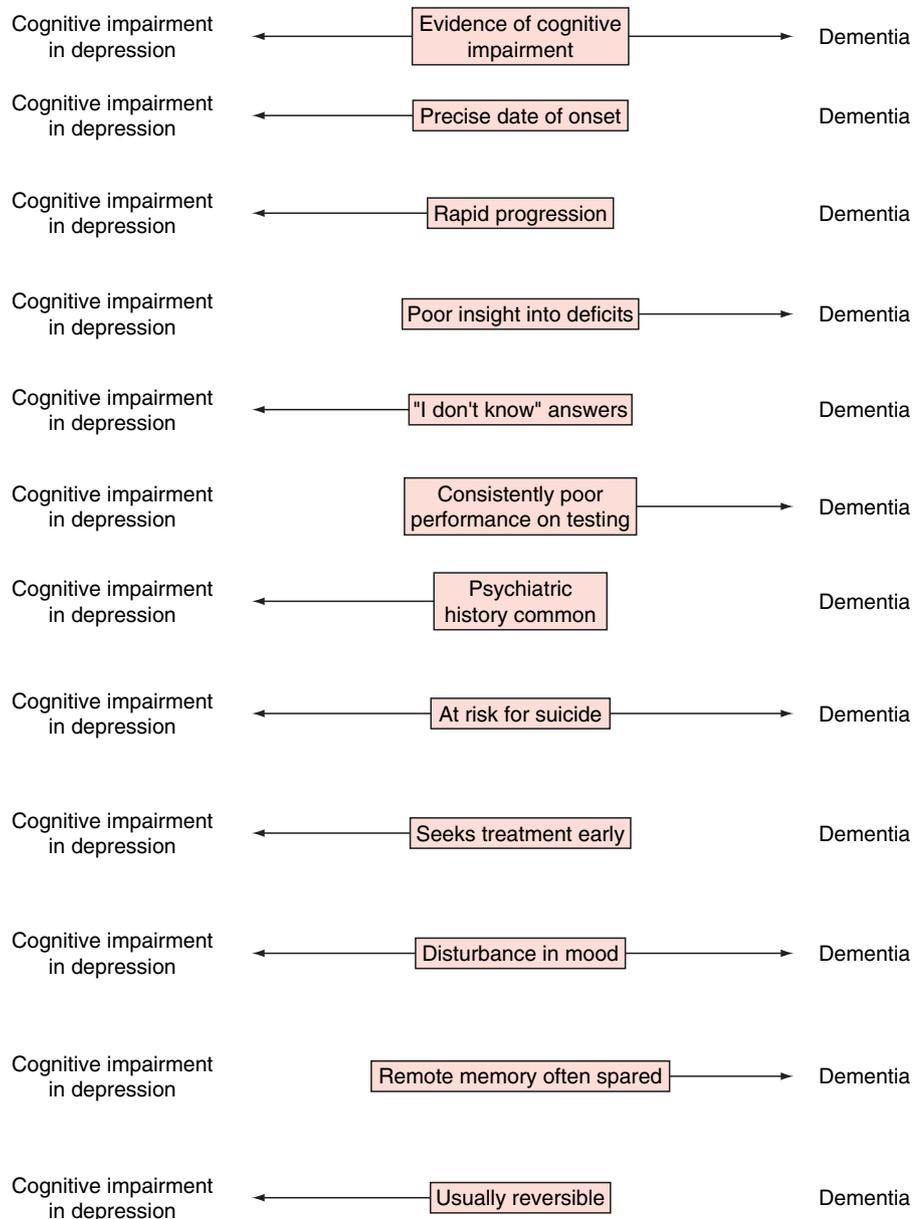

of age and abnormalities of memory do not always occur. Mental retardation must be considered in the differential diagnosis of dementias of childhood and adolescence along with such disorders as Wilson’s disease (hepatolenticular degeneration), lead intoxication, subacute sclerosing panencephalitis, HIV spectrum disorders and substance abuse, particularly abuse of inhalants. If an individual develops dementia before age 18 years and has an IQ in the mentally retarded range (i.e., below 70), an additional diagnosis of mental retardation may be justified.

