The symptoms of anorexia nervosa are remarkably homogeneous, and differences between patients in clinical manifestations are fewer than in most psychiatric illnesses. As described before, younger patients may not express verbally the characteristic fear of fatness or the overconcern with shape and weight, and some patients with longstanding anorexia nervosa may express a desire to gain weight but be unable to make persistent changes in their behavior. It has been suggested that in other cultures, the rationale given by patients for losing weight differs from the fear of fatness characteristic of cases in North America.

Men have anorexia nervosa far less frequently than women. However, when the syndrome does develop in a man, it is typical. There may be an increased frequency of homosexuality among men with anorexia nervosa.

### Differential Diagnosis

Although depression, schizophrenia and obsessive–compulsive disorder may be associated with disturbed eating and weight loss, it is rarely difficult to differentiate these disorders from anorexia nervosa. Individuals with major depression may lose significant amounts of weight but do not exhibit the relentless drive for thinness characteristic of anorexia nervosa. In schizophrenia, starvation may occur because of delusions about food, for example, that it is poisoned. Individuals with obsessive–compulsive disorder may describe irrational concerns about food and develop rituals related to meal preparation and eating but do not describe the intense fear of gaining weight and the pervasive wish to be thin that characterize anorexia nervosa.

A wide variety of medical problems cause serious weight loss in young people and may at times be confused with anorexia nervosa. Examples of such problems include gastric outlet obstruction, Crohn's disease and brain tumors. Individuals whose weight loss is due to a general medical illness generally do not show the drive for thinness, the fear of gaining weight and the increased physical activity characteristic of anorexia nervosa. However, the psychiatrist is well advised to consider any chronic medical illness associated with weight loss, especially when evaluating individuals with unusual clinical presentations such as late age at onset or prominent physical complaints, for example, pain and gastrointestinal cramping while eating.

### Course and Natural History

The course of anorexia nervosa is enormously variable. Some individuals have mild and brief illnesses and either never come to medical attention or are seen only briefly by their pediatrician or general medical physician. It is difficult to estimate the frequency of this phenomenon because such individuals are rarely studied.

Most of the literature on course and outcome is based on individuals who have been hospitalized for anorexia nervosa. Although such individuals presumably have a relatively severe illness and adverse outcomes, a substantial fraction, probably between one-third and one-half, make full and complete psychological and physical recoveries. On the other hand, anorexia nervosa is also associated with an impressive long-term mortality. The best data currently available suggest that 10 to 20% of patients who have been hospitalized for anorexia nervosa will, in the next 10 to 30 years, die as a result of their illness. Much of the mortality is due to severe and chronic starvation, which eventually terminates in sudden death. In addition, a significant fraction of patients commit suicide.

Between these two extremes are a large number of individuals whose lives are impaired by persistent difficulties with eating. Some are severely affected maintaining a chronic state of semistarvation, bizarre eating rituals and social isolation; others may gain weight but struggle with bulimia nervosa and strict rules about food and eating; and still others may recover initially but then relapse into another full episode. There is a high frequency of depression among individuals who have had anorexia nervosa and a significant frequency of drug and alcohol abuse, but psychotic disorders develop only rarely. Thus, in general, individuals either recover or continue to struggle with psychological and behavioral problems that are directly related to the eating disorder. It is of note that it is rare for individuals who have had anorexia nervosa to become obese.

It is difficult to specify factors that account for the variability of outcome in anorexia nervosa. A significant body of experience suggests that the illness has a better prognosis when

it begins in adolescence, but there are also suggestions that prepubertal onset may portend a difficult course. It is likely that the severity of the illness (e.g., the lowest weight reached, the number of hospitalizations) and the presence of associated symptoms, such as binge-eating and purging, also contribute to poor outcome. However, it is impossible to predict course and outcome in an individual with any certainty.

### Goals of Treatment

The first goal of treatment is to engage the patient and her or his family. For most patients with anorexia nervosa, this is challenging. Patients usually minimize their symptoms and suggest that the concerns of the family and friends, who have often been instrumental in arranging the consultation, are greatly exaggerated. It is helpful to identify a problem that the patient can acknowledge, such as weakness, irritability, difficulty concentrating, or trouble with binge-eating. The psychiatrist may then attempt to educate the patient regarding the pervasive physical and psychological effects of semistarvation and about the need for weight gain if the acknowledged problem is to be successfully addressed.

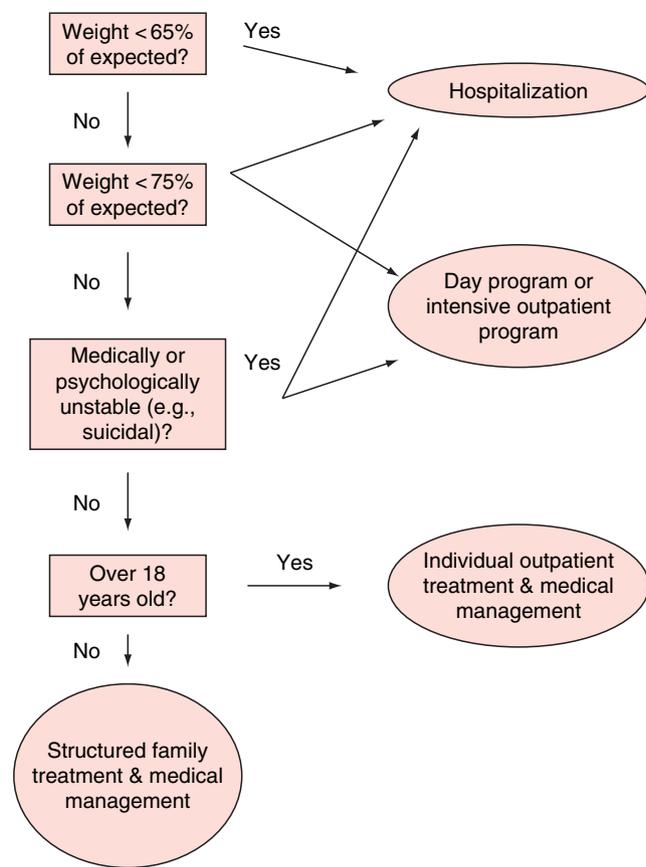

A second goal of treatment is to assess and address acute medical problems, such as fluid and electrolyte disturbances and cardiac arrhythmias. Depending on the severity of illness, this may require the involvement of a general medical physician. The additional but most difficult and time-consuming goals are the restoration of normal body weight, the normalization of eating and the resolution of the associated psychological disturbances. The final goal is the prevention of relapse.

### Treatment

A common major impediment to the treatment of patients with anorexia nervosa is their disagreement with the goals of treatment; many of the features of their illness are simply not viewed by patients as a problem. In addition, this may be compounded by a variety of concerns of the patient, such as basic mistrust of relationships, feelings of vulnerability and inferiority, and sensitivity to perceived coercion. Such concerns may be expressed through considerable resistance, defiance, or pseudocompliance with the psychiatrist's interventions and contribute to the power struggles that often characterize the treatment process. The psychiatrist must try to avoid colluding with the patient's attempts to minimize problems but at the same time allow the patient enough independence to maintain the alliance. Dealing with such dilemmas is challenging and requires an active approach on the part of the psychiatrist. In most instances, it is possible to preserve the alliance while nonetheless adhering to established limits and the need for change.

The initial stage of treatment should be aimed at reversing the nutritional and behavioral abnormalities (Figure 58.3). The intensity of the treatment required and the need for partial or full hospitalization should be determined by the current weight, the rapidity of weight loss, and the severity of associated medical and behavioral problems and of other symptoms such as depression. In general, patients whose weights are less than 75% of expected should be viewed as medically precarious and require intensive treatment such as hospitalization.

Most inpatient or day treatment units experienced in the care of patients with anorexia nervosa use a structured treatment approach that relies heavily on supervision of calorie intake by the staff. Patients are initially expected to consume sufficient calories to maintain weight, usually requiring 1500 to 2000 kcal/day

**Figure 58.3** Algorithm for choice of initial treatment of anorexia nervosa.

in four to six meals. After the initial medical assessment has been completed and weight has stabilized, calorie intake is gradually increased to an amount necessary to gain 2 to 5 lb/week. Because the consumption of approximately 4000 kcal beyond maintenance requirements is needed for each pound of weight gain, the daily calorie requirements become impressive, often in the range of 4000 kcal/day. Some eating disorder units provide only food while others rely on nutritional supplements such as Ensure or Sustacal. During this phase of treatment it is necessary to monitor patients carefully; many will resort to throwing food away or vomiting after meals. Careful supervision is also required to obtain accurate weights; patients may consume large amounts of fluid before being weighed or hide heavy articles under their clothing.

During the weight restoration phase of treatment patients require substantial emotional support. It is probably best to address fears of weight gain with education about the dangers of semistarvation and with the reassurance that patients will not be allowed to gain “too much” weight. Most eating disorders units impose behavioral restrictions, such as limits on physical activity, during the early phase of treatment. Some units use an explicit behavior modification regimen in which weight gain is tied to increased privileges and failure to gain weight results in bed rest.

A consistent and structured treatment approach, with or without an explicit behavior modification program, is generally successful in promoting weight recovery but requires substantial energy and coordination to maintain a supportive and nonpunitive

treatment environment. In most experienced treatment units, parenteral methods of nutrition, such as nasogastric feeding or intravenous hyperalimentation, are only rarely needed. Nutritional counseling and behavioral approaches can also be effective in helping patients expand their dietary repertoire to include foods they have been frightened of consuming.

As weight increases, individual, group and family psychotherapy can begin to address other issues in addition to the distress engendered by gaining weight. For example, it is typically important for patients to recognize that they have come to base much of their self-esteem on dieting and weight control and are likely to judge themselves according to harsh and unforgiving standards. Similarly, patients should be helped to see how the eating disorder has interfered with the achievement of personal goals such as education, sports, or making friends.

There is, present, no general agreement about the most useful type of psychotherapy or the specific topics that need to be addressed. Most eating disorders programs employ a variety of psychotherapeutic interventions. A number of psychiatrists recommend the use of individual and group psychotherapy using cognitive-behavioral techniques to modify the irrational overemphasis on weight. Although most authorities see little role for traditional psychoanalytic therapy, individual and group psychodynamic therapy can address such problems as insecure attachment, separation and individuation, sexual relationships and other interpersonal concerns. There is good evidence supporting the involvement of the family in the treatment of younger patients with anorexia nervosa. Family therapy can be helpful in addressing family members' fears about the illness; interventions typically emphasize parental cooperation, mutual support and consistency, and establishing boundaries regarding the patient's symptoms and other aspects of his or her life.

Despite the multiple physiological disturbances associated with anorexia nervosa, there is no clearly established role for medication. The earliest systematic medication trials in anorexia nervosa focused on the use of neuroleptics. Theoretically, such agents might help to promote weight gain, to reduce physical activity and to diminish the distorted thinking about shape and weight, which often reaches nearly delusional proportions. Early work in the late 1950s and 1960s using chlorpromazine led to substantial enthusiasm, but two placebo-controlled trials of the neuroleptics, sulpiride and pimozide, were unable to establish significant benefits. In recent years interest has grown in taking advantage of the impressive weight gain associated with some atypical antipsychotics; however, no controlled data supporting this intervention have yet appeared. Despite the frequency of depression among patients with anorexia nervosa, there is no good evidence supporting the use of antidepressant medication in their treatment.

Unfortunately, although controlled trials have provided some evidence of benefit, the impact of cyproheptadine, an antihistamine, in anorexia nervosa appears limited.

A large percentage of patients with anorexia nervosa remain chronically ill; 30 to 50% of patients successfully treated in the hospital require rehospitalization within 1 year of discharge. Therefore, posthospitalization outpatient treatments are recommended to prevent relapse and improve overall short- and long-term functioning. Several studies have attempted to evaluate the efficacy of various outpatient treatments for anorexia nervosa including behavioral, cognitive-behavioral and supportive psychotherapy, as well as a variety of nutritional counseling interventions. Although most of these treatments seem to be helpful,

the clearest findings to date support two interventions. For patients whose anorexia nervosa started before age 18 years and who have had the disorder for less than 3 years, family therapy is effective, and for adult patients, cognitive-behavioral therapy reduces the rate of relapse. Preliminary information suggests that fluoxetine treatment may reduce the risk of relapse among patients with anorexia nervosa who have gained weight, but additional controlled data are required to document the usefulness of this intervention.

## Refractory Patients

Some patients with anorexia nervosa refuse to accept treatment and thereby can raise difficult ethical issues. If weight is extremely low or if there are acute medical problems, it may be appropriate to consider involuntary commitment. For patients who are ill but more stable, the psychiatrist must weigh the short-term utility of involuntary treatment against the disruption of a potential alliance with the patient.

The goals of treatment may need to be modified for patients with chronic illness who have failed multiple previous attempts at inpatient and outpatient care. Treatment may be appropriately aimed at preventing further medical, psychological and social deterioration in the hope that the anorexia nervosa may eventually improve with time.

---

### Clinical Vignette 1

When Ms A was first evaluated for admission to an inpatient eating disorders program, she had been restricting her food intake for approximately 5 years and had been amenorrheic for 4 years. At the time of her admission, this 24-year-old, single, white woman weighed 71 lb at a height of 5 feet 1.5 inches. In 12th grade, Ms A menstruated for the first time and also developed "very large" breasts. She had a difficult first year at college, where she gained to her maximum weight of 120 lb. The following year, Ms A transferred to a smaller college, became a vegetarian "for ethical reasons", and began to significantly restrict her food intake. She limited herself to a total of 700 to 800 cal/day, with a maximum of 200 calories per meal and gradually lost weight in the next 5 years. Ms A did not binge, vomit, abuse laxatives, or engage in excessive exercise. She considered herself to be "obsessed with calories" and observed a variety of rituals regarding food and food preparation (e.g., obsessively weighing her food).

Although Ms A excelled academically, she had no close friends and had never been involved in a romantic relationship. She was quite close to her mother and sister and had always been dependent on her parents. After graduating (with honors) from college, Ms A worked at a series of temporary jobs but was unemployed and living at home with her mother at the time of admission. She had been in outpatient psychotherapy with two different therapists during the previous 2 years. The first therapist did not address her eating disorder, and Ms A continued to lose weight, from 90 to 80 lb. Although her second therapist confronted her about her anorexia nervosa and started her on desipramine at 20 mg/day for depressive symptoms, Ms A continued to lose weight.

During her first 5-month hospitalization, Ms A was treated with a multimodal program (behavioral weight

gain protocol, individual and family therapy, fluoxetine at 60–80 mg for obsessive–compulsive traits and depressive symptoms) and gained to a weight of 98 lb. At discharge, she was maintaining her weight on food but remained concerned about her weight and was particularly frightened of reaching “the triple digits” (i.e.,  $\geq 100$  lb). After leaving the hospital, Ms A continued with outpatient psychotherapy and fluoxetine for several months. She was then seriously injured in a car accident and, during a prolonged convalescent period, discontinued treatment for her eating disorder. Ms A remained unemployed, eventually moved in with her sister and her sister’s family, and gradually lost weight.

About 3.5 years after discharge, at age 27 years, Ms A again sought inpatient treatment. At admission, she weighed 83 lb but still felt “fat”. During hospitalization, she steadily gained weight and was prescribed sertraline at 100 mg/day for feelings of low self-esteem, anxiety and obsessional thinking. When she was discharged 5 months later, at a weight of 108 lb, she noted menstrual bleeding for the first time in more than 7 years. After leaving the hospital, Ms A continued taking medication and began outpatient cognitive–behavioral psychotherapy. For the next year, she continued to struggle with eating and weight issues but managed to maintain her weight and successfully expand other aspects of her life by independently supporting herself with a full-time job, making new friends and becoming involved in her first romantic relationship.

## Bulimia Nervosa

### Definition

The salient behavioral disturbance of bulimia nervosa is the occurrence of episodes of binge-eating. During these episodes, the individual consumes an amount of food that is unusually large considering the circumstances under which it was eaten. Although this is a useful definition and conceptually reasonably clear, it can be operationally difficult to distinguish normal overeating from a small episode of binge-eating. Indeed, the available data do not suggest that there is a sharp dividing line between the size of binge-eating episodes and the size of other meals. On the other hand, while the border between normal and abnormal eating may not be a sharp one, both patients’ reports and laboratory studies of eating behavior clearly indicate that, when binge-eating, patients with bulimia nervosa do indeed consume larger than normal amounts of food.

Episodes of binge-eating are associated, by definition, with a sense of loss of control. Once the eating has begun, the individual feels unable to stop until an excessive amount has been consumed. This loss of control is only subjective, in that most individuals with bulimia nervosa will abruptly stop eating in the midst of a binge episode if interrupted, for example, by the unexpected arrival of a roommate.

After overeating, individuals with bulimia nervosa engage in some form of inappropriate behavior in an attempt to avoid weight gain. Most patients who present to eating disorders clinics with this syndrome report self-induced vomiting or the

## DSM-IV-TR Criteria 307.51

### Bulimia Nervosa

- A. binge-eating. An episode Recurrent episodes of of binge-eating is characterized by both of the following:
- (1) eating in a discrete , period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances.
  - (2) a sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating).
- Recurrent
- B. compensatory behavior in order to prevent weight gain, inappropriate such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise.
- C. inappropriate compensatory The binge-eating and behaviors both occur, on average, at least twice a week for 3 months.
- D. influenced by body Self-evaluation is unduly shape and weight.
- E. exclusively The disturbance does not occur during episodes of anorexia nervosa.

*Specify type:*

**Purging type:** during the current episode of bulimia nervosa, the person has regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas.

**Nonpurging type:** during the current episode of bulimia nervosa, the person has used other inappropriate compensatory behaviors, such as fasting or excessive exercise, but has not regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

abuse of laxatives. Other methods include misusing diuretics, fasting for long periods and exercising extensively after eating binges.

The DSM-IV-TR criteria require that the overeating episodes and the compensatory behaviors both occur at least twice a week for 3 months to merit a diagnosis of bulimia nervosa. This criterion, although useful in preventing the diagnostic label from being applied to individuals who only rarely have difficulty with binge-eating, is clearly an arbitrary one.

Criterion D in the DSM-IV-TR definition of bulimia nervosa requires that individuals with bulimia nervosa exhibit an over concern with body shape and weight. That is, they tend to base much of their self-esteem on how much they weigh and how slim they look.

Finally, in the DSM-IV-TR nomenclature, the diagnosis of bulimia nervosa is not given to individuals with anorexia nervosa. Individuals with anorexia nervosa who recurrently engage

in binge-eating or purging behavior should be given the diagnosis of anorexia nervosa, binge-eating/purging subtype, rather than an additional diagnosis of bulimia nervosa.

In DSM-IV-TR, a subtyping scheme was introduced for bulimia nervosa in which patients are classed as having either the purging or the nonpurging type of bulimia nervosa. This scheme was introduced for several reasons. First, those individuals who purge are at greater risk for the development of fluid and electrolyte disturbances such as hypokalemia. Secondly, data suggest that individuals with the nonpurging type of bulimia nervosa weigh more and have less psychiatric illness compared with those with the purging type. Finally, most of the published literature on the treatment of bulimia nervosa has been based on studies of individuals with the purging type of this disorder.

## Epidemiology

Soon after bulimia nervosa was recognized as a distinct disorder, surveys indicated that many young women reported problems with binge-eating, and it was suggested that the syndrome of bulimia nervosa was occurring in epidemic proportions. Later careful studies have found that although binge-eating is frequent, the full-blown disorder of bulimia nervosa is much less common, probably affecting 1 to 2% of young women in the USA. Although sufficient research data do not exist to pinpoint specific epidemiological trends in the occurrence of bulimia nervosa, research suggests that women born after 1960 have a higher risk for the illness than those born before 1960.

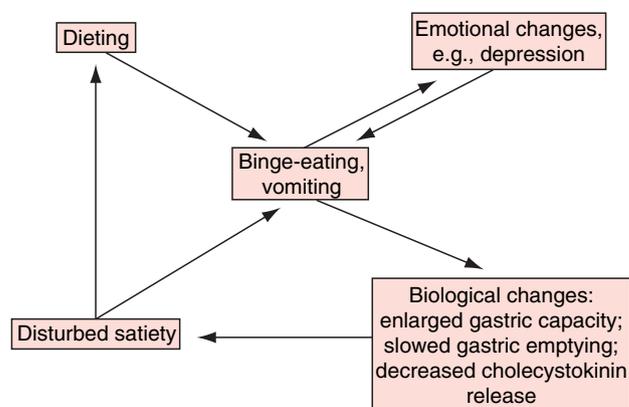

Evidence suggests an important role of sociocultural influences in the development of bulimia nervosa. For example, the frequency of the disorder has been reported to be increasing among immigrants to the USA and UK from nonWestern countries (Hsu, 1990). Although the rate of the disorder appears to be lower among nonwhite and nonWestern cultures, the frequency of bulimia nervosa has been reported to be increasing among these groups, especially among the higher socioeconomic classes. Surprisingly, several epidemiological and clinical studies in the USA found no relationship between bulimia nervosa and social class (Kendler *et al.*, 1991).

Among patients with bulimia nervosa who are seen at eating disorders clinics, there is an increased frequency of anxiety and mood disorders, especially major depressive disorder and dysthymic disorder, of drug and alcohol abuse, and of personality disorders. It is not certain whether this comorbidity is also observed in community samples or whether it is a characteristic of individuals who seek treatment.

## Etiology

As in the case of anorexia nervosa, the etiology of bulimia nervosa is uncertain. Several factors clearly predispose individuals to the development of bulimia nervosa, including being an adolescent girl or young adult woman. A personal or family history of obesity and of mood disturbance also appears to increase risk. Twin studies have suggested that inherited factors are related to the risk of developing bulimia nervosa, but what these factors are and how they operate are unclear.

Many of the same psychosocial factors related to the development of anorexia nervosa are also applicable to bulimia nervosa, including the influence of cultural esthetic ideals of thinness and physical fitness. Similarly, bulimia nervosa primarily affects women; the ratio of men to women is approximately 1 : 10. It also

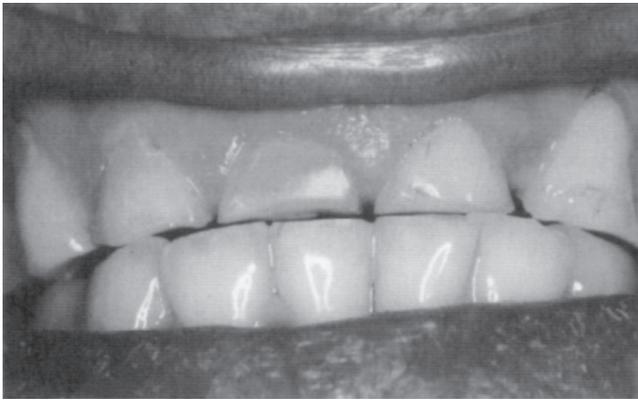

**Figure 58.4** Diagram illustrating factors that may perpetuate bulimia nervosa.

occurs more frequently in certain occupations (e.g., modeling) and sports (e.g., wrestling, running).