Patients with schizophrenia may also exhibit a variety of cognitive abnormalities, but this condition also has an early onset, a distinctive constellation of other symptoms (e.g., delusions, hallucinations, disorganized speech), and does not result from a medical condition or the persisting effects of a substance. Factitious disorder and malingering must be distinguished from dementia. The patient with factitious disorder and psychological symptoms may have some apparent cognitive deficits reminiscent of a dementia.

Dementia must also be distinguished from age-related cognitive decline (also known as benign senescence). Only when such changes exceed the level of altered function to be expected for the patient’s age is the diagnosis of dementia warranted (American Psychiatric Association, 1994).

### Physical and Neurological Examinations in Dementia

The physical examination may offer clues to the etiology of the dementia; however, in the elderly, one must be aware of the normal changes associated with aging and differentiate them from signs of dementia. Often the specific physical examination

**Figure 32.2** *Differential diagnosis of dementia and cognitive impairment in depression.*

findings indicate the area of the central nervous system affected by the etiological process. Parietal lobe dysfunction is suggested by such symptoms as astereognosis, constructional apraxia, anosognosia and problems with two-point discrimination (Kaufman, 1990a). The dominant hemisphere parietal lobe is also involved in Gerstmann's syndrome, which includes agraphia, acalculia, finger agnosia and right-left confusion.

Reflex changes such as hyperactive deep tendon reflexes, Babinski's reflex and hyperactive jaw jerk are indicative of cerebral injury. However, primitive reflexes such as the palmar-mental reflex (tested by repeatedly scratching the base of the patient's thumb, with a positive response being slight downward movement of the lower lip and jaw), which occurs in 60% of normal elderly people, and the snout reflex, seen in a third of elderly patients, are not diagnostically reliable for dementia (Wolfson and Katzman, 1983).

Ocular findings such as nystagmus (as in brain stem lesions), ophthalmoplegia (Wernicke-Korsakoff syndrome), anisocoria,

papilledema (hypertensive encephalopathy), cortical blindness (Anton's syndrome), visual field losses (CVA hemianopia), Kayser-Fleischer rings (Wilson's disease) and Argyll Robertson pupils (syphilis, diabetic neuropathy) can offer valuable clues to the etiology of the cognitive deficit (Victor and Adams, 1974).

Movement disorders including tremors (Parkinson's disease, drug intoxication, cerebellar dysfunction, Wilson's disease), chorea (Huntington's disease, other basal ganglia lesions), myoclonus (subacute sclerosing panencephalitis, Creutzfeldt-Jakob disease, Alzheimer's disease, anoxia) and asterixis (hepatic disease, uremia, hypoxia, carbon dioxide retention) should be noted.

Gait disturbances, principally apraxia (normal-pressure hydrocephalus, inhalant abuse, cerebellar dysfunction) and peripheral neuropathy (Korsakoff's syndrome, neurosyphilis, heavy metal intoxication, solvent abuse, isoniazid or phenytoin toxicity, vitamin deficiencies and HIV spectrum illnesses), are

**Table 32.3 Physical Signs Associated With Dementia or Delirium**

Physical Sign	Condition
Myoclonus	Creutzfeldt–Jakob disease
	Subacute sclerosing panencephalitis
	Postanoxia
	Alzheimer’s disease (10%)
	AIDS dementia
	Uremia
	Penicillin intoxication
	Meperidine toxicity
Asterixis	Hepatic encephalopathy
	Uremia
	Hypoxia
Chorea	Huntington’s disease
	Wilson’s disease
	Hypocalcemia
	Hypothyroidism
	Hepatic encephalopathy
	Oral contraceptives
	Systemic lupus erythematosus
	Carbon monoxide poisoning
	Toxoplasmosis
	Pertussis, diphtheria
	Peripheral neuropathy
Neurosyphilis	
Heavy metal intoxication	
Organic solvent exposure	
Vitamin B <sub>12</sub> deficiency	
Medications: isoniazid, phenytoin	

also common in dementia. Extrapyramidal symptoms in the absence of antipsychotics may indicate substance abuse, especially phencyclidine abuse, or basal ganglia disease. Although the many and varied physical findings of dementia are too numerous to mention here in any detail, it should be obvious that the physical examination is an invaluable tool in the assessment of dementia (Table 32.3).

### Mental Status Examination

The findings on the Mental Status Examination vary depending on the etiology of the dementia. Some common abnormalities have been discussed previously (see earlier section on clinical features). In general, symptoms seen on the Mental Status Examination, whatever the etiology, are related to the location and extent of brain injury, individual adaptation to the dysfunction, premorbid coping skills and psychopathology, and concurrent medical illness.

Disturbance of memory, especially primary and secondary memory, is the most significant abnormality. Confabulation may be present as the patient attempts to minimize the memory impairment. Disorientation and altered levels of consciousness may occur, but are generally not seen in the early stages of dementia uncomplicated by delirium. Affect may be affected as in the masked facies of Parkinson’s disease and the expansive affect

and labile mood of pseudobulbar palsy after cerebral injury. The affect of patients with hepatic encephalopathy is often described as blunted and apathetic. Lack of inhibition leading to such behavior as exposing oneself is common, and some conditions such as tertiary syphilis and untoward effects of some medication can precipitate mania. The Mental Status Examination, in conjunction with a complete medical history from the patient and informants and an adequate physical examination, is essential in the evaluation and differential diagnosis of dementia (Table 32.4).

## Degenerative Causes of Dementia

### Dementia of the Alzheimer Type

#### Historical Perspective

In 1906 Alois Alzheimer reported a case of presenile dementia in a 51-year-old woman who displayed progressive memory loss and disorientation.

Two years earlier, Alzheimer had written of miliary plaque formations that often appeared in the brains of patients with senile dementia. He and his coworkers subsequently described neurofibrillary changes and granulovacuolar degeneration in senile and presenile dementia (Bick, 1994). Almost 90 years later, Alzheimer’s disease is the most common form of dementia and remains a major focus of scientific investigation.

#### Epidemiology

Alzheimer’s disease is the most common cause of dementia, accounting for 55 to 65% of all cases. There were fewer than 3 million cases diagnosed in the USA in 1980, but the Census Bureau predicted that there will be more than 10 million American citizens with Alzheimer’s disease by the year 2050. Prevalence of the disease doubles with every 5 years between the ages of 65 and 85 years. Onset of symptoms occurs after the age of 40 years in 96% of cases.

**DSM-IV-TR Criteria** 294**Dementia of the Alzheimer Type**

- A. The development of multiple cognitive deficits manifested by both
- (1) memory impairment (impaired ability to learn new information or to recall previously learned information)
  - (2) one (or more) of the following cognitive disturbances:
    - (a) aphasia (language disturbance)
    - (b) apraxia (impaired ability to carry out motor activities despite intact motor function)
    - (c) agnosia (failure to recognize or identify objects despite intact sensory function)
    - (d) disturbance in executive functioning (i.e., planning, organizing, sequencing, abstracting)
- B. The cognitive deficits in criteria A1 and A2 each cause significant impairment in social or occupational functioning and represent a significant decline from a previous level of functioning.
- C. The course is characterized by gradual onset and continuing cognitive decline.
- D. The cognitive deficits in criteria A1 and A2 are not due to any of the following:
- (1) other central nervous system conditions that cause progressive deficits in memory and cognition (e.g., cerebrovascular disease, Parkinson's disease, Huntington's disease, subdural hematoma, normal-pressure hydrocephalus, brain tumor)
  - (2) systemic conditions that are known to cause dementia (e.g., hypothyroidism, vitamin B<sub>12</sub> or folic acid deficiency, niacin deficiency, hypercalcemia, neurosyphilis, HIV infection)
  - (3) substance-induced conditions

- E. The deficits do not occur exclusively during the course of a delirium.
- F. The disturbance is not better accounted for by another Axis I disorder (e.g., major depressive disorder, schizophrenia).