Although not proven, it seems likely that several factors serve to perpetuate the binge-eating once it has begun (Figure 58.4). First, most individuals with bulimia nervosa, because of both their concern regarding weight and their worry about the effect of the binge-eating, attempt to restrict their food intake when they are not binge-eating. The psychological and physiological restraint that is thereby entailed presumably makes additional binge-eating more likely. Secondly, even if mood disturbance is not present at the outset, individuals become distressed about their inability to control their eating, and the resultant lowering of self-esteem contributes to disturbances of mood and to a reduced ability to control impulses to overeat. In addition, cognitive-behavioral theories emphasize the role of rigid rules regarding food and eating, and the distorted and dysfunctional thoughts that are similar to those seen in anorexia nervosa. Interpersonal theories also implicate interpersonal stressors as a primary factor in triggering binge-eating. There is no evidence to suggest that a particular personality structure is characteristic of women with bulimia nervosa.

There are also indications that bulimia nervosa is accompanied by physiological disturbances that disrupt the development of satiety during a meal and therefore increase the likelihood of binge-eating. These disturbances include an enlarged stomach capacity, a delay in stomach emptying and a reduction in the release of cholecystokinin, a peptide hormone secreted by the small intestine during a meal that normally plays a role in terminating eating behavior. All these abnormalities appear to predispose the individual to overeat and therefore to perpetuate the cycle of binge-eating.

It has been suggested that childhood sexual abuse is a specific risk factor for the development of bulimia nervosa. Scientific support for this hypothesis is weak. The best studies to date have found that compared with women without psychiatric illness, women with bulimia nervosa do indeed report increased frequencies of sexual abuse. However, the rates of abuse are similar to those found in other psychiatric disorders and occur in a minority of women with bulimia nervosa. Thus, while early abuse may predispose an individual to psychiatric problems generally, it does not appear to lead specifically to an eating disorder and most patients with bulimia nervosa do not have histories of sexual abuse.

**Figure 58.5** Dental erosion of upper front teeth of a patient with longstanding bulimia nervosa.

### Pathophysiology

In a small fraction of individuals, bulimia nervosa is associated with the development of fluid and electrolyte abnormalities that result from the self-induced vomiting or the misuse of laxatives or diuretics. The most common electrolyte disturbances are hypokalemia, hyponatremia and hypochloremia. Patients who lose substantial amounts of stomach acid through vomiting may become slightly alkalotic; those who abuse laxatives may become slightly acidotic.

There is an increased frequency of menstrual disturbances such as oligomenorrhea among women with bulimia nervosa. Several studies suggest that the hypothalamic–pituitary–gonadal axis is subject to the same type of disruption as is seen in anorexia nervosa but that the abnormalities are much less frequent and severe.

Patients who induce vomiting for many years may develop dental erosion, especially of the upper front teeth (Figure 58.5). The mechanism appears to be that stomach acid softens the enamel, which in time gradually disappears so that the teeth chip more easily and can become reduced in size. Some patients develop painless salivary gland enlargement, which is thought to represent hypertrophy resulting from the repeated episodes of binge-eating and vomiting. The serum level of amylase is sometimes mildly elevated in patients with bulimia nervosa because of increased amounts of salivary amylase.

Most patients with bulimia nervosa have surprisingly few gastrointestinal abnormalities. As indicated earlier, it appears that the disorder is associated with an enlarged gastric capacity and delayed gastric emptying, but these abnormalities are not so severe as to be detectable on routine clinical examination. Potentially life-threatening complications such as an esophageal tear or gastric rupture occur, but fortunately rarely.

The longstanding use of syrup of ipecac to induce vomiting can lead to absorption of some of the alkaloids and to permanent damage to nerve and muscle.

### Diagnosis and Differential Diagnosis

#### Phenomenology

Bulimia nervosa typically begins after a young woman who sees herself as somewhat overweight starts a diet and, after some initial success, begins to overeat. Distressed by her lack of control and by her fear of gaining weight, she decides to compensate for the overeating by inducing vomiting or taking laxatives, methods

she has heard about from friends or seen in media reports about eating disorders. After discovering that she can successfully purge, the individual may, for a time, feel pleased in that she can eat large amounts of food and not gain weight. However, the episodes of binge-eating usually increase in size and in frequency and occur after a variety of stimuli, such as transient depression or anxiety or a sense that she has begun to overeat. Patients often describe themselves as “numb” while they are binge-eating, suggesting that the eating may serve to avoid uncomfortable emotional states. Patients usually feel intensely ashamed of their “disgusting” habit and may become depressed by their lack of control over their eating.

The binge-eating tends to occur in the late afternoon or evening and almost always while the patient is alone. The typical patient presenting to eating disorders clinics has been binge-eating and inducing vomiting five to 10 times weekly for 3 to 10 years. Although there is substantial variation, binges tend to contain 1000 or more calories and to consist of sweet, high-fat foods that are normally consumed as dessert, such as ice cream, cookies and cake. Although patients complain of “carbohydrate craving”, they only rarely binge-eat foods that are pure carbohydrates, such as fruits. Patients usually induce vomiting or use their characteristic compensatory behavior immediately after the binge and feel substantial relief that the calories are “gone”. In reality, it appears that vomiting is the only purging method capable of disposing of a significant number of ingested calories. The weight loss associated with the misuse of laxatives and diuretics is primarily due to the loss of fluid and electrolytes, not calories.

When not binge-eating, patients with bulimia nervosa tend to restrict their calorie intake and to avoid the foods usually consumed during episodes of binge-eating. Although there is some phenomenological resemblance between binge-eating and substance abuse, there is no evidence that physiological addiction plays any role in bulimia nervosa.

### Assessment

#### Special Issues in Psychiatric Examination and History

The assessment of individuals who may have bulimia nervosa is similar to that described for anorexia nervosa. The patient should be asked to describe a typical day’s food intake and a typical binge and the interviewer should assess whether the patient does indeed consume an unusually large amount of food as required by the DSM-IV definition of a binge. The interviewer should explicitly inquire about self-induced vomiting and whether syrup of ipecac is ever used to promote vomiting. The interviewer should ask about the use of laxatives, diuretics, diet pills and enemas. A weight history should be obtained, so the interviewer can determine whether the binge-eating was preceded by obesity or by anorexia nervosa, as is often the case. Because there is substantial comorbidity, the interviewer should ascertain whether there is a history of anxiety or mood disturbance or of substance abuse.

#### Physical Examination and Laboratory Findings

The patient should be weighed and the presence of dental erosion noted. Routine laboratory testing reveals an abnormality of fluid and electrolyte balance such as those described in the section on pathophysiology in about 10% of patients with bulimia nervosa.

## Differences in Presentation

Probably the greatest difference in presentation is between those individuals who purge and those who do not. Individuals with the nonpurging form of bulimia nervosa are more likely to be overweight at the time of presentation and to exhibit less general psychiatric illness compared with individuals who induce vomiting.

## Differential Diagnosis

Bulimia nervosa is not difficult to recognize if a full history is available. The binge-eating/purging type of anorexia nervosa has much in common with bulimia nervosa but is distinguished by the characteristic low body weight and, in women, amenorrhea. Some individuals with atypical forms of depression overeat when depressed; if the overeating meets the definition of a binge described previously (i.e., a large amount of food is consumed with a sense of loss of control) and if the binge-eating is followed by inappropriate compensatory behavior, occurs sufficiently frequently and is associated with over concern regarding body shape and weight, an additional diagnosis of bulimia nervosa may be warranted. Some individuals become nauseated and vomit when upset; this and similar problems are probably not closely related to bulimia nervosa and should be viewed as a somatoform disorder.

Many individuals who believe they have bulimia nervosa have a symptom pattern that fails to meet full diagnostic criteria because the frequency of their binge-eating is less than twice a week or because what they view as a binge does not contain an abnormally large amount of food. Individuals with these characteristics fall into the broad and heterogeneous category of atypical eating disorders. Binge-eating disorder (see section on binge-eating disorder), a category currently included in the DSM-IV appendix B for categories that need additional research, is characterized by recurrent binge-eating similar to that seen in bulimia nervosa but without the regular occurrence of inappropriate compensatory behavior.

## Course and Natural History

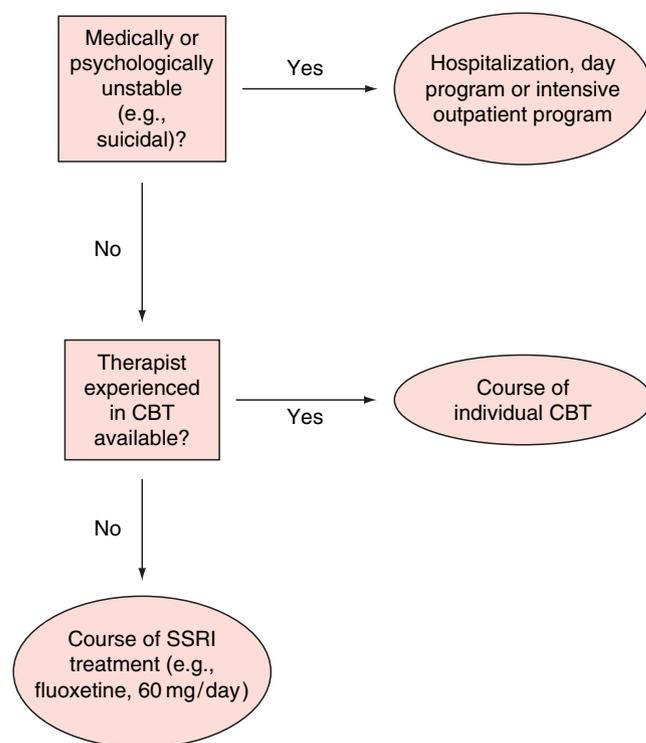

Over time, the symptoms of bulimia nervosa tend to improve although a substantial fraction of individuals continue to engage in binge-eating and purging. On the other hand, some controlled clinical trials have reported that structured forms of psychotherapy have the potential to yield substantial and sustained recovery in a significant fraction of patients who complete treatment. It is not clear what factors are most predictive of good outcome, but those individuals who cease binge-eating and purging completely during treatment are least likely to relapse.

## Goals of Treatment

The goals of the treatment of bulimia nervosa are straightforward. The binge-eating and inappropriate compensatory behaviors should cease and self-esteem should become more appropriately based on factors other than shape and weight.

## Treatment

The power struggles that often complicate the treatment process in anorexia nervosa occur much less frequently in the treatment of patients with bulimia nervosa. This is largely because the critical behavioral disturbances, binge-eating and purging, are less egosyntonic and are more distressing to these patients. Most bulimia nervosa patients who pursue treatment agree with the primary treatment goals and wish to give up the core behavioral features of their illness.

**Figure 58.6** Algorithm for choice of initial treatment of bulimia nervosa.

The treatment of bulimia nervosa has received considerable attention in recent years and the efficacies of both psychotherapy and medication have been explored in numerous controlled studies (Figure 58.6). The form of psychotherapy that has been examined most intensively is cognitive-behavioral therapy, modeled on the therapy of the same type for depression. Cognitive-behavioral therapy for bulimia nervosa concentrates on the distorted ideas about weight and shape, on the rigid rules regarding food consumption and the pressure to diet and on the events that trigger episodes of binge-eating. The therapy is focused and highly structured and is usually conducted in 3 to 6 months. Approximately 25 to 50% of patients with bulimia nervosa achieve abstinence from binge-eating and purging during a course of cognitive-behavioral therapy and in most, this improvement appears to be sustained. The most common form of cognitive-behavioral therapy is individual treatment, although it can be given in either individual or group format. The effect of cognitive-behavioral therapy is greater than that of supportive psychotherapy and of interpersonal therapy, indicating that cognitive-behavioral therapy should be the treatment of choice for bulimia nervosa.

The other commonly used mode of treatment that has been examined in bulimia nervosa is the use of antidepressant medication. This intervention was initially prompted by the high rates of depression among patients with bulimia nervosa and has now been tested in more than a dozen double-blind, placebo-controlled studies using a wide variety of antidepressant medications. Active medication has been consistently found to be superior to placebo, and although there have been no large “head-to-head” comparisons between different antidepressants, most antidepressants appear to possess roughly similar antibulimic potency. Fluoxetine at a dose of 60 mg/day is favored by many investigators because it has been studied in several large trials and appears to be at least as effective as, and better tolerated than, most

other alternatives. It is notable that it has not been possible to link the effectiveness of antidepressant treatment for bulimia nervosa to the pretreatment level of depression. Depressed and nondepressed patients with bulimia nervosa respond equally well in terms of their eating behavior to antidepressant medication.

Although antidepressant medication is clearly superior to placebo in the treatment of bulimia nervosa, several studies suggest that a course of a single antidepressant medication is generally inferior to a course of cognitive-behavioral therapy. However, patients who fail to respond adequately to, or who relapse following a trial of psychotherapy, may still respond to antidepressant medication.

### Special Features Influencing Treatment

A major factor influencing the treatment of bulimia nervosa is the presence of other significant psychiatric or medical illness. For example, it can be difficult for individuals who are currently abusing drugs or alcohol to use the treatment methods described, and many psychiatrists suggest that the substance abuse needs to be addressed before the eating disorder can be effectively treated. Other examples include the treatment of individuals with bulimia nervosa and serious personality disturbance and those with insulin-dependent diabetes mellitus who “purge” by omitting insulin doses. In treating such individuals, the psychiatrist must decide which of the multiple problems must be first addressed and may elect to tolerate a significant level of eating disorder to confront more pressing disturbances.

### Refractory Patients

Although psychotherapy and antidepressant medication are effective interventions for many patients with bulimia nervosa, some individuals have little or no response. There is no clearly established algorithm for the treatment of such refractory patients. Alternative interventions that may prove useful include other forms of psychotherapy and other medications such as opiate antagonists and the serotonin agonist fenfluramine. Hospitalization should also be considered as a way to normalize eating behavior, at least temporarily, and perhaps to initiate a more effective outpatient treatment.

## Binge-eating Disorder

### History

As noted earlier, binge-eating disorder is a proposed diagnostic category related to, but quite distinct from, bulimia nervosa. Individuals with binge-eating disorder, like individuals with bulimia nervosa, repeatedly engage in episodes of binge-eating but, unlike patients with bulimia nervosa, do not regularly utilize inappropriate compensatory behaviors. Binge-eating disorder has been the focus of sustained attention only in the last decade. The clinical utility of the information which quickly developed following the recognition of bulimia in the DSM nomenclature was an important source of interest in binge-eating disorder.

### Definition

Suggested diagnostic criteria for binge-eating disorder are included in an appendix of DSM-IV-TR which provides criteria sets for further study. These criteria require recurrent episodes of binge-eating, which are defined just as for bulimia nervosa. The major difference from bulimia nervosa is that individuals with binge-eating disorder do not regularly use inappropriate

compensatory behavior, although the precise meaning of “regularly” is not specified. Other differences from the definition of bulimia nervosa relate to the frequency of binge-eating: individuals with bulimia nervosa must binge-eat, on average, at least two times per week over the last 3 months, whereas individuals with binge-eating disorder must binge-eat at least 2 days per week over the last 6 months. A major reason for the difference in the criteria is that the end of a binge episode in bulimia nervosa is usually clearly marked by the occurrence of inappropriate compensatory behavior, like purging, whereas in binge-eating disorder, the end of a binge episode may be more difficult to identify precisely. The criteria attempt to deal with this definitional difficulty by requiring the frequency of binge-eating to be measured in terms of the number of days per week on which episodes occur and, because of the potential difficulty in distinguishing “normal” overeating from binge-eating, to require a 6 month duration, rather than 3 months for bulimia nervosa. In addition, the suggested DSM-IV-TR criteria for binge-eating disorder require that individuals report behavioral evidence of a sense of loss of control over eating, such as eating large amounts of food when not physically hungry. Finally, while there is some evidence that individuals with binge-eating disorder tend to be more concerned about body image than individuals of similar weight, the criteria for binge-eating disorder require only that there is marked distress over the binge-eating. Thus, the criteria for binge-eating disorder do not require that self-evaluation be overly influenced by concerns regarding body weight and shape, as is required for bulimia nervosa.

### Epidemiology

The epidemiology of binge-eating disorder is uncertain. Cross-sectional studies suggest that the prevalence of binge-eating disorder among adults is a few percent and that the prevalence is higher among obese individuals in the community and among obese individuals who attend weight loss clinics. Similarly, the frequency of binge-eating disorder increases with the degree of obesity. In contrast to anorexia nervosa and bulimia nervosa, individuals with binge-eating disorder are more likely to be men (the female to male ratio is roughly 1.5 : 1 compared with approximately 10 : 1 for anorexia nervosa and bulimia nervosa), from minority ethnic groups and middle-aged.

### Etiology

Very little is known about the etiology of binge-eating disorder. Binge-eating disorder is clearly associated with obesity, but it is uncertain to what degree the binge-eating is a contributor to and to what degree a consequence of, the obesity.

### Diagnosis and Differential Diagnosis

#### Phenomenology

In theory, binge-eating disorder should be easy to recognize on the basis of patient self-report: the individual describes the frequent consumption of large amounts of food in a discrete period of time about which he or she feels distressed and unable to control. Difficulties arise, however, because of uncertainty about what precisely constitutes a “large amount of food”, especially for an obese individual and regarding what constitutes a discrete period of time. Many individuals describe eating continuously during the day or evening, thereby consuming a large amount of food, but it is not clear whether such behavior is best viewed as binge-eating. Individuals who meet the proposed definition of binge-eating disorder clearly have increased complaints of

depression and anxiety compared with individuals of similar weight without binge-eating disorder.

### Assessment

The assessment of individuals who may have binge-eating disorder parallels that of individuals who may have bulimia nervosa. It is important to obtain a clear understanding of daily food intake and of what the individual considers a binge. As in the assessment of bulimia nervosa, the interviewer should inquire about the use of purging and other inappropriate weight control methods. Individuals who describe binge-eating disorder are likely to be obese, and it is important to obtain a history of changes in weight and of efforts to lose weight. The interviewer should also inquire about symptoms of mood disturbance and anxiety.

### Physical Examination and Laboratory Findings

The salient general medical issue is that of obesity. Individuals with binge-eating disorder who are obese should be followed by a primary care physician for assessment and treatment of the complications of obesity. There is no evidence suggesting that the behavioral disturbances characteristic of binge-eating disorder add to the physical risks of obesity. Whether the presence of binge-eating disorder affects the natural history of obesity is an intriguing but unanswered question.

### Differential Diagnosis

As noted above, the most difficult issue in the diagnostic assessment of binge-eating disorder is determining whether the eating pattern of concern to the individual meets the proposed definition of binge-eating. There are numerous varieties of unhealthy eating, such as the consumption of high fat foods and the nosology of these patterns of eating is poorly worked out.

Some individuals with atypical depression binge-eat when depressed; if the individual meets criteria for both binge-eating disorder and an atypical depression, both diagnoses should be made.

### Course and Natural History

As the recognition of binge-eating disorder is quite recent, there is little definitive information about the natural history of this disorder. However, both controlled treatment studies and follow-up studies of community samples indicate that there is substantial fluctuation over time in the frequency and severity of the cardinal symptoms of this disorder.

### Goals of Treatment

For most individuals with binge-eating disorder, there are three related goals. One is behavioral, to cease binge eating. A second focuses on improving symptoms of mood and anxiety disturbance which frequently are associated with binge-eating disorder. The third is weight loss for individuals who are also obese.

### Treatment

Treatment approaches to binge-eating disorder are currently under active study. There is good evidence that psychological (e.g.,

CBT) and pharmacological (e.g., SSRI) interventions which are effective for bulimia nervosa are also useful in reducing the binge frequency of individuals with binge-eating disorder and in alleviating mood disturbance. However, it is not clear how helpful these approaches are in facilitating weight loss. Standard behavioral weight loss interventions employing caloric restriction appear useful in helping patients to control binge-eating, but the benefits of such treatment have not been compared with those of more psychologically-oriented treatments, such as CBT.

## Comparison of DSM-IV/ICD-10 Diagnostic Criteria

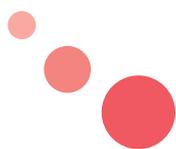

The ICD-10 Diagnostic Criteria for Research and the DSM-IV-TR criteria for anorexia nervosa differ in several ways. ICD-10 specifically requires that the weight loss be self-induced by the avoidance of “fattening foods” and that in men there be a loss of sexual interest and potency (corresponding to the amenorrhea requirement in women). Finally, in contrast to DSM-IV-TR which gives anorexia nervosa precedence over bulimia nervosa, ICD-10 excludes a diagnosis of anorexia nervosa if regular binge eating has been present.

For bulimia nervosa, the ICD-10 Diagnostic Criteria for Research and the DSM-IV-TR criteria for bulimia nervosa are similar except that ICD-10 requires a “persistent preoccupation with eating and a strong desire or sense of compulsion to eat”. Furthermore, whereas the ICD-10 definition requires a self-perception of being too fat (identical to an item in anorexia nervosa), the DSM-IV-TR criteria set requires instead that “self-evaluation is unduly influenced by body shape and weight”.

Both DSM-IV-TR and ICD-10 include categories unique to their systems. DSM-IV-TR has a category for “Binge-Eating Disorder” in its appendix of research categories whereas ICD-10 has categories for “Overeating associated with other psychological disturbances” and “Vomiting associated with other psychological disturbances”.

# Sleep and Sleep–Wake Disorders

## Physiological Regulation of Sleep and Wakefulness

Three physiological processes regulate sleep and wakefulness.

### Ultradian Rhythm of Rapid Eye Movement (REM) and Non-rapid Eye Movement (Non-REM) Sleep

Sleep consists of two major REM and non-REM sleep, which alternate throughout the sleep period. Sleep normally begins in the adult with non-REM sleep and is followed after about 70 to 90 minutes by the first REM period. Thereafter, non-REM sleep and REM sleep oscillate with a cycle length (the interval between onset of each non-REM or REM period) of about 80 to 110 minutes. This cycle of REM and non-REM sleep is an example of an ultradian rhythm, a biological rhythm with a cycle length considerably less than 24 hours.

On the basis of electroencephalographical (EEG) characteristics, non-REM sleep in humans is further divided into four stages: stage 1, a brief transitional stage between wakefulness and sleep; stage 2, which occupies the greatest amount of time during sleep; and stages 3 and 4, sometimes called delta sleep because of the characteristic high-amplitude slow EEG waves (delta waves) (Table 59.1). The amount of ocular activity per minute of REM sleep is quantified as REM density; this can be measured by either visual scoring (e.g., on an analogue scale from 0 to 8 per minute) or by computer analysis. Dreaming is commonly reported and is usually vivid when subjects are awakened from REM sleep but also occurs during non-REM sleep, especially at sleep onset during stage 1 sleep.

### Circadian (24-Hour) Rhythm of Sleep and Wakefulness

The rest–activity or sleep–wake cycle is an example of a circadian rhythm (Table 59.2). Other examples include the hypothalamic–pituitary–adrenal axis, thyroid-stimulating hormone and core body temperature. [Circadian rhythms can be characterized by three difference measures: 1) cycle length (**tau**) (e.g., the time between two peaks of the  $\sim$ 24 hour temperature curve); 2) amplitude (e.g., the difference between the minimum value of the cycle (**nadir**) and maximum value (**acrophase**), for example, the difference between the lowest and highest points in the 24 hour temperature curve; and 3) phase position of the rhythm (e.g., the time of day when the acrophase occurred).]