*Code based on type of onset and predominant features:*

**With early onset:** if onset is at age 65 years or below  
**294.11 With delirium:** if delirium is superimposed on the dementia

**294.12 With delusions:** if delusions are the predominant feature

**294.13 With depressed mood:** if depressed mood (including presentations that meet full symptom criteria for a major depressive episode) is the predominant feature. A separate diagnosis of mood disorder due to a general medical condition is not given.

**294.10 Uncomplicated:** if none of the above predominates in the current clinical presentation

**With late onset:** if onset is after age 65 years

**294.3 With delirium:** if delirium is superimposed on the dementia

**294.20 With delusions:** if delusions are the predominant feature

**294.21 With depressed mood:** if depressed mood (including presentations that meet full symptom criteria for a major depressive episode) is the predominant feature. A separate diagnosis of mood disorder due to a general medical condition is not given.

**294.0 Uncomplicated:** if none of the above predominates in the current clinical presentation

*Specify if:*

**With behavioral disturbance**

**Coding note:** Also code 331.0 Alzheimer's disease on Axis III.

Some authors separate Alzheimer's disease into senile and presenile forms, but the two disorders represent the same pathological process. Significantly, however, early-onset (that is, onset before the age of 65) Alzheimer's disease is associated with a more rapid course than later-onset disease.

Alzheimer's disease affects women three times as often as men, for unknown reasons. Furthermore, at least one study suggests that dementia, including Alzheimer's, is more common in black than in white American women (Heyman *et al.*, 1991). Comparison of population studies in diverse countries shows strikingly similar prevalence rates. Longitudinal studies have revealed the importance of family history as a risk factor; however, no consistent genetic pattern has been established. For Alzheimer's alone, the probability of developing dementia

if a first-degree relative (parent or sibling) is afflicted is four times greater than that of the general population, and if two or more first-degree relatives have the disease the risk is increased eightfold compared with a normal sample of US citizens. Among monozygotic twins 43% are concordant for the disorder, compared with only 8% of dizygotic twins.

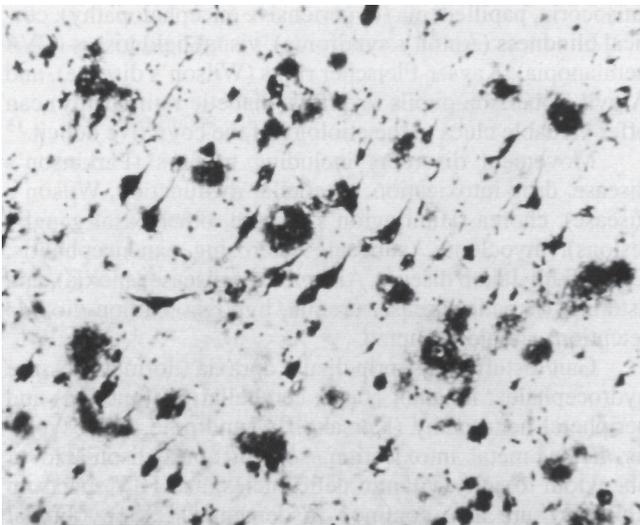

In addition to age, gender and family history, the presence of Down syndrome, a history of head trauma and a low level of education have been proposed as risk factors. Most studies concur that individuals with trisomy 21 develop the features of AD by age 35 years; however, studies have looked at the possibility that families with a member who has AD are more likely to produce offspring with Down syndrome and have had inconclusive results. Significant head injury, as either a single incident or

a chronic occurrence as in sports injuries, increases the risk of developing Alzheimer's by a factor of 2. An uneducated person older than 75 years is about twice as likely to develop dementia as one who has 8 years or more schooling, leading to the speculation that the cognitive processes involved in obtaining an education may be partially protective. Risk factors found in some but not all studies include myocardial ischemia in the elderly, having a child at 40 years or older, and exposure to aluminum (Katzman and Kawas, 1994).