The propensity for sleep and wakefulness varies in a circadian fashion, at least after infancy, and is modulated in part by one or more biological clocks. The suprachiasmatic nucleus (SCN) in the anterior hypothalamus plays a decisive role in the regulation of most circadian rhythms in humans and animals. The endogenous activity rhythms of the SCN are synchronized with the environment primarily by ambient light. Information regarding light reaching the retina is conveyed to the SCN directly through the retinohypothalamic tract and indirectly through the intergeniculate leaflet of the lateral geniculate body. Changes in light intensity, especially at dawn and dusk, are particularly important in synchronizing endogenous oscillators controlling rhythms of sleep–wake, cortisol, melatonin and core body temperature with one another and with the outside world.

If humans are allowed to choose their sleep–wake cycles in the absence of time cues such as daily light–dark signals or clocks, they usually show, as most mammalian species do, a sleep–wake cycle longer than 24 hours. The self-selected rest–activity cycle is typically about 24.5 to 25 hours in length, although it may increase, for example, to 36 hours (24 hours awake and 12 hours asleep). These observations imply that neurons within the SCN have an inherent rhythmicity of approximately 24.5 to 25 hours. Subjects in a time-free environment are said to be “free-running” because endogenous processes, such as a circadian oscillator, rather than environmental cues, determine their sleep–wake, endocrine and other rhythms.

The propensity for, character and duration of sleep are closely related to the phase position of the underlying circadian oscillator. If the daily temperature curve is used to index the phase position of the biological clock, sleep in general and REM sleep in particular occur most commonly near the nadir of the temperature rhythm. Thus, in persons who live a conventional sleep schedule (11 PM–7 AM), REM sleep is more common in the last half of the night when core body temperature is lowest than in the first half and more likely in morning naps than in afternoon naps. Furthermore, subjects tend to awaken on the rising phase of the temperature rhythm.

Appropriate exposure to light and darkness can change the phase position of the underlying biological oscillator or, in some circumstances, the amplitude of circadian rhythms. Bright light at the beginning of the subjective evening in conjunction with dark during the subjective morning delays and resets the phase position of the temperature, cortisol, melatonin and sleep–wake rhythms; dark in the subjective evening and bright light in the subjective morning have the opposite effect. The magnitude and direction of the changes induced by bright light or other Zeitgebers (“timegivers”) at any particular time form the **phase-response curve**.

**Table 59.1** Commonly Used Terms in Human Sleep Studies

Term	Definition
Delta wave	Electroencephalographic pattern conventionally defined as $\leq 75$ mV, $\leq 0.5$ Hz or cycles per second wave; the amplitude tends to decrease with normal aging
Non-REM sleep	Stages 1, 2, 3, and 4 sleep
Total sleep time	Non-REM and REM sleep time
REM latency	Time from onset of sleep to onset of REM sleep; declines from about 70–100 min in the 20s to 55–70 min in the elderly, short REM latency associated with narcolepsy, depression, and a variety of clinical conditions
REM sleep	Rapid eye movement sleep; characterized by low-voltage, relatively fast frequency EEG, bursts of rapid eye movements, and loss of tone (atonia) in the major antigravity muscles; associated with dreaming
Sleep efficiency	Percentage of time in bed spent in sleep; usually above 90% in the young, falls somewhat with age
Sleep latency	Time from “lights out” to onset of sleep
Stage 1 sleep	A brief transitional state of sleep between wakefulness and sleep, characterized by low-voltage, mixed-frequency EEG and slow eye movements; about 5% of total sleep time
Stage 2 sleep	Characterized by K complexes and sleep spindles (12–14 per cycle rhythms) in the EEG; usually about 45–75% of total sleep time
Stages 3 and 4 sleep	Sometimes referred to as delta sleep, based on amount of sleep delta waves in EEG, 20–50% of an epoch (i.e., 30 or 60 s) for stage 3, more than 50% for stage 4; amount per night declining from about 20–25% of total sleep time in the teens to nearly zero in the elderly
WASO	Wake time sleep onset
REM density	A measure of amount of ocular activity per minute of REM sleep

The phase position of the circadian oscillator can also be estimated in humans by the 24-hour rhythms of cortisol or melatonin secretion. Because these rhythms can be affected by exercise, meals, light and so forth, the conditions under which they are measured should be controlled. For example, clinical investigators may use a “constant routine” condition in which the subjects are kept awake in bed for 36 hours, under constant low-intensity. An alternative is to determine the onset of melatonin secretion under dark conditions (dim light melatonin onset). As discussed later, various strategies are under experimental

**Table 59.2** Commonly Used Terms in Chronobiology

Term	Definition
Acrophase	The time, at which the maximal point of a circadian rhythm occurs, i.e., maximal secretion of cortisol normally occurs at midmorning in humans.
Circadian rhythm	Refers to biological rhythms having a cycle length of about 24 h, derived from Latin <i>circa dies</i> , “about 1 d”; examples include the sleep–wake cycle in humans, temperature, cortisol and psychological variation in the 24-h day; characterized by exact cycle length ( $\tau$ ), amplitude and phase position.
Constant routine	An experimental method used to estimate amplitude and phase position of circadian temperature and neuroendocrine rhythms; the subject remains awake for about 36 h under dim light, with head elevated slightly, eating frequent equal-calorie meals, while blood samples are withdrawn unobtrusively every 20–30 min and rectal temperature is measured about once a minute.
Dim light melatonin onset (DLMO)	An experimental method for estimating the phase of melatonin onset; under dim light conditions starting in late afternoon, blood samples are withdrawn every 20–30 min to determine when melatonin secretion begins.
Nadir	Time when the minimal point of a circadian rhythm occurs.
Phase position	Temporal relationship between rhythms or between one rhythm and the environment; e.g., maximal daily temperature peak (acrophase) usually occurs in the late afternoon.
Phase-advanced rhythm	Phase position of biological rhythm occurs earlier than reference, i.e., the patient retires and arises early.
Phase-delayed rhythm	Phase position of biological rhythm occurs later than reference, i.e., the patient retires and arises late.
Phase-response curve	Graph showing the magnitude and direction of change in phase position of circadian rhythm depending upon timing of Zeitgeber with reference to the endogenous oscillator.
Tau	Cycle length, e.g., from one acrophase to the next of temperature.
Zeitgebers	Time cues, such as social activities, meals and bright lights, that influence phase position of rhythm.

development with the hope that appropriate administration of light–dark cycles, melatonin, vitamin B<sub>12</sub>, or specific medications will “nudge” and “squash” the circadian oscillator correctly better to manage clinical disorders of sleep–wakefulness, such as jet lag, delayed sleep syndrome and shift work. In addition, bright light has been shown to have antidepressant effects in patients with winter depression, some patients with major depressive disorder and patients with premenstrual dysphoric disorder.

If animals suffer lesions of the SCN, they no longer exhibit circadian rhythms of temperature, cortisol secretion, eating, drinking, or sleep–wakefulness. Sleep and wakefulness, for example, are taken in brief bouts throughout the 24-hour day. Total sleep time, however, may increase under these circumstances. No selective lesion of the human SCN has been documented.

### Homeostatic Regulation of Sleep–Wakefulness

Common experience suggests that the longer one is awake, the more likely one is to fall asleep. Furthermore, sleep reverses the sleepiness and other consequences of wakefulness. Thus, sleep can be said to perform a homeostatic function; it is a time of rest and restoration that overcomes the “ravages of wakefulness” (Daan *et al.*, 1984). Consistent with the hypothesis, sleep deprivation usually decreases sleep latency and increases sleep efficiency and delta sleep on recovery nights.

The precise regulation of sleep and wakefulness remains an area of intense investigation and theory. Two of the current theories of sleep–wake regulation include the two-process model (Daan *et al.*, 1984) and the opponent process model (Edgar *et al.*, 1993). The first postulates that sleep and wakefulness are regulated by a circadian process (process C), which sets the circadian thresholds for sleep and wakefulness, and a homeostatic process (process S), in which sleep propensity builds up with wakefulness and dissipates during non-REM sleep, especially delta sleep. The opponent process model postulates that the SCN promotes alertness and that duration of wakefulness facilitates sleep.

### Normal Age-related Changes in Sleep and Wakefulness

The newborn spends nearly 50% of total sleep time in REM sleep. Because infants may sleep up to 16 hours a day, the infant may spend 8 hours in REM sleep per day. Often to the consternation of the parents, the newborn has a polyphasic sleep–wake pattern, with short bouts of sleep and wakefulness throughout the 24-hour day, until several months of age when the child eventually sleeps through the night. Daytime napping, however, often persists until the age of 4 to 6 years. Stages 3 and 4 sleep increase in the early years. Maximal “depth” of sleep may occur during the prepubertal period, when children are often difficult to awake at night. Adolescents often still need at least 10 hours of sleep. Yet, during adolescence, stages 3 and 4 sleep decline and daytime sleepiness increases, partially in association with the normal Tanner stages of pubertal development. Teenagers are also phase delayed which means that they may not get sleepy until the early morning hours (e.g., 2–3 AM) and do not naturally wake up until the later morning hours. Early school start times and social pressures may produce mild sleep deprivation during weekdays, with some catch-up on weekends.

As adults enter middle age and old age, sleep often becomes more shallow, fragmented, and variable in duration and circadian timing compared with that of young adults. Stages 1 and 2 and wake time after sleep onset tend to increase; REM latency and stages 3 and 4 decline, probably at an earlier age in men than in women and possibly related to changes in brain structure and metabolism. Daytime sleepiness and napping usually increase with age, often as a function of disturbed nocturnal sleep. The elderly frequently choose an “early-to-bed, early-to-rise” pattern reflecting, in part, an apparent phase advance of the circadian clock. Even when they retire at the same time that they did when they were young, they still tend to wake up early, thus sleep-depriving themselves. This can lead to daytime sleepiness and napping. Although average total sleep time actually increases slightly after age 65 years, greater numbers of persons fall into either long-sleeping (>8 hours) or short-sleeping (<7 hours) subgroups. Psychiatrists should always consider the role of chronobiological factors when evaluating patients with sleep disorders, especially the elderly, who have more sleep–wake complaints than younger persons. The sleep–wake patterns of the early bedtimes of the elderly, short REM latency, sleep fragmentation at night and napping during the day may reflect a phase-advance and reduced amplitude of the circadian oscillator.

Factors that could contribute to these age-related patterns include loss of influence from Zeitgebers (light, work schedules, social demands, physical exercise) and a weaker signal from the circadian oscillator to effector systems. Indoor living conditions or loss of hearing and sight may deprive individuals of cues that synchronize the circadian system. In a significant number of totally blind persons, for example, the circadian oscillator free-runs in the normal environment, with resulting regular periods of insomnia and hypersomnia every 3 weeks as the circadian oscillator delays by about 45 minutes each 24 hours while the subject tries to maintain a normal sleep period (11PM–7AM). In a study of normally sighted elderly individuals in San Diego, California, exposure to self-selected bright light averaged 45 minutes and 90 minutes per day for healthy women and men, respectively; 30 minutes per day for patients with Alzheimer’s disease living at home; and 2 minutes for chronically ill, institutionalized patients (Jacobs *et al.*, 1989). Perhaps not surprisingly, the elderly in one nursing home study never spent more than an hour in either consolidated sleep or wakefulness throughout a 24-hour period (Jacobs *et al.*, 1989).

### Neurophysiology and Neurochemistry of Sleep

The non-REM–REM sleep cycle is regulated within the brain stem. Consistent with the concept that the brain stem regulates REM sleep, an Israeli soldier ceased having REM sleep after suffering a shrapnel wound to the brain stem (Lavie *et al.*, 1984). Some antidepressant medications, notably monoamine oxidase inhibitors (MAOIs), completely eliminate REM sleep when they are taken at high clinical doses for more than 2 weeks. No specific deleterious effects have been attributed to the loss of REM sleep in these patients. These observations underscore the mystery about the fundamental functions of REM sleep in particular and sleep in general.

No specific “sleep neurotransmitter” has been identified that is responsible for the induction or maintenance of sleep, but many different types of neurochemicals (neurotransmitters,

neuromodulators, neuropeptides, immune modulators) have been implicated. Adenosine is a potential sleep promoting neurotransmitter; its concentration in basal forebrain increases with prolonged wakefulness. Caffeine probably promotes alertness by blocking the adenosine  $A_1$ -receptor. Of particular importance to psychiatry, acetylcholine, released from neurons originating in the dorsal tegmentum, induces REM sleep and cortical activation. Serotonin and norepinephrine, on the other hand, inhibit REM sleep, possibly by inhibition of cholinergic neurons responsible for REM sleep. These physiological mechanisms may be involved in both depression and the sleep disturbances associated with depression and other neuropsychiatric disorders, such as short REM latency (see later). For example, depression may be associated with a functional serotonin deficiency. The suppression of REM sleep during treatment with antidepressants may reflect either enhanced serotonergic or noradrenergic neurotransmission or anticholinergic effects.

In addition, considerable current research suggests that sleep and immunological processes are intimately related. Several neuroimmunomodulators, such as specific interleukins or tumor necrosis factor, may promote sleep and sleep deprivation may alter immune function, for example, reducing activity of natural killer cells.

## Sleep Disorders

Sleep disorders can be divided into four major categories: 1) insomnias, disorders associated with complaints of insufficient, disturbed, or nonrestorative sleep; 2) hypersomnias, disorders of excessive sleepiness; 3) disturbances of the circadian sleep-wake cycle; and 4) parasomnias, abnormal behaviors or abnormal physiological events in sleep (American Psychiatric Association, 1994). By definition, the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (DSM-IV) limits itself to chronic disorders (at least 1 month in duration). On the other hand, the *International Classification of Sleep Disorders* includes sleep disorders of short-term and intermediate duration, which in fact are more common than chronic disorders (Diagnostic Classification Steering Committee Therapy MJC, 1990).

## General Approach to the Patient with a Sleep Disorder

Disorders of sleep and wakefulness are common. Insomnia complaints are reported by about one-third of adult Americans during a 1-year period; clinically significant obstructive sleep apnea may be seen in as many as 10% of working, middle-aged men; and sleepiness is an underrecognized cause of dysphoria, automobile accidents and mismanagement of patients by sleep-deprived physicians. Nearly all physicians will hear complaints of sleep problems. Psychiatrists may be even more likely than other medical specialists to receive these complaints. Of particular importance for mental disorders, prospective epidemiological studies suggest that persistent complaints of either insomnia or hypersomnia are risk factors for the later onset of depression, anxiety disorders and substance abuse.

This chapter attempts to provide a framework for psychiatrists and other mental health specialists to use in understanding the multiple causes of the sleep disorders, their diagnostic evaluation and their treatment. To assist the patient with a sleep

complaint, the psychiatrist needs to have a diagnostic framework with which to obtain the information needed about both the patient as a person and his or her disorder. Two issues are particularly important: 1) How long has the patient had the sleep complaint? Transient insomnia and short-term insomnia, for example, usually occur in persons undergoing acute stress or other disruptions, such as admission to a hospital, jet lag, bereavement, or change in medications. Chronic sleep disorders, on the other hand, are often multidetermined and multifaceted: 2) Does the patient suffer from any preexisting or comorbid disorders? Does another condition cause the sleep complaint, modify a sleep complaint, or affect possible treatments? In general, because common sleep disorders are frequently secondary to underlying causes, treatment should be directed at underlying medical, psychiatric, pharmacological, psychosocial, or other disorders.

A detailed history of the complaint and attendant symptoms must be obtained (Tables 59.3 and 59.4). Special attention should be given to the timing of sleep and wakefulness; qualitative and quantitative subjective measures of sleep and wakefulness; abnormal sleep-related behaviors; respiratory difficulties; medications or other substances affecting sleep, wakefulness, or arousal; expectations, concerns, attitudes about sleep, and efforts used by the patient to control symp-

**Table 59.3 Office Evaluation of Chronic Sleep Complaints**

Detailed history and review of the sleep complaint: predisposing, precipitating and perpetuating factors
Review of difficulties falling asleep, maintaining sleep and awakening early
Timing of sleep and wakefulness in the 24-h day
Evidence of excessive daytime sleepiness and fatigue
Bedtime routines, sleep setting, physical security, preoccupations, anxiety, beliefs about sleep and sleep loss, fears about consequences of sleep loss
Medical and neurological history and examination, routine laboratory examinations: look for obesity, short fat neck, enlarged tonsils, narrow upper oral airway, foreshortened jaw (retrognathia) and hypertension
Psychiatric history and examination
Use of prescription and nonprescription medications, alcohol, stimulants, toxins, insecticides and other substances
Evidence of sleep-related breathing disorders: snoring, orthopnea, dyspnea, headaches, falling out of bed, nocturia
Abnormal movements or behaviors associated with sleep disorders: "jerky legs," leg movements, myoclonus, restless legs, leg cramps, cold feet, nightmares, enuresis, sleepwalking, epilepsy, bruxism, sleep paralysis, hypnagogic hallucinations, cataplexy, night sweats and so on
Social and occupational history, marital status, living conditions, financial and security concerns, physical activity
Sleep-wake diary for 2 wk
Interview with bed partners or persons who observe patient during sleep
Tape recording of respiratory sounds during sleep to screen for sleep apnea

**Table 59.4 Selected Disorders and Terms Used in Clinical Sleep Disorders Medicine**

Term	Definition
Apnea index	Number of apneic events per hour of sleep; usually is considered pathological if $\geq 5$ .
Cataplexy	Sudden, brief loss of muscle tone in the waking stage, usually triggered by emotional arousal (laughing, anger, surprise), involving either a few muscle groups (i.e., facial) or most of major antigravity muscles of the body; may be related to muscle atonia normally occurring during REM sleep; is associated with narcolepsy.
Hypopnea	50% or more reduction in respiratory depth for 10 s or more during sleep.
Multiple Sleep Latency Test	An objective method for determining daytime sleepiness; sleep latency and REM latency are determined for four or five naps (i.e., a 20-min opportunity to sleep every 2 h between 10 AM and 6 PM); normal mean values are above 15 min.
Periodic limb movements in sleep index	Number of leg kicks per hour of sleep; usually is considered pathological if $\geq 5$ .
Polysomnography	Describes detailed, sleep laboratory-based, clinical evaluation of patient with sleep disorder; may include electroencephalographical measures, eye movements, muscle tone at chin and limbs, respiratory movements of chest and abdomen, oxygen saturation, electrocardiogram, nocturnal penile tumescence, esophageal pH, as indicated.
Respiratory disturbance index	Number of apneas and hypopneas per hour of sleep.
Sleep apnea	Sleep-related breathing disorder characterized by at least five episodes of apnea per hour of sleep, each longer than 10 s in duration.

toms; and the sleep–wake environment. The psychiatrist must be alert to the possibility that sleep complaints are somatic symptoms, which reflect individual ways of experiencing, expressing and coping with psychosocial distress, stress, or psychiatric disorders.

Sleep disorders vary with age and gender and, possibly, with culture and social class. As mentioned previously, the circadian timing of rest–activity, sleep duration at night, and daytime napping and sleepiness vary with age and gender. In addition, parasomnias are most common in boys, Kleine–Levin syndrome in adolescent boys, delayed sleep phase syndrome in adolescents and young adults, insomnia in middle-aged and elderly women, REM sleep behavior disorder and sleep-related breathing disorders in middle-aged men, and advanced sleep phase syndrome in the elderly. Sleep–wake patterns are also influenced by cultural or geographical factors, such as the siesta and late bedtime commonly associated with tropical climates, or the winter hypersomnia and summer hyposomnia said to occur near the Arctic circle. Insomnia is more common in lower than in middle and upper socioeconomic classes, perhaps reflecting the stress of poverty, crowding and lack of privacy, poor medical care, drugs and alcohol, lack of physical security and so forth.

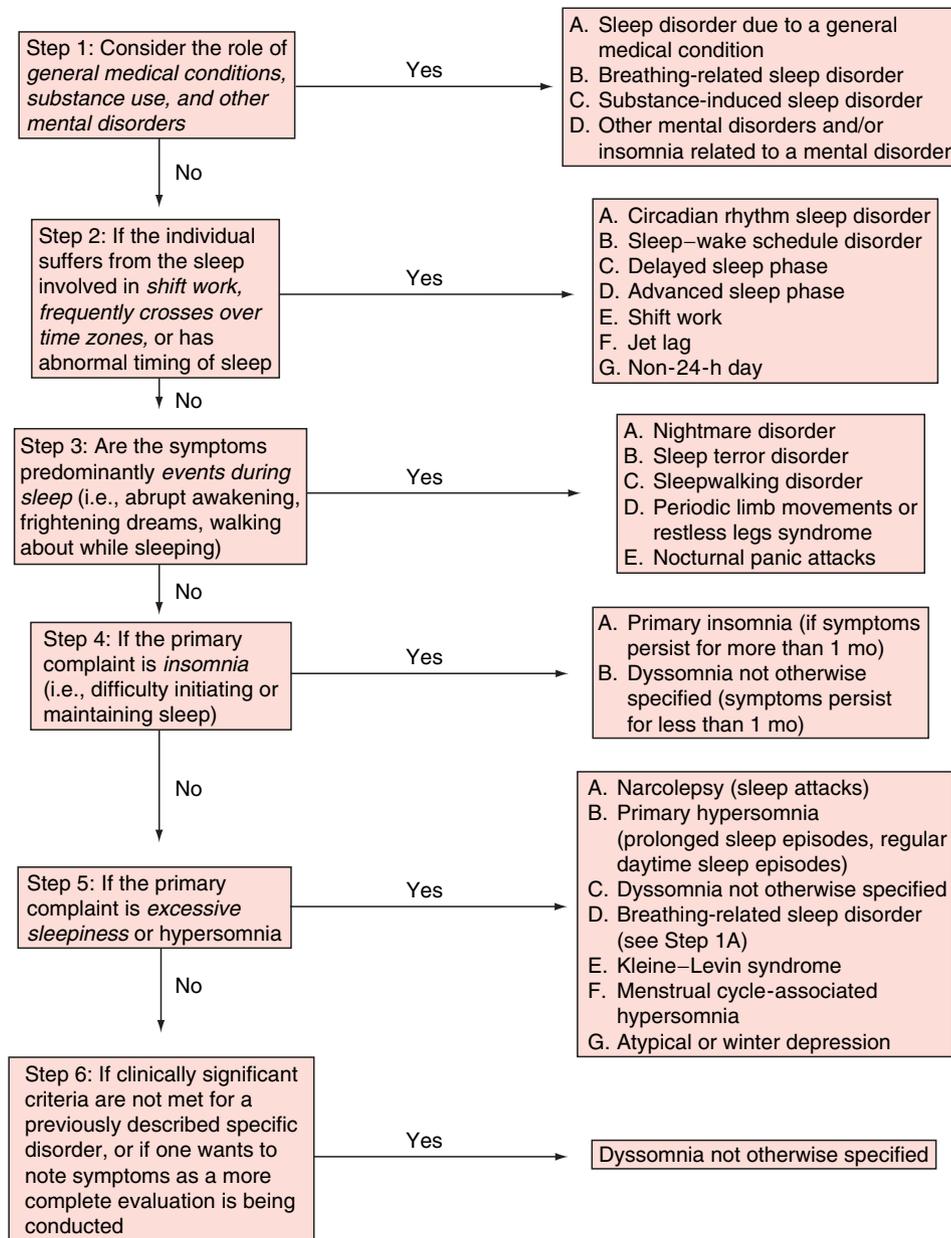

One approach to the differential diagnosis of persistent sleep disorders is suggested in the algorithm in Figure 59.1. First, determine whether the sleep complaint is due to another medical, psychiatric, or substance abuse disorder. Secondly, consider the role of circadian rhythm disturbances and sleep disorders associated with abnormal events predominantly during sleep. Finally, evaluate in greater detail complaints of insomnia (difficulty initiating or maintaining sleep) and excessive sleepiness.