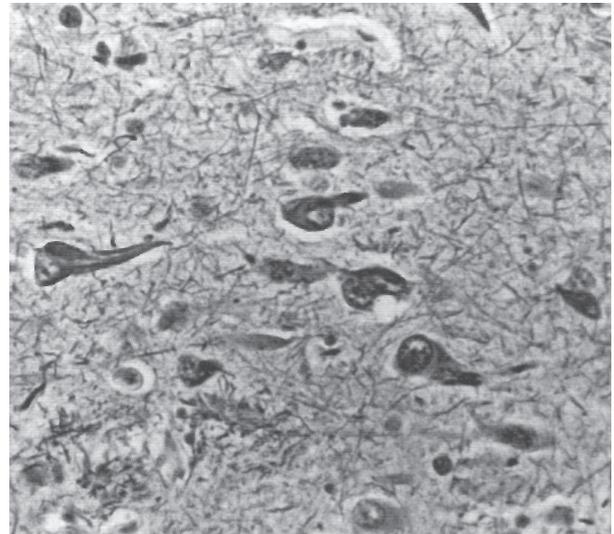

### Pathology

The etiology and pathogenesis of Alzheimer's disease are unknown. Multiple agents and pathways are probably involved in this disorder. Many hypotheses have been proposed regarding the cause and progression of Alzheimer's disease including genetic factors, slow or unconventional viruses, defective membrane metabolism, endogenous toxins, autoimmune disorders and neurotoxicity of such trace elements as aluminum and mercury.

The brains of patients with Alzheimer's disease contain many senile plaques, neurofibrillary tangles and Hirano's bodies (Figures 32.3 and 32.4). There is degeneration of nerve cells, but the significant atrophy seen on neurodiagnostic examination may be more the result of shrinkage of neurons and loss of dendritic spines than of actual neuronal loss (Wolf, 1980). The atrophy is most apparent in the associational cortex areas, and early decay on the primary motor and sensory areas are relatively spared (Figures 32.5 and 32.6). Significant degenerative changes in neurons are seen in the hippocampus, locus ceruleus and nucleus basalis of Meynert. With advancing disease, these changes, in effect, separate the hippocampus from the remainder of the brain. Initially, the parietal and temporal regions are most affected by plaques and tangles, accounting for the memory impairment and parietal lobe-associated syndromes (some apraxias, hemi-attention, anosognosia, Gerstmann's syndrome) occasionally associated with Alzheimer's disease. Neurofibrillary tangles do not correlate with the severity of

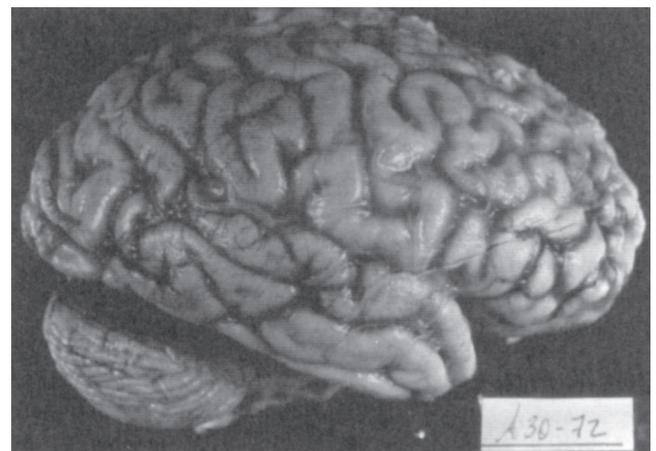

**Figure 32.3** Numerous neuritic plaques and neurofibrillary tangles in a patient with Alzheimer's disease. (Courtesy of Joseph Parker, MD, Duke University Medical Center, Durham, NC.)