### Role of the Sleep Laboratory in Clinical Sleep Disorders

Psychiatrists can usually diagnose most sleep disorders by traditional, simple but systematic clinical methods. Referral to a specialized sleep disorders center, however, should be considered in patients suspected of having severe intractable insomnia, persistent excessive daytime sleepiness and sleep disorders due to a general medical condition (such as narcolepsy, REM sleep behavior disorder, sleep apnea, periodic limb movements in sleep [PLMS], or sleep-related epilepsy). Specialists in sleep disorders medicine will evaluate the patient and, if necessary, arrange for sleep laboratory or ambulatory diagnostic procedures.

One of the most important and common laboratory examinations is all-night polysomnography, which typically records the EEG activity's eye movements with the electrooculogram, and muscle tone with the electromyogram from the chin (submental) muscles. These measures are used to determine sleep stages visually scored as 20- or 30-second epochs by a sleep technician. To evaluate sleep-related respiration and cardiovascular function, measures are made of nasal and oral air flow with a thermistor; of sounds of breathing and snoring with a small microphone near the mouth; of respiratory movements of the chest and abdominal walls; of heart rate with the electrocardiogram; and of blood-oxygen saturation with finger oximetry. To evaluate PLMS, an electromyogram from the shin (anterior tibial) muscles is obtained. Other more specialized tests include intraesophageal pressures, which increase during the upper airway resistance syndrome if respiration is impeded, nocturnal penile tumescence in the evaluation of impotence and core body temperature (usually rectal or tympanic membrane).

Daytime sleepiness can be evaluated in the sleep laboratory with the Multiple Sleep Latency Test, which measures sleep latency during opportunities for napping during the day (see Table 59.4). In addition, subjective sleepiness can be assessed by

**Figure 59.1** An algorithm for the differential diagnosis of persistent sleep disorder complaints.

a questionnaire, the Stanford Sleepiness Scale, in which the subject rates sleepiness on a 7-point scale at set intervals throughout the day.

Two research laboratory procedures have been developed for experimental measurement of circadian phase in humans: the constant routine method for temperature and neuroendocrine secretions, and the dim light melatonin onset method for melatonin (see Table 59.2).

According to DSM-IV-TR definitions (American Psychiatric Association, 1994), primary sleep disorders are presumed to arise from endogenous abnormalities in sleep-wake-generating mechanisms, timing mechanisms, sleep hygiene, or conditioning, rather than occurring secondary to medical or psychiatric disorders. Two types of primary sleep disorders are defined: **dyssomnias** (abnormalities in the amount, quality, or timing of sleep) and **parasomnias** (abnormal behaviors associated with sleep, such as

nightmares or sleepwalking). In addition, sleep disorders may be related to other mental disorders, general medical conditions, and substance abuse.

## Dyssomnias

### Primary Insomnia

According to DSM-IV-TR criteria, primary insomnia is a subjective complaint of poor, insufficient, or nonrestorative sleep lasting more than a month; associated with significant distress or impairment; and without obvious relationships to another sleep, medical, or psychiatric disorder or physiological effects of a substance. Primary insomnia is similar to some insomnia diagnoses in the *International Classification of Sleep Disorders*, including psychophysiological insomnia, which is often ascribed to

conditioned arousal factors; sleep state misperception, in which the magnitude of the subjective complaint often exceeds that of the objective abnormality; and idiopathic insomnia, with a childhood onset and lifelong course.

The etiology of primary insomnia is unclear, but it may be dependent more on the factors that perpetuate it than on those that precipitated it. In general surveys of the prevalence of insomnia in the population, about one in three people reported “insomnia” during the previous year, about one in six described it as “serious”, and about one in 12 called it “chronic” (Ancoli-Israel and Roth, 1999). The rates of insomnia are higher in women than in men, in the elderly than in the young, and in the lower than in the higher socioeconomic classes. In a survey conducted by the Gallup Poll for the National Sleep Foundation (Ancoli-Israel and Roth, 1999), the most common complaint of insomniacs is waking up feeling drowsy rather than specific complaints about sleep, implying that the sleepiness insomniacs experience could be associated with some morbidity. Compared with transient insomniacs or normal control subjects, chronic insomniacs reported greater difficulty enjoying family and social relationships, greater difficulty concentrating, more problems with memory, greater frequency of falling asleep while visiting friends, and more automobile accidents due to sleepiness. Nevertheless, only about 5% of patients with chronic insomnia ever sought medical attention specifically for insomnia. Only a minority of patients have ever used prescription sleeping pills. On the other hand, most psychiatrists do not routinely inquire about difficulties with sleep and wakefulness. If these patients with chronic or serious insomnia are to be helped, psychiatrists must be proactive and ask specific questions about sleep and its disorders.

### DSM-IV-TR Criteria 307.42

#### Primary Insomnia

- A. The predominant complaint is difficulty initiating or maintaining sleep, or nonrestorative sleep, for at least 1 month.
- B. The sleep disturbance (or associated daytime fatigue) causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- C. The sleep disturbance does not occur exclusively during the course of narcolepsy, breathing-related sleep disorder, circadian rhythm sleep disorder, or a parasomnia.
- D. The disturbance does not occur exclusively during the course of another mental disorder (e.g., major depressive disorder, generalized anxiety disorder, a delirium).
- E. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

The prevalence of primary insomnia is not known. Treatment of insomnia should, insofar as possible, be directed at identifiable causes, or those factors that perpetuate the disorders,

such as temperament and lifestyle, ineffective coping and defense mechanisms, inappropriate use of alcohol or other substances, maladaptive sleep–wake schedules and excessive worry about poor sleep. The harder these individuals try to sleep, the worse it is. They keep themselves awake by their apprehensions: “If I don’t get to sleep right now, I’ll make a bad impression tomorrow”. Cognitive–behavioral therapy (CBT) therefore is very effective, as shown by Morin and colleagues (1993). An 8-week group intervention aimed at changing maladaptive sleep habits and altering dysfunctional beliefs and attitudes about sleeplessness was effective in reducing sleep latency, waking up after sleep onset, and early morning awakening, and in increasing sleep efficiency. In a second study, Morin and colleagues (1999) found that CBT and pharmacological approaches were both effective for the short-term management of insomnia but that improvement was better sustained over time with the behavioral treatment.

### Diagnosis

Diagnosis and treatment of chronic insomnia are often challenging and difficult. Both the psychiatrist and the patient must be forbearing and realistic as they jointly explore the evolution, causes, manifestations and ramifications of the sleep complaint. In part, the diagnosis of primary insomnia is reached by exclusion after a careful differential diagnosis of other causes. Simple answers and simple solutions are rare. Even if insomnia is initially precipitated by a single event or condition, chronic insomnia is usually maintained by various predisposing and perpetuating factors. For example, a business woman in her early thirties had insomnia during a period of intense stress in her business, but it continued long after the stress had been satisfactorily resolved. Factors that contributed to chronicity included her lifelong somewhat obsessive, anxious personality structure and after the onset of her insomnia, her gradually escalating concerns about her insomnia; these resulted in advanced sleep phase as she tried to spend more time in bed for “rest” and use of wine and sleeping pills at bedtime to sleep. If all these factors can be properly sorted out and dealt with, both the psychiatrist and the patient will be gratified.

### Treatment of Chronic Primary Insomnia

Clinical management is often multidimensional, involving psychosocial, behavioral and pharmacological approaches. The relationship with the psychiatrist can often be important since many insomniac patients are skeptical that they can be helped overtly. They are focused on the symptom rather than the underlying causes, and are not psychologically minded. Behavioral treatments, in combination with addressing sleep hygiene, may be helpful in treating psychophysiological and other insomnias. Relaxation training (progressive relaxation, autogenic training, meditation, deep breathing) can all be effective if overtaught to become automatic. Two other behavioral therapies have been shown to be effective for insomnia: stimulus control and sleep restriction therapy (Bootzin and Nicassio, 1978; Spielman *et al.*, 1987; Morin *et al.*, 1994).

The aim of stimulus control therapy is to break the negative associations of being in bed unable to sleep (Table 59.5). It is especially helpful for patients with sleep-onset insomnia and prolonged awakenings. Sleep restriction therapy (Table 59.6) is based on the observation that more time spent in bed leads to more fragmented sleep. Both therapies may take 3 to 4 weeks or longer to be effective.

A wide variety of sedating medications have commonly been used as sleeping pills including benzodiazepines,

**Table 59.5 Sleep Hygiene and Stimulus Control Rules**

Curtail time spent awake while in bed.  
 Go to bed only when sleepy.  
 Do not remain in bed for more than 20–30 min while awake.  
 Get up at the same time each day.  
 Avoid looking at the bedroom clock.  
 Avoid caffeine, alcohol and tobacco near bedtime.  
 Exercise during the morning or afternoon.  
 Eat a light snack before bed.  
 Adjust sleeping environment for optimal temperature, sound and darkness.  
 Do not worry right before and in bed. Use the bed for sleeping.  
 Do not nap during the day.

**Table 59.6 Sleep Restriction Therapy**

Stay in bed for the amount of time you think you sleep each night, plus 15 min.  
 Get up at the same time each day.  
 Do not nap during the day.  
 When sleep efficiency is 85% (i.e., sleeping for 85% of the time in bed), go to bed 15 min earlier.  
 Repeat this process until you are sleeping for 8 h or the desired amount of time.  
 Example: if you report sleeping only 5 h a night and you normally get up at 6 AM, you are allowed to be in bed from 12:45 AM until 6 AM.

imidazopyridines (zolpidem), pyrazolopyrimidines (zaleplon), chloral hydrate, antihistamines (diphenhydramine, hydroxyzine, doxylamine), certain antidepressants (amitriptyline, doxepin, trimipramine, and trazodone), barbiturates and over-the-counter medications. However, they do vary in their pharmacokinetic properties and side effects (Table 59.7). The ideal sleeping pill would shorten latency to sleep; maintain normal physiological sleep all night without blocking normal behavioral responses to the crying baby or the alarm clock; leave neither hangover nor withdrawal effects the next day; and be devoid of tolerance and side effects such as impairment of breathing, cognition, ambulation and coordination. Furthermore, sleeping pills should not be habit-forming or addictive. Unfortunately, the ideal sleeping pill has not yet been found. Sleeping pills, if given in appropriate doses, are effective compared with placebo at least from a few days to a few weeks. More recent, developed sleeping pills (such as zaleplon) have demonstrated their superiority after 1 year in double-blind studies with a parallel placebo group. The question, however, is what is the lowest adequate dose for an individual patient, that is, the dose that will promote sleep with the least number of side effects.

The duration of action of these medications is important for several reasons (Table 59.8). Drugs with long half-life metabolites may have next-day hangover effects and tend to accumulate with repeated nightly administration, especially in the elderly, who metabolize and excrete the drugs more slowly than do the young. In addition, long half-life metabolites may act additively or synergistically the next day with alcohol, with drugs with sedative side effects, or during periods of decreased alertness, such as the afternoon dip in arousal levels. Because the elderly are more sensitive to both the benefits and the side effects at a given dose than are younger patients, a dose for the elderly

**Table 59.7 Clinical Characteristics of Sedative–Hypnotics**

Name	Dose (mg)	Absorption	Active Metabolite	Half-life
Chlordiazepoxide (Librium)	5–10	Intermediate	Yes	2–4 d
Diazepam (Valium)	2–10	Fast	Yes	2–4 d
Estazolam (ProSom)*	0.5–2.0	Intermediate	Yes	17 h
Flurazepam (Dalmane)*	7.5–30	Intermediate to fast	Yes	2–4 d
Clorazepate (Tranxene)	7.5–15	Fast	Yes	2–4 d
Clonazepam (Klonopin)	0.5–1.0	Intermediate	Yes	2–3 d
Quazepam (Doral)*	7.5–15	Intermediate	Yes	2–4 d
Oxazepam (Serax)	10–15	Slow	No	8–12 h
Lorazepam (Ativan)	0.5–4.0	Intermediate	No	10–20 h
Temazepam (Restoril)*	7.5–15	Slow	No	10–20 h
Alprazolam (Xanax)	0.25–2	Intermediate	No	14 h
Eszopiclone (Lunesta)*	1–3	Fast	Yes	4–6.5 h
Triazolam (Halcion)*	0.125–0.5	Intermediate	No	2–5 h
Zolpidem (Ambien)*	5–10	Fast	No	2–5 h
Zaleplon (Sonata)*	5–10	Fast	No	1 h

\*Marketed as a sleeping pill in the USA.

NB: At publication time the US Food and Drug Administration has approved ramelteon (Rozerem), the first medication to bind melatonin receptors MT<sub>1</sub> and MT<sub>2</sub>.

**Table 59.8 Comparison of Long and Short Half-life Hypnotics**

Measure	Half-life	
	Short	Long
Sedative hangover effects	+	++++
Accumulation with consecutive nightly use	0	+++
Tolerance	+++	+
Withdrawal insomnia	+++	+
Anxiolytic effects next day	0	+++
Amnesia	+++	++
Full benefits the first night	+++	++

*Note:* Although zaleplon is short acting, research suggests that it does not have some of the problems of other short-acting hypnotics, such as tolerance or withdrawal insomnia.

and debilitated patient should normally be about half of that for young and middle-aged patients.

Short half-life hypnotics usually produce less daytime sedation than long half-life drugs, but they often result in more rebound insomnia when they are discontinued. Whereas nearly all hypnotics and sedatives can produce amnesia, the problem may be more common with some short half-life drugs, especially for material that is learned during the periods of peak concentrations of drugs, for example, if the subject is awakened during the middle of the night. Administration of zaleplon 4 hours or more before arising in the morning does not appear to be associated with impairment in motor performance.

Patients should be educated about the anticipated benefits and limitations of sleeping pills, side effects and appropriate use, and should be followed up by office visits or phone calls regularly if prescriptions are renewed. Although hypnotics are usually prescribed for relatively short periods of time (2–6 weeks at most), about 0.5 to 1% of the population uses a hypnotic nearly every night for months or years. Whether this practice is good, useless, or bad remains controversial. Treatment of these patients should focus on the lowest possible effective dose – intermittently if possible – for the treatment of insomnia.

Hypnotics are relatively contraindicated in patients with sleep-disordered breathing; during pregnancy; in substance abusers, particularly alcohol abusers; and in those individuals who may need to be alert during their sleep period (e.g., physicians on call). In addition, caution should be used in prescribing hypnotics to patients who snore loudly; to patients who have renal, hepatic, or pulmonary disease; and to the elderly.

## Melatonin

Melatonin is synthesized and released from the pineal gland under dark ambient conditions at a time that is determined by the individual's internal biological clock located within the SCN at the anterior portion of the hypothalamus. For individuals who are synchronized with the local light–dark environment, melatonin

is usually secreted at night. The duration of secretion is approximately 8 to 12 hours, depending partially on age, season of the year and lighting conditions. Bright light prevents or terminates secretion of melatonin. For these reasons, melatonin has sometimes been called the “hormone” of the night or of sleep. In addition, nocturnal melatonin secretion appears to be blunted with normal aging, with administration of beta-adrenergic blockers (propranolol, pindolol, metoprolol), and in some populations of patient (including patients with mood disorders, premenstrual depression and panic disorder).

The functions of melatonin in humans are poorly understood, although in animals it has been implicated in seasonal behaviors, breeding, reproductive physiology and timing of adolescence.

The limited database available suggests that melatonin may eventually have a role in the prevention and treatment of circadian and sleep disturbances. Some evidence suggests that it has intrinsic hypnotic effects. Laboratory studies suggest that people are more likely to sleep during the period of endogenous melatonin secretion than during periods of the day without melatonin secretion. Furthermore, some but not all studies suggest that melatonin (0.3–10.0 mg) may induce and maintain sleep when administered to normal subjects or, in a few studies, to individuals with insomnia, jet lag, or other circadian rhythm disturbances. In addition, it is possible that melatonin administration can shift the phase position of the underlying biological clock. The entraining effects of a dose of 0.5 mg melatonin act like a “dark pulse”, that is, the phase-response curve is nearly opposite that of light. Melatonin-induced phase-advanced rhythms when administered in the late afternoon or early evening, and it delayed the circadian clock when administered in the early morning. Future research is needed to fulfill the promise that melatonin can be used to prevent or treat some forms of insomnia or other sleep disorders, especially in the elderly, or in cases associated with circadian rhythm disorders (jet lag, shift work, the non-24-hour-day syndrome, phase displacement), neurological disorders, or psychiatric disorders.

The scientific clinical database for the use of melatonin in humans is limited at this time. Few well-designed clinical trials exist to establish clinical benefits or risks in specific disorders or conditions. Little is known about optimal doses, timing of melatonin administration, duration of treatment, drug interactions, or populations at risk, if any. The safety of melatonin, especially melatonin available in health food stores, is unknown. Melatonin is currently treated by the US Food and Drug Administration as a nutritional supplement rather than a medication. Therefore, purity of the product, safety, efficacy, and claims by manufacturers are not carefully regulated in the USA. Physicians are advised to maintain a watchful eye at this time and to be prudently cautious about recommendations to patients and the public about the uses and benefits of melatonin.

Because the timing of melatonin secretion is regulated by the SCN, investigators and clinicians can measure plasma levels of melatonin in dim light conditions to determine the phase position of the circadian clock. A useful revision of this technique is called the dim light melatonin onset (DLMO, pronounced “dil-mo”) (Lewy and Sack, 1989). Using repeated measures of DLMO over periods of weeks, Lewy and Sack (1989) demonstrated that the circadian clock was “free-running” in a significant proportion of totally blind individuals, that is, the time of day at which melatonin secretion began completely drifted around the clock in a clockwise direction about every 3 weeks. Since the patients

tried to maintain a conventional bedtime (approximately 11PM–7AM), their wake–sleep cycle was in and out of synchrony with their own internal clock, creating significant difficulties in sleep and alertness at times during the month. Furthermore, Lewy and Sack found that appropriately-timed administration of melatonin synchronized the internal clock with the external light–dark cycle.

As footnoted in Table 59.7, the US FDA has very recently approved the first noncontrolled medication to offer a unique mechanism of action that permits extended use for problems with sleep onset in adults. Through the selective binding of melatonin receptors in the SCN, the alerting signal is dampened thereby facilitating sleep onset. The recommended dosage for ramelteon is 8 mg. It is rapidly absorbed from the stomach and broken down by first-pass metabolism in the liver through the CYP1A2 enzyme. Ramelteon should not be taken with high fat foods which apparently decrease absorption.

### Primary Hypersomnia

A specific diagnostic category for primary hypersomnia exists in DSM-IV-TR, defining a disorder characterized by clinically significant excessive sleepiness of at least 1 month's duration, with significant distress or impairment. The hypersomnia is not caused by another primary sleep disorder, a psychiatric disorder, a medical disorder, or a substance. Patients with primary hypersomnia usually present with complaints of long and nonrestorative nocturnal sleep, difficulty awakening ("sleep drunkenness"), and daytime sleepiness and intellectual dysfunction; do not experience the accessory symptoms of narcolepsy such as cataplexy, sleep paralysis and hypnagogic hallucinations; and often report frequent headaches and Raynaud's phenomena.

### Differential Diagnosis

Previously called non-REM narcolepsy, this relatively rare disorder is represented by perhaps 5 to 10% of patients presenting to sleep disorders centers for evaluation of hypersomnia. The diagnosis must be made on the basis of polysomnographic confirmation of hypersomnia; subjective complaints of excessive sleepiness are not adequate. A family history of excessive sleepiness may be present.

Although usually seen as a persistent complaint, primary hypersomnia includes recurrent forms, well defined with periods of excessive sleepiness of at least 3 days' duration occurring several times a year for at least 2 years. Among the recurrent or intermittent hypersomnia disorders are Kleine–Levin syndrome, usually seen in adolescent boys, and menstrual cycle-associated hypersomnia syndrome. In addition to hypersomnia (up to 18 hours per day), patients with Kleine–Levin syndrome often demonstrate aggressive or inappropriate sexuality, compulsive overeating and other bizarre behaviors. The rare nature of this syndrome and its unusual behaviors may be mistaken for psychosis, malingering, or a personality disorder.

Another syndrome, idiopathic recurring stupor, has been described and may be confused with hypersomnia. Patients experience attacks of stupor or coma as infrequently as once or twice a year to as often as once a week. The duration of each episode varies from 2 hours to 4 days. Unlike patients with hypersomnia, these patients are in a stuporous coma-like state and cannot be easily aroused or awakened. Furthermore, unlike the EEG of hypersomnia with its sleep spindles and K complexes, the EEG during stupor is characterized by diffuse activity at 13 to 18 Hz. Because the episode can be promptly but temporarily

## DSM-IV-TR Criteria 307.44

### Primary Hypersomnia

- A. The predominant complaint is excessive sleepiness for at least 1 month (or less if recurrent) as evidenced by either prolonged sleep episodes or daytime sleep episodes that occur almost daily.
- B. The excessive sleepiness causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- C. The excessive sleepiness is not better accounted for by insomnia and does not occur exclusively during the course of another sleep disorder (e.g., narcolepsy, breathing-related sleep disorder, circadian rhythm sleep disorder, or a parasomnia) and cannot be accounted for by an inadequate amount of sleep.
- D. The disturbance does not occur exclusively during the course of another mental disorder.
- E. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

*Specify if:*

**Recurrent:** if there are periods of excessive sleepiness that last at least 3 days occurring several times a year for at least 2 years

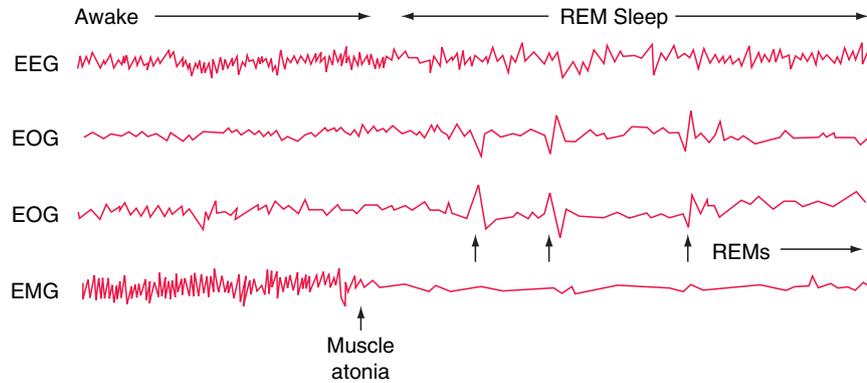

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

reversed by administration of flumazenil, a benzodiazepine receptor antagonist, a search was made for an endogenous ligand for the benzodiazepine receptor in plasma and cerebrospinal fluid. The investigators discovered significantly increased levels of "endonepine 4" in blood and cerebrospinal fluid during periods of coma or stupor, suggesting that this syndrome is caused by this endogenous benzodiazepine-like compound. The syndrome occurs predominantly in men; mean age at onset is age 47 years (range, age 22–67 years). The cause is unknown.