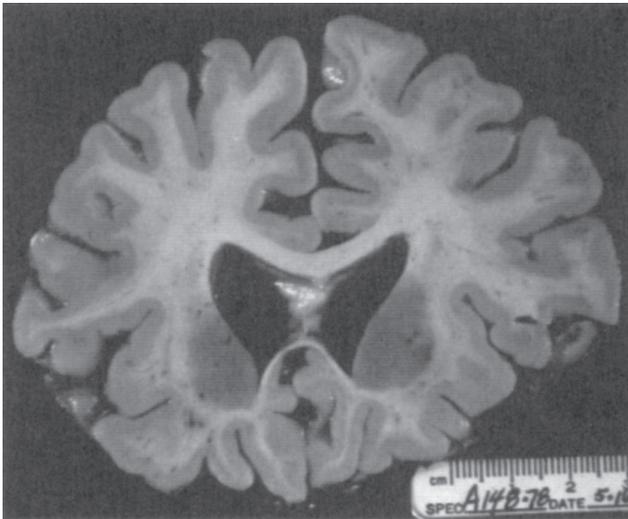

**Figure 32.4** Intraneuronal neurofibrillary tangles with neuritic plaques in a patient with Alzheimer's disease. (Courtesy of Joseph Parker, MD, Duke University Medical Center, Durham, NC.)

the dementia; however, the concentration of neuritic plaques is directly associated with the severity of the disease (Kaufman, 1990a).

Neurochemically, the brains of patients with Alzheimer's disease exhibit significant cholinergic abnormalities (Kaufman, 1990b). There is a profound decrease in acetylcholine (ACh) in almost all patients, as well as decreased immunological activity of somatostatin- and corticotropin-releasing factors (Kaufman, 1990b). The enzyme required for ACh synthesis, choline acetyltransferase, is also greatly reduced. Other studies suggest involvement of noradrenergic and serotonergic systems in later-onset disease and diminished gamma-aminobutyric acid (GABA) (Kaufman, 1990b). Specifically, the noradrenergic deficiencies seen in younger patients may be connected to changes in the locus coeruleus, and abnormalities of serotonin to effects

**Figure 32.5** Gross specimen showing prominent frontal lobe atrophy in a patient with Alzheimer's disease. (Courtesy of Joseph Parker, MD, Duke University Medical Center, Durham, NC.)

**Figure 32.6** Cortical and white matter atrophy. (Courtesy of Joseph Parker, MD, Duke University Medical Center, Durham, NC.)

on the raphe nuclei (Korvath *et al.*, 1989). The serotonergic neurons of the raphe nuclei in patients with Alzheimer's disease contain six to 39 times as many neurofibrillary tangles as those of age-appropriate control subjects, and noradrenergic neurons from the locus ceruleus of patients with Alzheimer's disease show neuronal loss of 40 to 80%. Unfortunately, despite these observed neurochemical abnormalities, neurotransmitter-related treatment with cholinergic and GABAergic agents has proved largely unsuccessful.

Although the involvement of cholinergic transmission along the hippocampus and nucleus basalis is essential to the ability to learn new information, it seems that many of the symptoms of Alzheimer's disease are not explainable solely on the basis of cholinergic abnormalities. Thus, investigators have examined a number of other potential etiological or contributory agents. Some researchers have investigated the role of beta-amyloid protein in Alzheimer's disease, and some assert that this material, a significant component of all plaques, is a major contributor to the neurodegenerative changes in the disease as both an initiator and a promotor of the disease. Supporting this assertion are genetic studies of families with inheritable forms of presenile dementia, which show that disease occurrence is linked to mutations involving beta-amyloid-related systems (Kidd, 1963). This hypothesis targets the protein found in senile plaques; other investigators have focused on the neurofibrillary tangles and the identification of a major component of its helical filament, the tau protein. Specifically, these researchers analyzed the possibility that modification of tau protein, predominantly by phosphorylation, is an important feature of AD.