Aside from associated medical and psychiatric disorders, the frequency and importance of hypersomnia and daytime sleepiness in otherwise healthy individuals have been increasingly recognized. Sleepiness, for example, as a result of sleep deprivation, disrupted sleep, or circadian dyssynchronization, probably plays a major role in mistakes and accidents in sleepy drivers, interns and medical staff, and industrial workers. Psychiatrists have an obligation to recognize and advise their patients about the dangers inherent in acute or chronic sleepiness.

### Treatment

Clinical management is controversial owing to the lack of controlled studies. As in narcolepsy, the stimulant compounds are the most widely used and most often successful of the treatment options available. However, some patients are intolerant of stimulants or report no significant therapeutic effects. For patients intolerant of, or insensitive to, stimulants, some success has been obtained with the use of stimulating antidepressants, both of the MAOI and the selective serotonin reuptake inhibitor (SSRI)

**Figure 59.2** REM-onset sleep in a patient with narcolepsy. EEG, electroencephalogram; EOG, electrooculogram; EMG, electromyogram; REMs, rapid eye movements.

classes. Methysergide, a serotonin receptor antagonist, may be effective in some treatment-resistant cases but must be used with caution in view of the possibility of pleural and retroperitoneal fibrosis with persistent, uninterrupted use. Careful documentation should be maintained of interruption of drug use at regular intervals and of physical examinations that find the absence of obvious side effects of any sort.

## Narcolepsy

Narcolepsy is associated with a pentad of symptoms: 1) excessive daytime sleepiness, characterized by irresistible “attacks” of sleep in inappropriate situations such as driving a car, talking to a supervisor, or social events; 2) cataplexy, which is sudden bilateral loss of muscle tone, usually lasting seconds to minutes, generally precipitated by strong emotions such as laughter, anger, or surprise; 3) poor or disturbed nocturnal sleep; 4) hypnagogic hallucinations, varied dreams at sleep onset; and 5) sleep paralysis, a brief period of paralysis associated with the transitions into, and out of, sleep.

The disorder is lifelong. The first symptom is usually excessive sleepiness, typically developing during the late teens and early twenties. The full syndrome of cataplexy and other symptoms unfolds in several years.

Narcolepsy is now understood as an inherited, physiological disturbance of REM sleep regulation. Narcoleptic patients often enter REM sleep right after sleep onset (the “sleep-onset REM periods”), reflecting an abnormally short or even nonexistent first non-REM sleep period (Figure 59.2). Several of the core symptoms of narcolepsy can be understood as abnormal physiological representations of normal REM sleep. For example, cataplexy can be understood as an abrupt presentation during wakefulness of the paralysis normally seen in REM sleep. Cataplexy is usually triggered by an emotional stimulus. Sleep-onset REM periods may be subjectively appreciated as hypnagogic hallucinations, which may be accompanied by sleep paralysis. Dissociated REM sleep inhibition of the voluntary musculature may lead to complaints of cataplexy and sleep paralysis.

In recent years, a potential biochemical abnormality has been identified in both canine and human narcolepsy. Narcoleptic dogs appear to have a nonfunctional receptor (OX2R) for orexin (hypocretin), a peptide neurotransmitter that has also been associated with feeding and energy metabolism. “Knock-out” mice, which no longer make this peptide, appear to have a narcoleptic-like syndrome. Levels of orexin/hypocretin have been reported to be low in both autopsied brains and spinal fluid in human narcoleptics.

### DSM-IV-TR Criteria 347

#### Narcolepsy

- A. Irresistible attacks of unrefreshing sleep that occur daily for at least 3 months.
- B. The presence of one or both of the following:
  - (1) cataplexy (i.e., brief episodes of sudden bilateral loss of muscle tone, most often in association with intense emotion)
  - (2) recurrent intrusions of elements of REM sleep into the transition between sleep and wakefulness, as manifested by either hypnopompic or hypnagogic hallucinations or sleep paralysis at the beginning or end of sleep episodes
- C. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or another general medical condition.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

## Diagnosis

Narcolepsy is not a rare disease; the prevalence rate of 0.03 to 0.16% approximates that of multiple sclerosis. Observers may mistake classic sleepiness in its mild form as withdrawal, poor motivation, negativism and hostility. The hypnagogic imagery and sleep paralysis symptoms, alone and in combination, may resemble bizarre psychiatric illness. Like many medical disorders, narcolepsy presents a wide range of severity, from mild to cases so severe that employment is functionally impossible. Partial remissions and exacerbations occur. Sleep paralysis and hypnagogic imagery may be seen without cataplexy; cataplexy may present in isolation without other REM-associated phenomena. The presence of REM sleep onset at night or during daytime naps, an important sleep laboratory parameter, remains the most valid and reliable method available for diagnosing narcolepsy. Because of the seriousness of the disorder and likelihood that amphetamine or other stimulants will be used to treat the patient at some time, it is important that the diagnosis of narcolepsy be objectively verified as soon as possible. Furthermore, stimulant abusers have been known to feign symptoms of narcolepsy to obtain prescriptions. Narcolepsy is associated with significant social and financial impairment for affected individuals and their

families. For example, automobile accidents may result from either sleepiness or cataplexy. Most states prohibit narcoleptic patients from driving, at least as long as they are symptomatic.

## Treatment

The major goals of treatment of narcolepsy include: 1) to improve quality of life, 2) to reduce excessive daytime sleepiness (EDS), and 3) to prevent cataplectic attacks.

The major wake-promoting medications are: modafinil, amphetamine, dextroamphetamine and methylphenidate. Modafinil is preferred on grounds of efficacy, safety, availability, and low risk of abuse and diversion. The pharmacological treatment of cataplexy, sleep paralysis and hypnagogic hallucinations includes administration of activating SSRIs such as fluoxetine and tricyclic antidepressants such as protriptyline. Another new drug, sodium oxybate xyrem, appears to be well tolerated and beneficial for the treatment of cataplexy, daytime sleepiness and inadvertent sleep attacks (Littner *et al.*, 2001; US Xyrem Multi-center Study Group, 2002).

## Breathing-related Sleep Disorder

The essential feature of this disorder is sleep disruption resulting from sleep apnea or alveolar hypoventilation, leading to complaints of insomnia or, more commonly, excessive sleepiness. The disorder is not accounted for by other medical or psychiatric disorders or by medications or other substances.

## Diagnosis

The major diagnostic criterion for sleep apnea is cessation of breathing lasting at least 10 seconds and an apnea index (number of apneic events per hour of sleep) of five or more. Most apneic episodes are terminated by transient arousals. Hypopneas (50% decrease in respiration) may also produce arousal or hypoxia even when complete apneas do not occur. Therefore, rather than just the apnea index, a respiratory disturbance index (number of respiratory events, or number of apneas plus hypopneas per hour of sleep) is used. Whereas the criterion for the respiratory disturbance index has not been fully established, many psychiatrists use a respiratory disturbance index of 10 or greater for purposes of diagnosis. Each time respiration ceases, the individual must awaken to start breathing again. Once the person goes back to sleep, breathing stops again. This pattern continues throughout the night. Clinically, however, it is not unusual to see patients who stop breathing for 60 to 120 seconds with each event and experience hundreds of events per night. Many individuals with BRSD cannot sleep and breathe at the same time and therefore spend most of the night not breathing and not sleeping. In contrast, the central alveolar hypoventilation syndrome is not associated with either apneas or hypopneas, but impaired ventilatory control or hypoventilation results in hypoxemia. It is most common in morbid obesity.

Sleep apnea is characterized by repetitive episodes of upper airway obstruction that occur during sleep, resulting in numerous interruptions of sleep continuity, hypoxemia, hypercapnia, bradycardia, and pulmonary and systemic hypertension. It may be associated with snoring, morning headaches, dry mouth on awakening, excessive movements during the night, falling out of bed, enuresis, cognitive decline and personality changes, and complaints of either insomnia or, more frequently, hypersomnia and excessive daytime sleepiness. The typical patient with clinical sleep apnea is a middle-aged man who is overweight or who has anatomical conditions narrowing his upper airway.

## DSM-IV-TR Criteria 780.59

### Breathing-related Sleep Disorder

- A. Sleep disruption, leading to excessive sleepiness or insomnia, that is judged to be due to a sleep-related breathing condition (e.g., obstructive or central sleep apnea syndrome or central alveolar hypoventilation syndrome).
- B. The disturbance is not better accounted for by another mental disorder and is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or another general medical condition (other than a breathing-related disorder).

**Coding note:** Also code sleep-related breathing disorder on Axis III.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

There are three types of apnea. The first is obstructive sleep apnea, which involves the collapse of the pharyngeal airway during inspiration, with partial or complete blockage of airflow. The person still attempts to breathe, and one can observe the diaphragm moving, but the airway is blocked and therefore there is no air exchange. It can be caused by bagginess or excessive pharyngeal mucosa and a large uvula, fatty infiltration at the base of the tongue, or collapse of the pharyngeal walls. The resulting decreased air passage compromises alveolar ventilation and causes blood-oxygen desaturation and strenuous attempts at inspiration through the narrowed airway, all of which lighten and disrupt sleep. Hypercapnia, which results either from obstructive sleep apnea or from lung disease, reduces breathing without the presence of disruptive inspiratory efforts.

The second type is central sleep apnea, which results from failure of the respiratory neurons to activate the phrenic and intercostal motor neurons that mediate respiratory movements. There is no attempt to breathe, and although the airway is not collapsed, there is no respiration. This type of apnea is more commonly associated with heart disease. The third type is mixed sleep apnea, which is a combination, generally beginning with a central component and ending with an obstructive component.

The lifetime prevalence of BRSD in adults has been estimated to be 9% in men and 4% in women. The prevalence does increase with age, particularly in postmenopausal women. The prevalence in the elderly has been estimated to be 28% in men and 19% in women.

During apneas and hypopneas, the blood-oxygen level often drops to precarious levels. In addition, one often sees cardiac arrhythmias and nocturnal hypertension in association with the respiratory disturbances. The cardiac arrhythmias include bradycardia during the events and tachycardia after the end of the events. It is not unusual to see premature ventricular contractions, trigeminy and bigeminy, asystole, second-degree atrioventricular block, atrial tachycardia, sinus bradycardia and ventricular tachycardia. However, the electrocardiogram taken during the waking state might be normal. It is only during the respiratory events during sleep that the abnormalities appear.

BRSD, especially central sleep apnea, is commonly seen in patients with congestive heart failure. Cor pulmonale may also be a consequence of longstanding BRSD and is seen in both sleep apnea syndrome and primary hypoventilation. Patients may present with unexplained respiratory failure, polycythemia, right ventricular failure and nocturnal hypertension. About 50% of patients with BRSD have hypertension, and about one-third of all hypertensive patients have BRSD. In the large cross-sectional study, it was found that both systolic and diastolic blood pressure (SDB) as well as the prevalence of hypertension increased significantly with increasing SDB (Nieto *et al.*, 2000). It has also been shown that there is a dose–response association between SDB at baseline and hypertension 4 years later suggesting that SDB may be a risk factor for hypertension and consequent cardiovascular morbidity.

The most common symptoms of BRSD include excessive daytime sleepiness and snoring. The excessive daytime sleepiness probably results from sleep fragmentation caused by the frequent nocturnal arousals occurring at the end of the apneas and possibly from hypoxemia. The excessive daytime sleepiness is associated with lethargy, poor concentration, decreased motivation and performance, and inappropriate and inadvertent attacks of sleep. Sometimes the patients do not realize they have fallen asleep until they awaken.

The second complaint is loud snoring, sometimes noisy enough to be heard throughout or even outside the house. Often the wife has complained for years about the snoring and has threatened to sleep elsewhere if she has not moved out already. Bed partners describe a characteristic pattern of loud snoring interrupted by periods of silence, which are then terminated by snorting sounds. Snoring results from a partial narrowing of the airway caused by multiple factors, such as inadequate muscle tone, large tonsils and adenoids, long soft palate, flaccid tissue, acromegaly, hypothyroidism, or congenital narrowing of the oral pharynx. Snoring has been implicated not only in sleep apnea but also in angina pectoris, stroke, ischemic heart disease and cerebral infarction, even in the absence of complete sleep apneas. Because the prevalence of snoring increases with age, especially in women, and because snoring can have serious medical consequences, the psychiatrist must give serious attention to complaints of loud snoring. Snoring is not always a symptom of BRSD. Approximately 25% of men and 15% of women are habitual snorers.

Patients with BRSD are frequently overweight. In some patients, a weight gain of 20 to 30 lb might bring on episodes of BRSD. The same fatty tissue seen on the outside is also present on the inside, making the airway even more narrow. Because obstructive sleep apnea is always caused by the collapse of the airway, in patients of normal weight, anatomical abnormalities (such as large tonsils, long uvula) must be considered.

Other symptoms of BRSD include unexplained morning headaches, nocturnal confusion, automatic behavior, dysfunction of the autonomic nervous system, or night sweats. The severity of BRSD will depend on the severity of the cardiac arrhythmias, hypertension, excessive daytime sleepiness, respiratory disturbance index, amount of sleep fragmentation and amount of oxygen desaturation.

Mild to moderate sleep-related breathing disturbances increase with age, even in elderly subjects without major complaints about their sleep. The frequency is higher in men than in women, at least until the age of menopause, after which the rate in women increases and may approach that of men. With use of the apnea

index of five or more apneic episodes per hour as a cutoff criterion, prevalence rates range from 27 to 75% for older men and from 0 to 32% for older women. In general, the severity of apnea in these older persons is mild (an average apnea index of about 13) compared with that seen in patients with clinical sleep apnea. However, older men and women with mild apnea have been reported to fall asleep at inappropriate times significantly more often than older persons without apnea. Furthermore, the frequency of sleep apnea and other BRSDs is higher in individuals with hypertension, congestive heart failure, obesity, dementia and other medical conditions.

Increased mortality rates have been noted in excessively long sleepers, therefore sleep apnea may account for some of these excess deaths. This is also consistent with evidence that excess deaths from all causes increase between 2 and 8 AM, specifically deaths related to ischemic heart disease in patients older than 65 years. There have been several studies suggesting that untreated sleep apnea in the elderly may lead to shorter survival.

The clinical significance of relatively mild “subclinical” sleep apneas is not fully understood yet. Psychiatrists should be aware, however, that such disturbances might be associated with either insomnia or excessive daytime sleepiness. Furthermore, for some patients with sleep apnea, administration of hypnotics, alcohol, or other sedating medications is relatively contraindicated. The risk is not yet known, but reports indicate that benzodiazepines as well as alcohol may increase the severity of mild sleep apnea. Therefore, psychiatrists should inquire about snoring, gasping, and other signs and symptoms of sleep apnea before administering a sleeping pill. If patients have excessive sleepiness or morning hangover effects while taking benzodiazepines, major tranquilizers, or other sedating medications, the psychiatrist should consider the possibility of an iatrogenic BRSD due to medications.

The diagnosis of BRSD must be differentiated from other disorders of excessive sleepiness such as narcolepsy (Table 59.9). Patients with BRSD will not have cataplexy, sleep-onset paralysis, or sleep-onset hallucination. Narcolepsy is not usually associated with loud snoring or sleep apneas. In laboratory recordings, patients with BRSD do not usually have sleep-onset REM periods either at night or in multiple naps on the Multiple Sleep Latency Test. However, one must be aware that both BRSD and narcolepsy can be found in the same patient. BRSD must also be distinguished from other hypersomnias, such as those related to major depressive disorder or circadian rhythm disturbances.

**Table 59.9 Clinical Symptoms of Breathing-related Sleep Disorders**

Daytime Symptoms	Night-time Symptoms
Excessive daytime sleepiness	Loud snoring
Memory loss	Hypertension
Decreased mental function	Cardiac arrhythmias
Morning headache	Leg kicks
Automatic behavior	Confusion
Lethargy	Impotence
	Choking–gasping

## Treatment of Sleep Apnea

Sleep apnea is sometimes alleviated by weight loss, avoidance of sedatives, use of tongue-retaining devices and breathing air under positive pressure through a face mask (continuous positive airway pressure [CPAP]). Oxygen breathed at night may alleviate insomnia associated with apnea that is not accompanied by impeded inspiration. Surgery may be helpful, for example, to correct enlarged tonsils, a long uvula, a short mandible, or morbid obesity. Pharyngoplasty, which tightens the pharyngeal mucosa and may also reduce the size of the uvula, or the use of a cervical collar to extend the neck, may relieve heavy snoring. Although tricyclic antidepressants are sometimes used in the treatment of clinical sleep apnea in young adults, they may cause considerable toxic effects in older people. The newer shorter-acting nonbenzodiazepine hypnotics seem to be safer in these patients and may be considered in those patients who snore.

## Circadian Rhythm Sleep Disorder (Sleep–Wake Schedule Disorders)

Circadian rhythm disturbances result from a mismatch between the internal or endogenous circadian sleep–wake system and the external or exogenous demands on the sleep–wake system. The individual’s tendency to sleep–wakefulness does not match that of her or his social circumstances or of the light–dark cycle. Although some individuals do not find this mismatch to be a problem, for others the circadian rhythm disturbance interferes with the ability to function properly at times when alertness or sleepiness is desired or required. For those individuals, insomnia, hypersomnia, sleepiness and fatigue result in significant discomfort and impairment. The circadian rhythm disturbances include delayed sleep phase, advanced sleep phase, shift work, jet lag and non-24-hour-day syndrome.

## Diagnosis

The diagnosis is based on a careful review of the history and circadian patterns of sleep–wakefulness, napping, alertness and behavior. According to DSM-IV criteria, the diagnosis of circadian rhythm sleep disorder requires significant social or occupational impairment or marked distress related to the sleep disturbance. It is often useful for patients with chronic complaints to keep a sleep–wake diary covering the entire 24-hour day each day for several weeks. If possible, an ambulatory device that measures rest–activity, such as a wrist actigraph, might supplement the sleep–wake diary. Wrist actigraphs record acceleration of the wrist at frequent intervals, such as every minute, and save it for later display. Because the wrist is mostly at rest during sleep, the record of wrist rest–activity provides a fairly accurate estimate of the timing and duration of sleep–wakefulness. In addition, some commercial wrist activity devices have a built-in photometer, which provides a record of ambient light–darkness against which the rest–activity pattern can be compared.

## Delayed and Advanced Sleep Phase Disorders

Delayed sleep phase refers to a delay in the circadian rhythm in the sleep–wake cycle. These individuals are generally not sleepy until several hours after “normal” bedtime (i.e., 2–3 AM). If allowed to sleep undisturbed, they will sleep for 7 or 8 hours, which means they awaken at 10 to 11 AM. People with delayed sleep phase are considered extreme “owls”. They may or may

## DSM-IV-TR Criteria 307.45

### Circadian Rhythm Sleep Disorder

- A. persistent or recurrent A. pattern of sleep disruption leading to excessive sleepiness or insomnia that is due to a mismatch between the sleep–wake schedule required by a person’s environment and his or her circadian sleep–wake pattern.
- B. The sleep disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- C. The disturbance does not occur exclusively during the course of another sleep disorder or other mental disorder.
- D. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

*Specify type:*

**Delayed sleep phase type:** a persistent pattern of late sleep onset and late awakening times, with an inability to fall asleep and awaken at a desired earlier time

**Jet lag type:** sleepiness and alertness that occur at an inappropriate time of day relative to local time, occurring after repeated travel across more than one time zone

**Shift work type:** insomnia during the major sleep period or excessive sleepiness during the major awake period associated with night shift work or frequently changing shift work

### Unspecified type

not complain of sleep-onset insomnia. They usually enjoy their alertness in the evening and night and have little desire to sleep beginning at 10 PM or midnight. Their problem is trying to wake up at normal times (i.e., 6–7 AM). In essence, their rhythm is shifted to a later clock time relative to conventional rest–activity patterns.

Individuals with delayed sleep phase often choose careers that allow them to set their own schedules, such as freelance writers. Delayed sleep phase occurs commonly in late adolescence and young adulthood, such as in college students. As many of these individuals age, however, their endogenous sleep–wake rhythm advances and they eventually are able to conform themselves to a normal rest period at night.

For others, however, this phase shift of the endogenous oscillator may lead at a later age to the advanced sleep phase. In this condition, individuals become sleepy earlier in the evening (e.g., 7–8 PM). They will also sleep for 7 to 8 hours, but that means they awaken at 2 to 3 AM. These individuals are “larks”, being most alert in the morning. They complain of sleep maintenance insomnia, that is, they cannot stay asleep all night long. This condition is more prevalent in the elderly than in the young. The etiology of extreme “night owls” and “larks” is probably multifaceted but, in some cases, appears to reflect genetic factors.

## Treatment

Clinical management includes chronobiological strategies to shift the phase position of the endogenous circadian oscillator in the appropriate direction. For example, exposure to bright light in the morning advances the delayed sleep phase, that is, individuals will become sleepy earlier in the evening. On the other hand, administration of bright light in the evening acts to delay the circadian rhythm, that is, individuals will become sleepy later in the evening. Light is usually administered in doses of 2500 lux for a period of 2 hours per day, although the ideal intensity and duration are yet to be determined. For some individuals, spending more time outdoors in bright sunlight may be sufficient to treat the sleep phase. For example, individuals with delayed sleep phase should be encouraged to remove blinds and curtains from their windows, which would allow the sunlight to pour into their bedrooms in the morning when they should arise. In addition, gradual adjustments of the timing of the sleep–wake cycle may be used to readjust the phase position of the circadian oscillator. For example, patients with delayed phase disorder can be advised to delay the onset of sleep by 2 to 3 hours each day (i.e., from 4 to 7 to 10 AM, and so on) until the appropriate bedtime. After that, they should maintain regular sleep–wake patterns, with exposure to bright light in the morning.

## Shift Work

Shift work problems occur when the circadian sleep–wake rhythm is in conflict with the rest–activity cycle imposed by the externally determined work schedule. Nearly a quarter of all American employees have jobs that require them to work outside the conventional 8 AM to 5 PM schedule. Different patterns include rotating schedules and more or less permanent evening and night schedules. Rotating schedules, particularly rapidly shifting schedules, are difficult because constant readjustment of the endogenous circadian oscillator to the imposed sleep–wake cycle is necessary. In both rotating and shift work schedules, further difficulties are encountered because the worker is usually expected to readjust to a normal sleep–wake cycle on weekends and holidays. Even if the worker can adjust his or her circadian system to the work schedule, he or she is then out of synchrony with the rhythm of family and friends during off-duty hours. These individuals, therefore, are constantly sleep deprived and constantly sleepy. They endure impaired performance and increased risk of accidents, somatic complaints and poor morale; hypnotics, stimulants and alcohol are used excessively in relationship to unusual or shifting work schedules. Shift work schedules may have played a role in human errors that contributed to the Three Mile Island and Chernobyl accidents and the Challenger disaster.

## Treatment

No totally satisfactory methods currently exist for managing shift work problems. Because people vary in their ability to adjust to these schedules, self-selection or survival of the fittest may be involved for those who can find other employment or work schedules. Older individuals appear to be less flexible than younger persons in adjusting to shift work. Some experiments suggest that the principles of chronobiology may be useful in reducing the human costs of shift work. For example, because the endogenous pacemaker has a cycle length ( $\tau$ ) longer than 24 hours, rotating shift workers do better when their schedules move in a clockwise direction (i.e., morning to evening to night) rather than in the other direction. Appropriate exposure to bright lights and

darkness may push the circadian pacemaker in the correct direction and help stabilize its phase position, especially in association with the use of dark glasses outside and blackout curtains at home to maintain darkness at the appropriate times for promotion of sleep and shifting of the circadian pacemaker. Naps may also be useful in reducing sleep loss. Modest amounts of coffee may maintain alertness early in the shift but should be avoided near the end of the shift.

## Jet Lag

Jet lag occurs when individuals travel across several time zones. Traveling east advances the sleep–wake cycle and is typically more difficult than traveling west (which delays the cycle). Jet lag may be associated with difficulty initiating or maintaining sleep or with daytime sleepiness, impaired performance and gastrointestinal disturbance after rapid transmeridian flights. Individuals older than 50 years appear to be more vulnerable to jet lag than are younger persons.

## Management

Considerable research and theorizing are under way better to prevent and manage the problems associated with jet lag. Some efforts before departure may be useful to prevent or ameliorate these problems. For persons who plan to readjust their circadian clock to the new location, it may be possible to move the sleep–wake and light–dark schedules appropriately before departure. In addition, good sleep hygiene principles should be respected before, during and after the trip. For example, many people are sleep deprived or in alcohol withdrawal when they step on the plane because of last-minute preparations or farewell parties. Whereas adequate fluid intake on the plane is necessary to avoid dehydration, alcohol consumption should be avoided or minimized because it causes diuresis and may disrupt sleep maintenance.

On arriving at the destination, it may be preferable to try to maintain a schedule coinciding with actual home time if the trip is going to be short. For example, the individual should try to sleep at times that correspond to the usual bedtime or with the normal midafternoon dip in alertness. If, on the other hand, the trip will be longer and it is desirable to synchronize the biological clock with local time, exposure to appropriate schedules of bright light and darkness may be helpful, at least theoretically. Unfortunately, the exact protocols have not been established in all instances yet and require further research and experimentation. In addition, some of these protocols require avoidance of bright light at certain times, necessitating wearing dark goggles, for example, when traveling.

In addition to synchronizing the clock with the new environment, sleep and rest should be promoted by good sleep hygiene principles, by avoidance of excessive caffeine and alcohol and, possibly, by administration of short-duration hypnotics. Care should be taken, however, to avoid hangover effects or amnesia associated with hypnotics. Because individual responses to sleeping pills vary considerably from person to person, it is often helpful to develop experience with specific compounds and doses before departure.

## Non-24-Hour-Day Syndrome

The non-24-hour-day (or “hypernyctohemeral”) syndrome is characterized by free-running in the natural environment, that is, the subject goes to bed and arises about 45 minutes later each day. The average duration of the sleep–wake cycle is about 24.5 to 25.0 hours. During the course of about 3 weeks, the subject’s

sleep–wake cycle “goes around the clock” as the timing of the sleep period gradually delays. The lengthened sleep–wake cycle of these patients in the natural environment is similar to that of normal subjects living in a time-free environment. The disorder appears to be relatively common in patients with total blindness, because they no longer perceive visual Zeitgebers. In many cases, the cause is unknown, but it is sometimes observed in individuals who are socially or linguistically isolated. Management may include bright light therapy in the morning to entrain the endogenous oscillator. Administration of vitamin B<sub>12</sub> may be helpful, perhaps by enhancing the effectiveness of Zeitgebers.

The prevalence of circadian rhythm disturbances has not been established. Approximately two-thirds of shift workers have difficulty with their schedules. Circadian rhythm disturbances must be differentiated from sleep-onset insomnia due to other causes (such as pain, caffeine consumption), early morning insomnia due to depression or alcohol use, and changes in sleep patterns due to lifestyle or lifestyle changes.

### Periodic Limb Movements in Sleep

Periodic limb movements in sleep (PLMS), previously called nocturnal myoclonus, is a disorder in which repetitive, brief and stereotyped limb movements occur during sleep, usually about every 20 to 40 seconds. Dorsiflexions of the big toe, ankle, knee and sometimes the hip are involved (Table 59.10)

#### Diagnosis

Questioning of the patient or bed partner often yields reports of restlessness, kicking, unusually cold or hot feet, disrupted and torn bedclothes, unrefreshing sleep, insomnia, or excessive daytime sleepiness. Patients may be unaware of these pathological leg movements or arousals, although their bed partners may be all too aware of the kicking, frequent movements and restlessness. If these disorders are strongly suspected, the patient should probably be referred to a sleep disorders laboratory for evaluation and an overnight polysomnogram with tibial electromyograms. These disorders are often associated with transient arousals in the EEG recording. Diagnosis is made when the periodic limb movement index (number of leg jerks per hour of sleep) is five or greater, accompanied by arousals. The jerks occur primarily in the legs but may also appear in less severe forms in the arms. The movements can be bilateral or unilateral and occur in stage 1 and stage 2 sleep. Patients often have reduced deep sleep because the jerks continually awaken them.

A related disturbance, restless legs syndrome, is associated with disagreeable sensations in the lower legs, feet, or thighs that occur in a recumbent or resting position and cause an almost

irresistible urge to move the legs. Whereas almost all patients with restless legs syndrome have PLMS, not all patients with PLMS have restless legs syndrome. Restless legs syndrome may be frequent in patients with uremia and rheumatoid arthritis or in pregnant women. Both PLMS and restless legs syndrome usually occur in middle-aged people, but many patients report having had the same sensations as adolescents and even as children. It has been suggested that both conditions are familial, perhaps due to an autosomal dominant gene.

Individuals with PLMS are reported to sleep about an hour less per night than control subjects without PLMS. Interestingly, the prevalence of PLMS is not higher in insomniac patients than in those without insomnia. Complaints of excessive daytime sleepiness increase in individuals with PLMS, probably consequent to the numerous sleep interruptions. The psychiatrist may find it useful to talk with a bed partner, who will often describe kicking and leg twitches during sleep in individuals with PLMS. The myoclonic movements are not related to seizure disorder but should be distinguished from seizures. Because complaints of insomnia and daytime sleepiness are not uncommon, other insomnias, sleep apnea and narcolepsy should be ruled out.

Prevalence of PLMS in young and middle-aged adults has not been fully established. In sleep disorders clinic populations, about 11% of those complaining of insomnia are diagnosed with PLMS. In the elderly, however, this condition is extremely common; more than 45% have at least five leg kicks per hour of sleep.

#### Treatment

Because the pathogenesis of PLMS is usually unknown, treatment is often symptomatic (Table 59.11). Some studies suggest that the movements arise subcortically from the brain or spinal cord; others suggest subclinical peripheral neuropathy. At the present time, dopaminergic agents such as levodopa (L-dopa), pergolide, or pramipexole generally provide the most effective treatment for both PLMS and restless legs. Opiates, such as oxycodone and propoxyphene, have also been demonstrated to be effective in the treatment of PLMS and restless legs syndrome. Anticonvulsants, such as carbamazepine and gabapentin, have been shown to be effective in treatment of restless legs syndrome. Clonazepam, a benzodiazepine anticonvulsant, is effective in the treatment of PLMS and possibly for restless legs syndrome. Other benzodiazepines have also been used to treat these conditions, as they will decrease some of the awakenings but may have no effect on the number of leg movements.

### Parasomnias

The parasomnias are a group of disorders characterized by disturbances of either physiological processes or behavior associated with sleep, but not necessarily causing disturbances of sleep or wakefulness.

#### Nightmare Disorder

The essential feature of this disorder is the repeated occurrence of frightening dreams that lead to full awakenings from sleep. The dreams or awakenings cause the individual significant distress or dysfunction. By DSM-IV-TR definition, the disorder is excluded if the nightmare occurs in the course of another mental or medical disorder or as a direct result of a medication or

**Table 59.10** Features of Periodic Limb Movements in Sleep

Leg kicks every 20–40 s
Duration of 0.5–5 s
Complaints of:
Insomnia
Excessive sleepiness
Restless legs
Very cold or hot feet
Uncomfortable sensations in legs

**Table 59.11** Pharmacologic Treatment Options in RLS/PLMS

Medication	Dosage Range	Side Effects	Advantages	Disadvantages
L-dopa/carbidopa	25/100–100/400/D	Dyskinesia Loss of efficacy Nausea Hallucinations	Low cost	Breakthrough restlessness
Pergolide	0.05–1 mg	Dyskinesia Nausea Rhinitis Dizziness	High rate of response	Frequent side effects
Pramipexole	0.25–0.875 mg	Orthostasis Dizziness Sedation	High rate of response Good tolerance	Expense
Anticonvulsants	Variable	Sedation	Low cost Sleep promotion	Variable response
Opiates	Variable	Nausea Constipation	Low cost	Variable response Abuse potential
Clonazepam	0.5–2 mg	Sedation Dizziness	Sleep promotion	Variable response Abuse potential

substance. Many, but not all, nightmares occur during REM sleep; REM nightmares take place most often during the last half of the night when REM sleep is most common (see nightmares in post traumatic stress disorder). Whereas more than half of the adult population probably experiences an occasional nightmare, nightmares start more commonly in children between the ages of 3 and 6 years. The exact prevalence is unknown.

### DSM-IV-TR Criteria 307.47

#### Nightmare Disorder

- A. Repeated awakenings from the major sleep period or naps with detailed recall of extended and extremely frightening dreams, usually involving threats to survival, security, or self-esteem. The awakenings generally occur during the second half of the sleep period.
- B. On awakening from the frightening dreams, the person rapidly becomes oriented and alert (in contrast to the confusion and disorientation seen in sleep terror disorder and some forms of epilepsy).
- C. The dream experience, or the sleep disturbance resulting from the awakening, causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- D. The nightmares do not occur exclusively during the course of another mental disorder (e.g., a delirium, post traumatic stress disorder) and are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

#### Treatment

The disorder is usually self-limited in children but can be helped sometimes with psychotherapy, desensitization, or rehearsal instructions. Secondary nightmares, as in post traumatic stress disorder (PTSD), can be difficult to treat.

#### Sleep Terror Disorder

This disorder is defined as repeated abrupt awakenings from sleep characterized by intense fear, panicky screams, autonomic arousal (tachycardia, rapid breathing and sweating), absence of detailed dream recall, amnesia for the episode, and relative unresponsiveness to attempts to comfort the person. Because sleep terrors occur primarily during delta sleep, they usually take place during the first third of the night. These episodes may cause distress or impairment, especially for caretakers who witness the event. Sleep terrors may also be called night terrors, *pavor nocturnus*, or incubus.

The prevalence of the disorder is estimated to be about 1 to 6% in children and less than 1% in adults. In children, it usually begins between the ages of 4 and 12 years and resolves spontaneously during adolescence. It is more common in boys than in girls. It does not appear to be associated with psychiatric illness in children. In adults, it usually begins between 20 and 30 years of age, has a chronic undulating course, is equally common in men and women, and may be associated with psychiatric disorders, such as PTSD, generalized anxiety disorder, borderline personality disorder and others. An increased frequency of enuresis and somnambulism has been reported in the first-degree relatives of patients with night terrors.

#### Treatment

Nocturnal administration of benzodiazepines has been reported to be beneficial, perhaps because these drugs suppress delta sleep, the stage of sleep during which sleep terrors typically occur.

**DSM-IV-TR Criteria 307.46****Sleep Terror Disorder**

- A. Recurrent episodes of abrupt awakening from sleep, usually occurring during the first third of the major sleep episode and beginning with a panicky scream.
- B. Intense fear and signs of autonomic arousal, such as tachycardia, rapid breathing, and sweating, during each episode.
- C. Relative unresponsiveness to efforts of others to comfort the person during the episode.
- D. No detailed dream is recalled and there is amnesia for the episode.
- E. The episodes cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- F. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

**Sleepwalking Disorder**

This disorder is characterized by repeated episodes of motor behavior initiated in sleep, usually during delta sleep in the first third of the night. While sleepwalking, the patient has a blank staring face, is relatively unresponsive to others, and may be confused or disoriented initially on being aroused from the episode. Although the person may be alert after several minutes of awakening, complete amnesia for the episode is common the next day. Sleepwalking may cause considerable distress, for example, if a child cannot sleep away from home or go to camp because of it. By DSM-IV definition, pure sleepwalking is excluded if it occurs as a result of a medication or substance or is due to a medical disorder. However, sleepwalking may be an idiosyncratic reaction to specific drugs, including tranquilizers and sleeping pills.

Most behaviors during sleepwalking are routine and of low-level intensity, such as sitting up, picking the sheets, or walking around the bedroom. More complicated behaviors may also occur, however, such as urinating in a closet, leaving the house, running, eating, talking, driving, or even committing murder. A real danger is that the individual will be injured by going through a window or falling from a height.

Whereas about 10 to 30% of children have at least one sleepwalking episode, only about 1 to 5% have repeated episodes. The disorder most commonly begins between the ages of 4 and 8 years and usually resolves spontaneously during adolescence. Genetic factors may be involved, because sleepwalkers are reported to have a higher than expected frequency of first-degree relatives with either sleepwalking or sleep terrors. Sleepwalking may be precipitated in affected patients by gently sitting them up during sleep, by fever, or by sleep deprivation. Adult onset of sleepwalking should prompt the search for possible medical, neurological, psychiatric, pharmacological, or other underlying causes, such as nocturnal epilepsy.

**DSM-IV-TR Criteria 307.46****Sleepwalking Disorder**

- A. Repeated episodes of rising from bed during sleep and walking about, usually occurring during the first third of the major sleep episode.
- B. While sleepwalking, the person has a blank, staring face, is relatively unresponsive to the efforts of others to communicate with him or her, and can be awakened only with great difficulty.
- C. On awakening (either from the sleepwalking episode or the next morning), the person has amnesia for the episode.
- D. Within several minutes after awakening from the sleepwalking episode, there is no impairment of mental activity or behavior (although there may initially be a short period of confusion or disorientation).
- E. The sleepwalking causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- F. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

**Treatment**

No treatment for sleepwalking is established, but some patients respond to administration of benzodiazepines or sedating antidepressants at bedtime. The major concern should be the safety of the sleepwalker, who may injure herself or himself or someone else during an episode.

**REM Sleep Behavior Disorder**

This disorder, like sleepwalking, is associated with complicated behaviors during sleep such as walking, running, singing and talking. In contrast to sleepwalking, which occurs during the first third of the night during delta sleep, REM sleep behavior disorder usually occurs during the second half of the night during REM sleep. It apparently results from an intermittent loss of the muscle atonia that normally accompanies REM sleep, thus allowing the patient to act out her or his dream. Also, in contrast to sleepwalking, memory for the dream content is usually good. Furthermore, the idiopathic form typically occurs in men during the sixth or seventh decade of life. The cause or causes remain unknown. It has been reported in a variety of neurological disorders and during withdrawal from sedatives or alcohol; during treatment with tricyclic antidepressants or biperiden (Akineton); and in various neurological disorders including dementia, subarachnoid hemorrhage and degenerative neurological disorders.

**Treatment**

Nocturnal administration of clonazepam, 0.5 to 1 mg, is usually remarkably successful in controlling the symptoms of this disorder. Patients and their families should be educated about the

nature of the disorder and warned to take precautions about injuring themselves or others.

### Nocturnal Panic Attacks

The typical daytime panic attack, as bizarre and frightening as it may seem to the patient experiencing it, is often fairly obvious to the assessing psychiatrist. Symptoms of anxiety, sweating, tremor, dizziness, chest pain and palpitations occur “out of the blue” with or without specific behavioral or associational stimuli. Once it has been diagnosed, treatment options may include pharmacotherapy with one of several classes of drugs, behavioral therapy, or a combined approach.

When these symptoms occur at night, the task of the assessing psychiatrist is greatly complicated. The patient may assume that the cause is a nightmare or a night terror and may be resistant to the diagnosis of an anxiety disorder, particularly if the symptoms are absent or mild during the daytime. Patients with panic disorder often have not only disturbed subjective sleep but also panic attacks during sleep. Psychiatrists should remember that panic attacks could occur exclusively during sleep, without daytime symptoms, in some patients. Conversely, a report of “awakening in a state of panic” may be associated with a variety of other disorders including obstructive sleep apnea, gastroesophageal reflux, nocturnal angina, orthopnea, nightmares, night terrors and others.

### Sleep-related Epilepsy

Some forms of epilepsy occur more commonly during sleep than during wakefulness and may be associated with parasomnia disorders. Nocturnal seizures may at times be confused with sleep terror, REM sleep behavior disorder, paroxysmal hypnogenic dystonia, or nocturnal panic attacks (Culebras, 1992). They may take the form of generalized convulsions or may be partial seizures with complex symptoms. Nocturnal seizures are most common at two times: the first 2 hours of sleep, or around 4 to 6 AM. They are more common in children than in adults. The chief complaint may be only disturbed sleep, torn up bedsheets and blankets, morning drowsiness (a postictal state), and muscle aches. Some patients never realize they suffer from nocturnal epilepsy until they share a bedroom or bed with someone who observes a convulsion.

### Sleep Disturbances Related to Other Psychiatric Disorders

Subjective and objective disturbances of sleep are common features of many psychiatric disorders. General abnormalities include dyssomnias (such as insomnia and hypersomnia), parasomnias (such as nightmares, night terrors and nocturnal panic attacks) and circadian rhythm disturbances (early morning awakening). Before assuming that a significant sleep complaint invariably signals a psychiatric diagnosis, mental health specialists should go through a careful differential diagnostic procedure to rule out medical, pharmacological, or other causes. Even if the sleep complaint is primarily related to an underlying psychiatric disorder, sleep disorders in the mentally ill may be exacerbated by many other factors, such as increasing age; comorbid psychiatric, sleep and medical diagnoses; alcohol and substance abuse; effects of psychotropic or other medications; use of caffeinated beverages, nicotine, or other substances; lifestyle; past episodes of psychiatric illness (persisting “scars”); and cognitive, conditioned and coping characteristics such as anticipatory anxiety about sleep as bedtime nears. Some features of these sleep

disorders may persist during periods of clinical remission of the psychiatric disorder and may be influenced by genetic factors. Finally, even if the sleep complaint is precipitated by a nonpsychiatric factor, psychiatric and psychosocial skills may be useful in ferreting out predisposing and perpetuating factors involved in chronic sleep complaints.

Although signs and symptoms of sleep disturbance are common in most psychiatric disorders, an additional diagnosis of insomnia or hypersomnia related to another mental disorder is made according to DSM-IV-TR criteria only when the sleep disturbance is a predominant complaint and is sufficiently severe to warrant independent clinical attention. Many of the patients with this type of sleep disorder diagnosis focus on the sleep complaints to the exclusion of other symptoms related to the primary psychiatric disorder. For example, they may seek professional help with complaints of insomnia or oversleeping when they should be at work, excessive fatigue, or desire for sleeping pills, but initially, they minimize or strongly deny signs and symptoms related to poor mood, anxiety, obsessive rumination, alcohol abuse, or a personality disorder.

### Sleep Disturbances in Psychiatric Disorders: “Chicken or Egg?”

Whether sleep disturbances “cause” psychiatric disorders can be debated. At one level, this hypothesis seems unlikely because normal subjects vary considerably in their amount and type of sleep. Occasional extreme short sleepers, “needing” and sleeping as little as an hour a day for many years, have been reported, who appeared to be psychologically and medically normal in other respects. Furthermore, prolonged partial or selective sleep deprivation in normal volunteers does not apparently precipitate major psychiatric disorders. Normal control subjects have been kept awake for as long as 11 consecutive days in experiments to test the effect of sleep deprivation. Such experiments may cause dysphoria and dysfunction but not depression or dementia. Moreover, patients with narcolepsy or depression have been deprived of REM sleep for more than a year while being treated with high doses of MAOIs; if anything, they were better because their primary mood disorder improved during the course of treatment. Finally, total or partial sleep deprivation for one night has antidepressant effects in about half of depressed patients, including severely depressed melancholic, endogenous, or delusional patients.

These observations neither prove nor disprove the hypothesis that sleep disturbance does not cause psychiatric disorders. After all, experimental disruption of sleep in normal control subjects is highly artificial, usually conducted in supportive environments in well-screened, self-selected, healthy subjects. Likewise, people may vary in their sleep needs, but as far as we know, everyone needs to sleep; it may just be that individuals vary in the threshold of sleep disturbance beyond which they can go before manifesting psychiatric symptoms. Most important, chronic subjective sleep disturbances may be risk factors for certain vulnerable individuals. Thus, specific sleep characteristics may predispose to, or be a risk factor for, later development of psychiatric or substance abuse disorders. Again, the complaint of chronic insomnia or hypersomnia or normal short sleep cannot always be equated with objective sleep abnormalities, but it should at least alert the psychiatrist to the possibility that the patient deserves careful monitoring for a time.

Sleep disruption may be particularly harmful to some persons, for example, bipolar disorder patients, whether euthymic or depressed, in whom sleep deprivation may precipitate a manic

episode. Mania is not uncommon with jet lag or work-related sleep deprivation in bipolar disorder patients. Behavioral and apparent personality changes with sleep deprivation are probably common but more often ignored in everyday life. The irritability of sleep-deprived children is known to most parents; and who of us has not had a “bad day” after a “bad night”?

Whereas insomnia is probably the most common sleep complaint in most psychiatric disorders, hypersomnia is not infrequently reported, especially in association with the following: bipolar mood disorder during depressed periods; major depressive disorder with atypical features (i.e., hypersomniac, hyperphagic patients with “leaden paralysis” and loss of energy); seasonal (winter) depression; stimulant abusers during withdrawal; some patients with personality disorders; and patients who are heavily sedated with anxiolytic, antipsychotic, or antidepressant medications, among other disorders.

### Polysomnographic Features of Sleep in Psychiatric Disorders

More studies of sleep and sleep-related phenomenology have been conducted in **depression** than in any other disorder. Despite the common clinical impression that early morning wakefulness is a predominant symptom in depression, most of the objective measures in recent years have implicated abnormalities occurring at sleep onset and during the first non-REM and REM periods: prolonged sleep latency; reduced stages 3 and 4 sleep; increased duration and REM density of the first REM period; and associated neuroendocrine abnormalities, including growth hormone, thyroid-stimulating hormone and melatonin. Furthermore, some studies have suggested that short REM latency or reduced delta sleep ratio (amount of delta waves in first

non-REM periods compared with second non-REM periods) may predict relapse in depressed patients. Some of these sleep-related abnormalities appear to persist during periods of clinical remission, such as short REM latency, loss of stages 3 and 4 sleep, and blunted nocturnal growth hormone release. Genetic factors may influence some of these measures, including short REM latency. Preliminary data suggest that short REM latency may be a genetic marker for depression in first-degree relatives of patients with mood disorders.