Aluminum, the third most common element in the universe, is absorbed from the gastrointestinal tract, lungs, nasal passage and skin. Crapper and Dalton (1972) reported increased aluminum in the brain of patients with Alzheimer's disease, with about a quarter of such samples showing concentrations three standard deviations above the control values. Other studies of bulk brain aluminum in patients with Alzheimer's disease have shown no such elevation. The current consensus appears to be that although aluminum and other

elements such as iron and mercury might accelerate neuronal degeneration in AD, these elements are not primary etiological agents. The role of genetic factors in the development of AD has received increased attention as the role of the apolipoprotein (APO) E4 allele as a major genetic susceptibility risk factor has been confirmed by numerous studies (Katzman, 1994). Corder and colleagues (1993) studied 234 members of 42 families with late-onset AD. Of 95 affected members, 80% had the E4 allele, compared with 26% in the general population (Corder *et al.*, 1993). Furthermore, in these families, 91% of those homozygous for E4 had developed Alzheimer's disease by 80 years of age – evidence that the APO E4 allele is causing these familial cases (Corder *et al.*, 1993). In a study of 176 autopsy specimens of confirmed AD, Schmechel and coworkers in 1993 found that 65% of patients carried at least one APO E4 gene. Examination of all such studies indicates that between 25 and 40% of AD cases can be attributable to this marker, making its presence one of the most common risk factors yet discovered for AD.

Finally, several studies suggest that changes in membrane function, metabolism and morphology are involved in the pathology of AD. Nonetheless, the basic molecular defect responsible for AD dementia has not been defined.

The neuropathology of Alzheimer's disease should be compared with the normal neuropathic effects of aging. These include the following:

1. The leptomeninges become more fibrotic and are more adherent to the brain surface with increased opacity.
2. The ventricles show slight to moderate enlargement that increases with the passage of time.
3. The distance between the dura and the brain is increased.
4. Sulci widen and gyri become narrower.
5. The number of neurons decreases slightly.
6. The weight of the brain decreases in the fourth and fifth decades, with significant decrease by the age of 80 years.
7. Neurofibrillary tangles and senile plaques occur in virtually every elderly individual by the 10th decade of life (Berg *et al.*, 1994).

### Laboratory and Radiological Findings

The role of laboratory determinations in the evaluation for AD is to exclude other causes of dementia, especially those that may prove reversible or arrestable. Before death, AD is largely a diagnosis of exclusion. Throughout the course of this disorder, laboratory values are essentially normal. Some nonspecific changes may occur, but electroencephalography and lumbar puncture are not diagnostic. As the disease progresses, computed tomography (CT) and magnetic resonance imaging (MRI) may show atrophy in the cerebral cortex and hydrocephalus *ex vacuo*. MRI may show nonspecific alteration of white matter (leukoariosis), and eventually the electroencephalogram (EEG) shows diffuse background slowing.

Pneumoencephalography has demonstrated enlarged ventricles and widening of cortical sulci in Alzheimer's disease, and positron emission tomography in the later stages shows decreased cerebral oxygen and glucose metabolism in the frontal lobes. At present, in the work-up of a patient with a slowly progressive dementia, a good family history, physical examination, and laboratory and radiographic tests to rule out other causes of dementia, are the most effective tools in the diagnosis of Alzheimer's disease.

## Clinical Features

The course and clinical features of AD parallel those discussed for dementia in general. Typically, the early course of AD is difficult to ascertain because the patient is usually an unreliable informant, and the early signs may be so subtle as to go unnoticed even by the patient's closest associates. These early features include impaired memory, difficulty with problem solving, preoccupation with long past events, decreased spontaneity, and an inability to respond to the environment with the patient's usual speed and accuracy. Patients may forget names, misplace household items, or forget what they were about to do. Often the individuals have insight into these memory deficits and occasionally convey their concerns to family members. Such responses as "You're just getting older", and "I do that sometimes myself" are common from these family members and as a result the patient becomes depressed, which can further affect cognitive functioning. Anomia, or difficulty with word finding, is common in this middle stage of Alzheimer's disease. Eventually the patient develops schemes, word associations and excuses ("I never was very good in math") to assist in retention and cover up deficits. The patient may also employ family members as a surrogate memory (Karp, 1984).