Even though the polygraphic sleep findings in depression do not appear to be diagnostically specific, they remain among the best documented biological abnormalities of any psychiatric disorder at this time. One challenge is to understand their pathophysiological mechanism. Because of the shallow, fragmented sleep and response to sleep deprivation, the sleep of patients with depression has been described as “overaroused”. For instance, the antidepressant response of sleep deprivation may “dampen down” an overly aroused limbic system in a subgroup of patients. Several studies have shown that responders to sleep deprivation differ from nonresponders at baseline assessment before sleep deprivation by having a higher level of metabolic activity in the cingulate gyrus and that this overactivity approaches normality with clinical improvement.

The sleep disturbances of **schizophrenic** patients are often similar to those of depressed patients, including short REM latency and reduced delta sleep, total sleep time and sleep efficiency. Interestingly, while making nightly “sleep checks” on hospitalized patients, nurses are more accurate in judging sleep time in schizophrenic patients than in depressive patients, who often appear to be asleep when they are actually awake.

Although less well studied, the sleep of patients with **anxiety** disorders, such as generalized anxiety disorder, panic disorder, obsessive–compulsive disorder, acute stress disorder and PTSD, is often disturbed. **Panic** attacks, for example, may occur occasionally during sleep itself, usually at the transition between stage 2 and delta sleep. Patients with panic disorders during sleep are also likely to experience panic attacks during wakefulness either with relaxation or after sleep deprivation.

Patients with **obsessive–compulsive** disorder frequently endure difficulties in the initiation and maintenance of sleep. They often have elaborate compulsive rituals before going to bed, for example, concerns about “germs” may necessitate long showers and fresh, clean “sterilized” pajamas and sheets each night. Polysomnographic features are sometimes similar to those described in major depressive disorder, even though the patients do not have symptoms that meet full diagnostic criteria for major depressive disorder.

Classic symptoms of **post traumatic stress** disorder include nightmares, night terrors and violent thrashing about during sleep. These patients are easily aroused. Combat survivors with PTSD sometimes seek a physically “secure” sleeping environment in which to sleep and wake up frequently during the night to “check the perimeter”. These sleep problems in Vietnam veterans who suffer from PTSD are often complicated by chronic conditioning, alcohol and substance abuse, depression, anxiety, and significant interpersonal and social problems. Total sleep time is usually reduced with variable and inconsistent disturbances of REM sleep. Successful treatment of the disorder and the sleep complaints has been traditionally difficult. The nightmares of PTSD appear to occur in both non-REM and REM sleep. While SSRIs are often recommended in the treatment of PTSD, some of the activating antidepressants appear to worsen subjec-

**Table 59.12** Sleep-related Characteristics Associated with Depression

Short REM latency (state, possibly trait)
Reduced amounts of stages 3 and 4 sleep (state and trait)
Difficulties initiating and maintaining sleep
Increased amounts of ocular movement during REM sleep (REM density), especially during the first REM period
A redistribution of REM sleep toward the beginning of sleep: increased duration of the first REM period
Low arousal thresholds to auditory stimulation
Elevated core body temperature during sleep
Blunted or reduced levels of plasma growth hormone (state and trait)
Elevated levels of plasma cortisol, increased number of pulses, and earlier onset of the morning rise in cortisol levels
Reduced levels of plasma testosterone
Blunted levels of thyroid-stimulating hormone at sleep onset
Reduced nocturnal levels of plasma melatonin
Longer but flattened periods of prolactin release
Elevated cerebral glucose metabolic rate during the first non-REM period
Faster induction of REM sleep after administration of cholinergic agonists
Antidepressant effect of total and partial sleep deprivation and, possibly, selective REM sleep deprivation

tive complaints of sleep. Nefazodone, a sedative antidepressant, slowly improved subjective sleep quality, mood, and the number of reported nightmares. Phenelzine and other MAOIs have also been reported to improve sleep and nightmares, but the possibility of serious drug interactions, alcoholism and poor compliance limit their usefulness. More recently, Raskin and colleagues have reported a significant reduction in nightmares and overall improvement in combat veterans with PTSD who were treated with prazosin, an alpha-1-adrenergic receptor antagonist (Taylor and Raskin, 2002).

Changes in sleep patterns may occur in patients with eating disorders. Night bingeing and increased sleep after eating are commonly reported in bulimic patients, who are also reported to eat and shop for food while sleepwalking. The patient frequently does not remember these nocturnal episodes; they often become known from family or friends who have observed the behavior or from physical evidence of shopping or eating behaviors. Patients with anorexia are often hyperactive, needing little sleep. Given the degree of physical and psychic stress associated with eating disorders, it is surprising how limited are the objective sleep disturbances associated with these disorders.

### General Approaches to the Clinical Management of Sleep Disorders in Psychiatric Patients

The sleep complaint in the patient with an apparent psychiatric disorder deserves the same careful diagnostic and therapeutic attention that it does in any patient. Just because a patient is depressed does not mean that the complaint of insomnia or hypersomnia can be explained away as a symptom of depression. Too many patients with depression have been found to have a BRSD; too many patients with panic disorder to have insomnia secondary to caffeineism. Chronic sleep complaints are multidetermined and multifaceted, even in many psychiatric patients. Differential diagnosis remains the first obligation of the psychiatrist before definitive treatment, which should be aimed at the underlying cause or causes.

Nonspecific treatments, such as use of sleep hygiene principles, are often helpful for both the sleep complaints and the underlying psychiatric disorders. In particular, bipolar disorder patients and patients whose daily activities are poorly organized (like patients with chronic schizophrenia and patients with certain personality disorders) may benefit from fairly rigid sleep–wake and light–dark schedules to synchronize circadian rhythms and impose structure on their behavior. Physical exercise, meditation, relaxation methods, sleep restriction therapy and cognitive psychotherapy may help patients manage anxiety, rumination and conditioned psychophysiological insomnia that often cause sleeplessness at night and fatigue during the day. Partial or total sleep deprivation may be like “paradoxical intention” therapy in the treatment of major depressive disorder or premenstrual dysphoric disorder but should probably be avoided in bipolar depression.

Medications may either help or hurt. Whether the patient should have drugs with sedating or activating properties should be considered. Timing and dose are important considerations in the context of pharmacokinetic and pharmacodynamic properties of drugs. Night-time administration of sedating drugs may improve sleep and reduce daytime oversedation. Clinically significant drug side effects such as oversedation or activation may

be more likely early in treatment than later, after tolerance has developed. On the other hand, some sedating medications, even short half-life sleeping aids, may have disinhibiting effects, even late into the next day, especially in elderly and cognitively impaired individuals. Doses of sleeping pills and other medications should usually be reduced by about half in the elderly compared with the dose for a young adult.

In general, avoid polypharmacy. Sleeping pills should be prescribed reluctantly to patients who receive adequate doses of antidepressants. Although coadministration of a benzodiazepine may improve sleep during the first week of antidepressant therapy, a low dose of zolpidem, zaleplon, trazodone, or other sedating antidepressant at night in addition to the antidepressant may be less likely to produce tolerance and may have additive antidepressant benefits. Antipsychotic medications should not be administered as sleeping aids unless the patient is psychotic or otherwise unresponsive to other medications.

### Sleep Disorders in Other Medical Conditions

A sleep disorder due to a general medical condition is defined in DSM-IV-TR as a prominent disturbance in sleep severe enough to warrant independent clinical attention. Subtypes include insomnia, hypersomnia, parasomnia and mixed types. As a general rule, any disease or disorder that causes pain, discomfort, or a heightened state of arousal in the waking state is capable of disrupting or interfering with sleep. Examples of this phenomenon include pain syndromes of any sort, arthritic and other rheumatological disorders, prostatism and other causes of urinary frequency or urgency, chronic obstructive lung disease and other pulmonary conditions. Many of these conditions increase in prevalence with advancing age, suggesting at least one reason that sleep disorders are more likely to be seen in senior populations. The following include disorders known to cause disturbances in sleep: rheumatoid arthritis, fibromyalgia, chronic obstructive pulmonary conditions, congestive heart failure, peptic ulcer disease, GERD, rectal urgency, Parkinson’s disease, Huntington’s chorea, advanced Alzheimer’s disease and hereditary progressive dystonia.

### Sleep in Elderly with Dementia

The sleep of older adults with dementia is extremely disturbed, with severely fragmented sleep, often to the extent that there is not a single hour in a 24-hour day that is spent fully awake or asleep. Patients with mild to moderate dementia have extremely fragmented sleep at night, while those with severe dementia are extremely sleepy during both the day and night. Sleep stages also change with dementia, with significantly lower amounts of stages 3, 4 and REM sleep, and significantly more awakenings, as well as more time spent awake during the night. This results in increased stage 1 sleep and decreased sleep efficiency. It has also been shown that there is a high prevalence of sleep apnea in patients with dementia, with as many as 80% having symptoms that meet the criteria for diagnosis. The sleep changes and disruption seen are likely due to the neuronal degeneration found in Alzheimer’s disease. Neuronal structures damaged in patients with dementia include the basal forebrain and the reticular formation of the brain stem, the same structures implicated in sleep regulation.

The nocturnal awakenings seen in dementia patients are often accompanied by agitation, confusion and wandering. These behaviors have been referred to as “sundowning” as it was believed

that they typically occurred as the sun set. A recent study (Martin *et al.*, 2000) challenged the idea of sundowning by showing that peak levels of agitation occur during various times of the day, but more often in the afternoon, rather than in the evening or night.

It has been suggested that agitation or sundowning may be a circadian rhythm disorder. Sleep disruption in demented individuals may be amenable to treatment using bright light exposure. Others have tested this theory by exposing patients with dementia to bright light. The results have been mixed, but in general support the theory that increased light exposure, whether during the morning or evening, will improve both sleep and behavior to some extent.

### Substance-induced Sleep Disorder

An important aspect of the evaluation of any patient, particularly those with sleep disorders, is the review of medications and other substances (including prescription, over-the-counter and recreational drugs, as well as alcohol, stimulants, narcotics, coffee and caffeine, and nicotine) and exposure to toxins, heavy metals, and so forth. These substances may affect sleep and wakefulness during either ingestion or withdrawal, causing most commonly insomnia, hypersomnia, or, less frequently, parasomnia or mixed types of difficulties. On the basis of DSM-IV-TR criteria, a diagnosis of substance-induced sleep disorder may be made if the disturbance of sleep is sufficiently severe to warrant independent clinical attention and is judged to result from the direct physiological effects of a substance. Substance-induced sleep disorder cannot result from mental disorder or occur during delirium. If appropriate, the context for the development of sleep symptoms may be indicated by specifying with onset during intoxication or with onset during withdrawal.

The recognition of substance-related sleep disturbances usually depends on active searching by the psychiatrist, beginning with a careful history, physical examination, laboratory and toxicological testing, and information (with permission) from former health care providers or friends and relatives. Patients may not know what prescription medications they are taking or the doses, and may forget to mention over-the-counter medications, coffee, occupational or environmental toxins, and so forth. In the case of alcohol and drugs of abuse, they may deny to themselves and others their use, or quantity, or frequency of use. Substance dependence and abuse is often associated with other psychiatric diagnoses or symptoms. When comorbidity does exist, it is important to establish, if possible, whether the sleep disturbance is primary or secondary, that is, whether the sleep disturbance is substance-induced (secondary) or whether the substance use

#### DSM-IV-TR Criteria

##### Substance-induced Sleep Disorder

- A. prominent disturbance in sleep that is sufficiently severe to warrant independent clinical attention.
- B. There is evidence from the history, physical examination, or laboratory findings of either (1) or (2):
  - (1) the symptoms in criterion A developed during, or within a month of, substance intoxication or withdrawal

(2) medication use is etiologically related to the sleep disturbance

- C. The disturbance is not better accounted for by a sleep disorder that is not substance induced. Evidence that the symptoms are better accounted for by a sleep disorder that is not substance induced might include the following: the symptoms precede the onset of the substance use (or medication use); the symptoms persist for a substantial period of time (e.g., about a month) after the cessation of acute withdrawal or severe intoxication, or are substantially in excess of what would be expected given the type or amount of the substance used or the duration of use; or there is other evidence that suggests the existence of an independent non-substance-induced sleep disorder (e.g., a history of recurrent non-substance-related episodes).
- D. The disturbance does not occur exclusively during the course of a delirium.
- E. The sleep disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

**Note:** This diagnosis should be made instead of a diagnosis of substance intoxication or substance withdrawal only when the sleep symptoms are in excess of those usually associated with the intoxication or withdrawal syndrome, and when the symptoms are sufficiently severe to warrant independent clinical attention.

##### Code

[specific substance]–induced sleep disorder:

(291.8 alcohol; 292.89 amphetamine; 292.89 caffeine; 292.89 cocaine; 292.89 opioid; 292.89 sedative, hypnotic, or anxiolytic; 292.89 other [or unknown] substance)

*Specify* type:

**Insomnia type:** if the predominant sleep disturbance is insomnia

**Hypersomnia type:** if the predominant sleep disturbance is hypersomnia

**Parasomnia type:** if the predominant sleep disturbance is a parasomnia

**Mixed type:** if more than one sleep disturbance is present and none predominates

*Specify* if:

**With onset during intoxication:** if criteria are met for intoxication with the substance and the symptoms develop during the intoxication syndrome

**With onset during withdrawal:** if criteria are met for withdrawal from the substance and the symptoms develop during, or shortly after, a withdrawal syndrome

functions as a form of “self-medication” for sleep disturbance, in which the sleep disturbance would be considered primary. Many patients with alcoholism experience secondary depression during the first few weeks of withdrawal from alcohol and exhibit short REM latency and other sleep changes similar to those reported in primary depression. This secondary depression usually remits spontaneously. Likewise, about one-third of patients with unipolar depression and about three-fifths of patients with bipolar disorder, manic type, have a substance use pattern that meets diagnostic criteria for alcoholism or substance abuse at some point. Prognosis and treatment may be altered in comorbid states, depending on whether the sleep disturbance is primary or secondary. In general, treatment should be aimed at the primary diagnosis after management of any acute withdrawal condition that may exist.

### Alcohol

Alcohol is probably the most commonly self-administered “sleeping aid”. Although it may be sedating, especially in middle-aged or elderly or sleep-deprived persons, its usefulness as a hypnotic is limited by potential disinhibiting and arousing effects, gastric irritation, falling blood-alcohol levels in the early part of the night with mild withdrawal symptoms and sleep fragmentation at the end of the night, morning headaches and hangover effects, tolerance with repeated use, and exacerbation of BRSDs such as apnea.

Virtually any type of sleep disturbance has been attributed to the effects of alcohol or alcohol withdrawal in patients with alcohol abuse or dependence. Insomnia may occur during episodes of drinking and acute and chronic withdrawal. Complaints of insomnia and objective disruption of sleep continuity and stages 3 and 4 sleep have been reported for up to several years in some abstinent patients. Hypersomnia may occur during heavy bouts of drinking, sometimes with peripheral compression neuropathies, or as “terminal hypersomnia” after delirium tremens. Circadian sleep disturbances may also occur during bouts of drinking, including periods of short polyphasic sleep–wake episodes. Parasomnias include sleepwalking and enuresis.

Because alcohol may temporarily improve the poor sleep of the chronic alcoholic individual, sleep disturbance may be a factor in relapse. Treatment of the sleep disturbances of the chronic but abstinent alcoholic individual is difficult. Nonpharmacological approaches include sleep hygiene and sleep restriction, as well as attention to general nutrition, physical health and psychosocial supports. Use of benzodiazepines or other hypnotics is not generally recommended because of cross-tolerance or deliberate or inadvertent overdose.

### Nicotine

Aside from medical complications, such as coughing that may interfere with sleep, smoking has been associated with both difficulty in falling asleep and getting up in the morning suggesting that nicotine may phase delay the circadian oscillator. Furthermore, compared with nonsmokers, men who smoked reported more nightmares, women who smoked reported more daytime sleepiness. Furthermore, as blood-nicotine levels fall during the night, smokers go into relative withdrawal and start craving a cigarette. One of the best measures of nicotine dependence is how long the smoker can wait in the morning for the first smoke. Abstinence from smoking is associated with lighter and more fragmented sleep, daytime sleepiness on the Multiple Sleep Latency Test, irritability, craving and other subjective emotional distress.

### Amphetamines, Cocaine and Caffeine

Stimulants initially prolong sleep onset and reduce REM sleep, sleep continuity, and sleep duration, but tolerance usually develops. During acute withdrawal, hypersomnia and excessive REM sleep occur for the first week or so but may be followed by a few days of insomnia.

Like the stimulants, caffeine usually promotes arousal and delays sleep, but withdrawal may be associated with hypersomnia. It is probably the most commonly self-administered stimulant, for example, the morning cup of coffee to “get going”. Caffeine has some benefits as a mild stimulant to overcome sleepiness.

### Opiates

Short-term use of opiates may increase sleep and subjective sleep quality and reduce REM sleep, especially in patients who need an analgesic for relief of pain, but these drugs may also disrupt sleep. Tolerance usually develops with repeated administration. Withdrawal may be associated with hypersomnia or the “nods”.

### Sedatives, Hypnotics and Anxiolytics

Tolerance usually develops with repeated administration of the sedating effects of barbiturates, chloral hydrate and even benzodiazepines. This is true especially with short half-life agents, with the possible exception of zaleplon. As mentioned earlier, 1 or 2 days of withdrawal insomnia may occur after a few days of administration of short half-life benzodiazepines, such as triazolam, but not with the newer nonbenzodiazepine hypnotics, such as zolpidem and zaleplon.

Potential side effects associated with sedating medications during the sleep period include falls and fractures, difficulty arousing to the telephone or the crying infant, amnesia, impairment of cognitive and motor skills, drug-induced sleepwalking, and possibly, BRSDs.

### Other Substances

Many medications produce sleep disturbance, including those with central or autonomic nervous system effects, like adrenergic agonists and antagonists, dopamine agonists and antagonists, cholinergic agonists and antagonists, antihistamines and steroids. Among the prescription drugs associated frequently with sleep disorders are the SSRIs, which have been connected with overarousal and insomnia in some patients and, more commonly, sedation in other patients. Coadministration of trazodone at night has been shown, in a double-blind, placebo-controlled study, to be effective in managing fluoxetine-induced insomnia in depressed patients (Nierenberg *et al.*, 1994). Additional sleep-related disturbances occasionally associated with the SSRIs include sleepwalking, REM sleep behavior disorder and rapid eye movements during non-REM sleep.

### Comparison of DSM-IV/ICD-10 Diagnostic Criteria

For primary insomnia, the ICD-10 Diagnostic Criteria for Research and the DSM-IV-TR criteria are almost identical except that ICD-10 requires a frequency of at least three times a week for at least a month, whereas DSM-IV-TR does not specify a required frequency. For primary hypersomnia, the ICD-10 Diagnostic Criteria for Research and the DSM-IV-TR criteria are almost identical except that ICD-10 also counts sleep drunkenness as a presenting symptom. Furthermore, ICD-10 requires that the

problems occur nearly every day for at least 1 month (or recurrently for shorter periods of time).

Since narcolepsy and breathing-related sleep disorder are included in Chapter VI (Diseases of the Nervous System) in ICD-10, there are no diagnostic criteria provided for these conditions.

For circadian rhythm sleep disorder, the ICD-10 Diagnostic Criteria for Research and the DSM-IV-TR criteria are almost identical except that ICD-10 specifies that the problems occur nearly every day for at least 1 month (or recurrently for shorter periods of time) (DSM-IV-TR has no specified duration). This condition is referred to in ICD-10 as “Nonorganic disorder of the sleep-wake cycle”.

The ICD-10 Diagnostic Criteria for Research and the DSM-IV-TR criteria for nightmare disorder and sleepwalking disorder are essentially identical. The ICD-10 Diagnostic Criteria for Research and the DSM-IV-TR criteria sets for sleep terror disorder are almost identical except that ICD-10 explicitly limits the duration of the episode to less than 10 minutes.

Although dissimilar in behavioral expressions, the disorders in this chapter share the feature of impulse dyscontrol. Individuals who experience such dyscontrol are overwhelmed by the urge to commit certain acts that are often apparently illogical or harmful. The outcome of each of these behaviors is often harmful, either for the afflicted individual (trichotillomania, pathological gambling) or for others (intermittent explosive disorder, pyromania, kleptomania).

The trait of impulsivity has been the subject of increasing interest in psychiatry. New research findings seem to associate various forms of impulsive behavior with biological markers of altered serotonergic function. These include impulsive suicidal behavior, impulsive aggression and impulsive fire-setting. Impulsivity is also a focus of interest in the increasing attention paid to the behavioral phenomenology of borderline personality disorder. In all these circumstances, impulsivity is conceived of as the rapid expression of unplanned behavior, occurring in response to a sudden thought. (This is seen by some as the polar opposite of obsessional behavior, in which deliberation over an act may seem never-ending.) Although the sudden and unplanned aspect of the behavior may be present in the impulse disorders (such as in intermittent explosive disorder and kleptomania), the primary connotation of the word impulsivity, as used to describe these conditions, is the irresistibility of the urge to act.

The National Comorbidity Survey Replication (NCS-R) (Kessler *et al.*, 2005) extended the definition of impulse control disorders described in this chapter to include intermittent explosive disorder, attention deficit hyperactivity disorder (ADHD), conduct disorder (CD) and oppositional defiant disorder (ODD). This decision was based on the fact that ADHD and anger symptoms often persist throughout adulthood. The NCS-R found that the combined lifetime prevalence for these disorders is greater than that of mood (20.8%) or substance abuse disorders (14.6%). Impulse control disorders in the extended definition had a 12 month prevalence of 8.9% and a lifetime prevalence of 24.8%. Moreover, this group was judged to have a greater proportion functioning at the serious level than either anxiety or substance abuse disorders, with approximately half of all lifetime cases receiving no treatment. An important objective in studying the impulse control disorders in this fashion was to highlight how common hostility and aggression are in psychiatric disorders, two dimensions often not receiving sufficient diagnostic consideration but which are significantly present as comorbidities with other disorders.

Trichotillomania, pyromania and pathological gambling may involve episodes in which a sudden desire to commit the act of hair-pulling, fire-setting, or gambling is followed by rapid expression of the behavior. But in these conditions, the individual may spend considerable amounts of time fighting off the urge, trying not to carry out the impulse. The inability to resist the im-

pulse is the common core of these disorders, rather than the rapid transduction of thought to action. A decision tree for the differential diagnosis of impulsive behaviors may be seen in Figure 60.1.