Because memory loss is usually most obvious for newly acquired material, the patient tries to avoid unfamiliar activities. Typically, the patient is seen by the physician when confusion, aggression, wandering, or some other socially undesirable behavior ensues. At that time, disorders of perception and language may appear. The patient often turns to a spouse to answer questions posed during the history taking. By this time the affected individual has lost insight into his or her dementia and abandons attempts to compensate for memory loss. Finally, in the late stage of Alzheimer's disease, physical and cognitive effects are marked. Disorders of gait, extremity paresis and paralysis, seizures, peripheral neuropathy, extrapyramidal signs and urinary incontinence are seen, and the patient is often no longer ambulatory. The aimless wandering of the middle stage has been replaced by a mute, bedridden state and decorticate posture. Myoclonus occasionally occurs. Significantly, affective disturbances remain a distinct possibility throughout the course of the illness. AD progresses at a slow pace for 8 to 10 years to a state of complete helplessness.

## Treatment

The two principles of management in AD are to treat what is treatable without aggravating existing symptoms and to support caregivers, who are also victims of this disease. Despite the significant decrease in ACh and choline acetyltransferase in Alzheimer's disease, treatments based on the cholinergic hypothesis have been unsuccessful (Kaufman, 1990a) Because vasopressin levels are slightly decreased in the hippocampus of patients with Alzheimer's disease and somatostatin is adversely affected as well, attempts were made to replace these agents with little effect. In the belief that improving blood flow might be of benefit, such agents as the metabolic enhancer and vasodilator ergoloid mesylates (Hydergine) (an ergot alkaloid) were tried. Hydergine did seem to have some benefit; however, these effects may have been related to its mild antidepressant action. Onset of action of any beneficial effects of Hydergine was quite long. Corticotropin release is promoted by corticotropin-releasing factor, which is decreased in patients with AD, but clinical trials with corticotropin were disappointing. Despite lackluster effects of physostigmine, a second cholinesterase inhibitor has shown promise. Tetrahydroaminoacridine (tacrine) produced significant

cognitive improvement in 16 of 17 patients with AD in an early study (Summers *et al.*, 1986). Subsequent studies have been less impressive, but significant improvement in a number of scales measuring cognitive performance illustrated the benefit of this agent for some patients. Side effects, particularly hepatic and cholinergic, were noted; however, in 1993 the US Food and Drug Administration (USFDA) approved of tacrine for the treatment of AD. Donepezil, an inhibitor of acetylcholinesterase, has also been utilized in an attempt to enhance cholinergic function by inhibiting its breakdown. This agent must be given early in the course of the dementia.

Whereas much attention has been focused on research aimed at understanding and altering the pathogenesis of AD, less work has been done regarding appropriate pharmacotherapy of the varied psychological manifestations of the disease. Depression is often associated with AD. If antidepressant medication is to be used, low doses (about one-third to one-half of the usual initial dose) are advised and only agents with minimal anticholinergic activity should be employed. Appropriate choices would be the selective serotonin reuptake inhibitors such as paroxetine, fluoxetine, sertraline and citalopram. Sertraline and citalopram are least likely to cause drug-drug interactions. Even these agents have the potential to increase confusion in Alzheimer's patients. Agents such as trazodone and mirtazapine have occasionally been employed because of their sedating properties. If tricyclic antidepressants are used, the secondary amines (desipramine, nortriptyline) are recommended over the tertiary ones (amitriptyline, doxepin). Careful attention to the possible side effects of these agents, particularly orthostatic hypotension, lowering of the seizure threshold, excessive fatigue, urinary retention, constipation, confusion and accelerated memory impairment, is suggested. Most clinicians now feel that tricyclic antidepressants are inappropriate for this patient population.