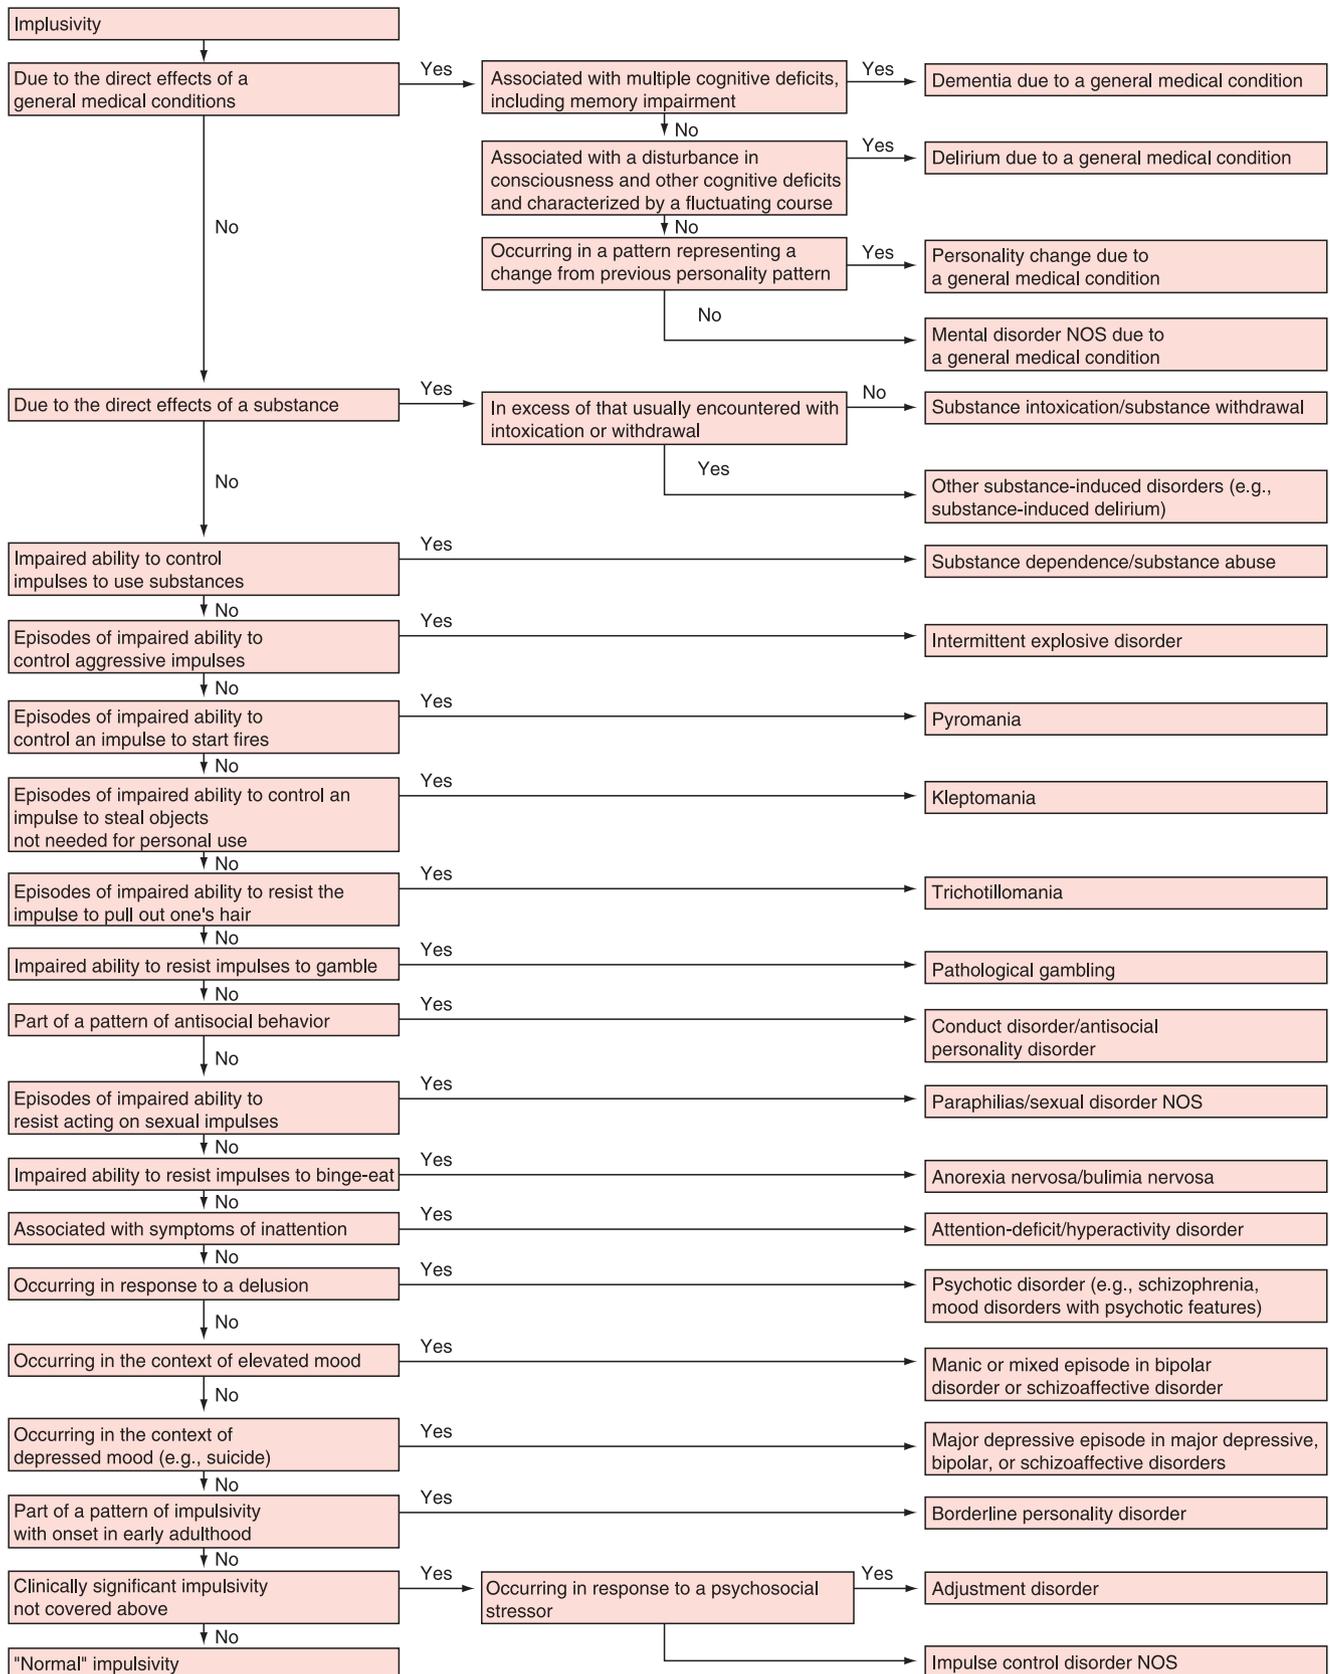

Other than sharing the essential feature of impulse dyscontrol, it is unclear whether the conditions in this chapter bear any relationship to each other. Emerging perspectives on the neurobiology of impulsivity suggest that impulsive behaviors, across diagnostic boundaries, may share an underlying pathophysiological diathesis. As noted earlier, markers of altered serotonergic neurotransmission have been associated with a variety of impulsive behaviors: suicidality, aggressive violence, pyromania and conduct disorder. These observations have led to speculation that decreased serotonergic neurotransmission may result in decreased ability to control urges to act. In accord with this model, these disorders may be varying expressions of a single disturbance – or closely related disturbances – of serotonergic function. Although such markers of altered serotonergic function have been demonstrated among impulsive fire-setters and impulsive violent offenders, there is, as yet, insufficient research on these conditions to accept or dismiss this theory.

It has been noted that these conditions are embedded in similar patterns of comorbidity with other psychiatric disorders. High rates of comorbid mood disorder and anxiety disorder appear typical of these disorders. This contextual similarity, combined with the common feature of impulsivity, may further support the notion that these conditions are – at the level of core diathesis – related to each other.

Although these conditions have historically been considered uncommon, later investigations suggest that some of them may be fairly common. Trichotillomania, for example, was once considered rare. However, surveys indicate that the lifetime prevalence of the condition may exceed 1% of the population. Pathological gambling may be present in up to 3% of the population. Extrapolation from the known incidence of comorbid conditions suggests that kleptomania may have a 0.6% incidence. It would seem reasonable to suspect that individuals with pyromania and kleptomania may seek to avoid detection and may therefore be underrepresented in research and clinical samples.

Treatment protocols for these conditions have not been well studied. Few treatment studies of these specific conditions have been performed. Attempts to treat these conditions are usually formulated by extrapolation from treatments that have been developed for other conditions.

The aggressive quality of kleptomania, pyromania and intermittent explosive disorder and the self-damaging nature of trichotillomania and pathological gambling have presented tempting substrates for the application of traditional analytical concepts. From this perspective, these behaviors have been seen

**Figure 60.1** *Differential diagnosis of impulsivity. Impulsivity is a tendency to act in a sudden, unpremeditated and excessively spontaneous fashion. Other decision trees that should be considered are those for aggressive behavior, catatonia, delusions, depressed mood, euphoric or irritable mood, disorganized or unusual behavior, distractibility, eating behavior, self-mutilation and suicide ideation or attempt. (NOS, not otherwise specified.)*

as symptomatic expressions of unconscious conflict, often sexual in nature. Other formulations include desires for oral gratification and masochistic wishes to be caught and punished, motivated by a harsh, guilt-inducing superego. The increasing influence of object relations theory was reflected in increasing emphasis on narcissistic psychopathology and histories of disturbed early parenting. As successful behavioral interventions were developed for other conditions, case reports of behavioral treatments for these conditions emerged. Reports of hypnotic treatments are also prominent in the literature.

The contemporary medical and psychological literature reflects, not surprisingly, prevailing general interests in current research and theory. As pharmacological treatments are applied to an increasing range of symptoms, the impulse disorders in this chapter present new opportunities to widen the application of thymoleptic and anxiolytic and, more recently, (atypical) neuroleptic medication. Some are reconceptualizing the idea of mood and obsessional disorders, widening them into affective and obsessional spectrums, encompassing various impulse disorders into these domains.

As part of the ongoing dynamic of evolving theory, the very concept of impulsivity is still in ferment. Attempts further to refine the idea of impulsivity are reflected in a perspective offered by Van Ameringen and associates (1999). In a discussion of preliminary evidence indicating that trichotillomania may be preferentially responsive to neuroleptics, they suggest that individuals with trichotillomania may have features in common with the subgroup of obsessive compulsive disorder (OCD) patients who have comorbid Tourette's syndrome (TS). These authors offer a thoughtful model, applying the idea of an "Impulsion" (Shapiro and Shapiro, 1992), an action performed until a sense of "rightness" is achieved, rather than a compulsion, which is designed to reduce an anxiety brought on by an obsession. They go on to note one formulation of OCD, which divides symptoms into three types: symmetry/hoarding, pure obsessions and contamination/cleaning. The symmetry/hoarding factor – impulsion-driven behavior – was differentially related to OCD with comorbid TS. They point to recent data suggesting that the OCD/TS subgroup is not as responsive to SSRI medication alone as other OCD subtypes, but responds better to SSRI/neuroleptic combinations. These observations, taken together with their report of enhanced response of trichotillomania to neuroleptics, is the basis for their argument that trichotillomania should be seen as more similar to OCD/TS than OCD, more impulsion than compulsion. The idea of anxiously seeking "rightness" is consistent with the clinical experience of many individuals with trichotillomania and is a thoughtful addition to the other attributes associated with impulsivity: anxiety reduction, irresistibility of action and rapidity of its execution.

Trichotillomania provides an example of the convergence of current research techniques and treatment perspectives. The absence of new psychodynamic formulations would seem to reflect not an abandonment of dynamic theory but an acceptance that such models are most useful in understanding individual patients rather than providing universal explanations for the symptom. Dynamic considerations may be useful in trying to understand why particular circumstances may provoke episodes of the problem behavior for a particular individual. But there is no available evidence that dynamic therapy, when employed as a sole mode of treatment, is efficacious in the treatment of trichotillomania or other conditions in this chapter.

Not all these conditions are, as yet, receiving significant attention. Trichotillomania, intermittent explosive disorder and

pathological gambling have become the focus of increasing interest. Kleptomania and pyromania, however, remain stepchildren of research. Perhaps the legal implications of these behaviors and their entanglement with similar, but not impulsively motivated, behaviors complicate the availability of sufficient cases to facilitate research.

Because of the limited body of systematically collected data, the following sections largely reflect accumulated clinical experience. Therefore, the practicing psychiatrist should be particularly careful to consider the exigencies of individual patients in applying treatment recommendations.

## Intermittent Explosive Disorder

### Definition

Patients with intermittent explosive disorder have a problem with their temper (see DSM-IV-TR criteria). This definition highlights the centrality of impulsive aggression in intermittent explosive disorder. Impulsive aggression, however, is not specific to intermittent explosive disorder. It is a key feature of several psychiatric disorders and nonpsychiatric conditions and may emerge during the course of yet other psychiatric disorders. Therefore, the definition of intermittent explosive disorder as formulated in the DSM-IV-TR is essentially a diagnosis of exclusion. As described in criterion C, a diagnosis of intermittent explosive disorder is made only after other mental disorders that might account for episodes of aggressive behavior have been ruled out. The individual may describe the aggressive episodes as "spells" or "attacks". The symptoms appear within minutes to hours and, regardless of the duration of the episode, may remit almost as quickly. As in other impulse control disorders, the explosive behavior may be preceded by a sense of tension or arousal and is followed immediately by a sense of relief or release of tension.

### DSM-IV-TR Criteria 312.34

#### Intermittent Explosive Disorder

- A. Several discrete episodes of failure to resist aggressive impulses that result in serious assaultive acts or destruction of property.
- B. The degree of aggressiveness expressed during the episodes is grossly out of proportion to any precipitating psychosocial stressors.
- C. The aggressive episodes are not better accounted for by another mental disorder (e.g., antisocial personality disorder, borderline personality disorder, a psychotic disorder, a manic episode, conduct disorder, or attention-deficit/hyperactivity disorder) and are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., head trauma, Alzheimer's disease).

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

Although not explicitly stated in the DSM-IV-TR definition of intermittent explosive disorder, impulsive aggressive behavior may have many motivations that are not meant to be included

within this diagnosis. Intermittent explosive disorder should not be diagnosed when the purpose of the aggression is monetary gain, vengeance, self-defense, social dominance, or expressing a political statement or when it occurs as a part of gang behavior. Typically, the aggressive behavior is egodystonic to individuals with intermittent explosive disorder, who feel genuinely upset, remorseful, regretful, bewildered, or embarrassed about their impulsive aggressive acts.

### Etiology and Pathophysiology

Since the second half of the 19th century, two main lines of explanation, which are to a large extent complementary, have been developed to account for the existence of individuals with episodic impulsive aggression. One line of explanation viewed the etiology of impulsive aggression as stemming from the effects of early childhood experiences and possibly childhood trauma on the development of self-control, frustration tolerance, planning ability and gratification delay, which are all important for self-prevention of impulsive aggressive outbursts. Early experiences with “good-enough” mothering that fosters phase-appropriate delay of gratification and the development of the potential for imitation and identification with the mother are considered important for normal development. Too much or too little frustration, as well as overgratification or undergratification, may impair the normal development of the ability to anticipate frustration and delay gratification.

A second line of explanation, which has yielded numerous positive findings during the past 15 years, views impulsive aggression as the result of variations in brain mechanisms that mediate behavioral arousal and behavioral inhibition. A rapidly growing body of evidence has shown that impulsive aggression may be related to defects in the brain serotonergic system, which acts as an inhibitor of motor activity. Although the majority of studies involved patients who suffered from impulsive aggression in the context of disorders other than intermittent explosive disorder, their findings may be relevant to the behavioral dimension of impulsive aggression, of which intermittent explosive disorder is a “pure” form. A number of researchers have confirmed a relationship between levels of 5-hydroxyindoleacetic acid (5-HIAA) in the CSF and impulsive or aggressive behaviors. Others have divided aggressive behaviors into impulsive and nonimpulsive forms, and found that reduced CSF 5-HIAA levels were correlated with impulsive aggression only. Pharmacological challenge studies of the serotonergic system have also demonstrated that low serotonergic responsiveness (as measured by the neuroendocrine response to serotonergic agonists) correlates with scores of impulsive aggression. Studies of impulsive aggression among alcoholics have further defined a probable relationship between such behaviors and diminished serotonergic function.

The literature on serotonin and suicide, which may be viewed as an extreme form of self-directed aggression, suggests another link between serotonin and aggression. Postmortem studies found that brain stem levels of serotonin were decreased in suicide victims, and reduced imipramine binding, which is thought to be associated with reduced presynaptic serotonergic binding sites, was found in the brains of suicide completers. Furthermore, an increase in postsynaptic 5-hydroxytryptamine (5-HT<sub>2</sub>) receptors was found in the brains of suicide completers, and this finding was confirmed in subsequent studies. An increase in 5-HT<sub>2</sub> receptors, which are thought to be mostly postsynaptic, may reflect the brain’s reaction to a decrease in functional serotonergic neurons, with consequent upregulation of postsynaptic serotonin binding sites.

Another line of neurobiological evidence links impulsive aggression with dysfunction of the prefrontal cortex. Studies of neuropsychiatric patients with localized structural brain lesions have demonstrated that some bilateral lesions in the prefrontal cortex may be specifically associated with a chronic pattern of impulsive aggressive behaviors. Neurological studies suggest that the prefrontal cortical regions associated with impulsive aggression syndromes are involved in the processing of affective information and the inhibition of motor responsiveness, both of which are impaired in patients with impulsive aggression. Interictal episodes of aggression may occur among some individuals with epilepsy. In a quantitative MRI study of such episodes among individuals with temporal lobe epilepsy (TLE) (Woermann *et al.*, 2000) three groups (24 TLE patients with aggressive behavior, 24 TLE patients without such behavior and 35 nonpatient controls) were compared. The researchers concluded that the aggressive behavior was associated with a reduction of frontal neocortical gray matter.

Biological studies implicate the serotonergic system and the prefrontal cortex in the pathogenesis of impulsive aggression. The diagnosis of intermittent explosive disorder is sometimes considered in forensic settings; the biological correlates of impulsive aggression focus attention on, but do not solve, the complicated problem of personal responsibility for impulsive violent acts that are correlated with objective biological findings. Data from a study of visual-evoked potentials and EEGs in a large group of children and adolescents who demonstrated aggressive behavior also suggest that such behavior may be associated with altered innate characteristics of central nervous system function (Bars *et al.*, 2001).

### Assessment and Differential Diagnosis

#### Phenomenology and Variations in Presentation

Episodes of violent behavior appear in several common psychiatric disorders such as antisocial personality disorder, borderline personality disorder and substance use disorders and need to be distinguished from the violent episodes of patients with intermittent explosive disorder, which are apparently rare. The study of Felthous and coworkers (1991), in which 15 men with rigorously diagnosed DSM-III-R intermittent explosive disorder were identified from among a group of 443 men who complained of violence, permitted some systematic observations about the “typical violent episode” as reported by patients with intermittent explosive disorder.

In the vast majority of instances, the subjects with intermittent explosive disorder identified their spouse, lover, or girlfriend or boyfriend as a provocateur of their violent episodes. Only one was provoked by a stranger. For most, the reactions occurred immediately and without a noticeable prodromal period. Only one subject stated that the outburst occurred between 1 and 24 hours after the perceived provocation. All subjects with intermittent explosive disorder denied that they intended the outburst to occur in advance. Most subjects remained well oriented during the outbursts, although two claimed to lose track of where they were. None lost control of urine or bowel function during the episode. Subjects reported various degrees of subjective feelings of behavioral dyscontrol. Only four felt that they completely lost control. Six had good recollection of the event afterward, eight had partial recollection and one lost memory of the event afterward. Most subjects with intermittent explosive disorder attempted to help or comfort the victim afterwards.

## Assessment

### Special Issues in the Psychiatric Examination and History

The DSM-IV-TR diagnosis of intermittent explosive disorder is essentially a diagnosis of exclusion, and the psychiatrist should evaluate and carefully rule out more common diagnoses that are associated with impulsive violence. The lifelong nonremitting history of impulsive aggression associated with antisocial personality disorder and borderline personality disorder, together with other features of antisocial behavior (in antisocial personality disorder) or impulsive behaviors in other spheres (in borderline personality disorder), may distinguish them from intermittent explosive disorder, in which baseline behavior and functioning are in marked contrast to the violent outbursts. Other features of borderline personality disorder such as unstable and intense interpersonal relationships, frantic efforts to avoid abandonment and identity disturbance may also be elicited by a careful history. More than in most psychiatric diagnoses, collateral information from an independent historian may be extremely helpful. This is especially true in forensic settings. Of note, patients with intermittent explosive disorder are usually genuinely distressed by their impulsive aggressive outbursts and may voluntarily seek psychiatric help to control them. In contrast, patients with antisocial personality disorder do not feel true remorse for their actions and view them as a problem only insofar as they suffer their consequences, such as incarceration and fines. Although patients with borderline personality disorder, like patients with intermittent explosive disorder, are often distressed by their impulsive actions, the rapid development of intense and unstable transference toward the psychiatrist during the evaluation period of patients with borderline personality disorder may be helpful in distinguishing it from intermittent explosive disorder.

Other causes of episodic impulsive aggression are substance use disorders, in particular alcohol abuse and intoxication. When the episodic impulsive aggression is associated only with intoxication, intermittent explosive disorder is ruled out. However, as discussed earlier, intermittent explosive disorder and alcohol abuse may be related, and the diagnosis of one should lead the psychiatrist to search for the other.

Neurological conditions, such as dementias, focal frontal lesions, partial complex seizures and postconcussion syndrome after recent head trauma, may all present as episodic impulsive aggression and need to be differentiated from intermittent explosive disorder. Other neurological causes of impulsive aggression include encephalitis, brain abscess, normal-pressure hydrocephalus, subarachnoid hemorrhage and stroke. In these instances, the diagnosis would be personality change due to a general medical condition, aggressive type, and it may be made with a careful history and the characteristic physical and laboratory findings.

Individuals with intermittent explosive disorder may have comorbid mood disorders. Although the diagnosis of a manic episode excludes intermittent explosive disorder, the evidence for serotonergic abnormalities in both major depressive disorder and impulse control disorders supports the clinical observation that impulsive aggression may be increased in depressed patients, leading ultimately to completed suicide.

### Physical Examination and Laboratory Findings

The physical and laboratory findings relevant to the diagnosis of intermittent explosive disorder and the differential diagnosis of impulsive aggression may be divided into two main groups: those

associated with episodic impulsive aggression but not diagnostic of a particular disorder and those that suggest the diagnosis of a psychiatric or medical disorder other than intermittent explosive disorder. No laboratory or physical findings are specific for intermittent explosive disorder.

The first group of findings that are associated with impulsive aggression across a spectrum of disorders includes soft neurological signs such as subtle impairments in hand–eye coordination and minor reflex asymmetries. These signs may be elicited by a comprehensive neurological examination and simple pencil-and-paper tests such as parts A and B of the Trail Making Test. Measures of central serotonergic function such as CSF 5-HIAA levels, the fenfluramine neuroendocrine challenge test, and positron emission tomography of prefrontal metabolism also belong to this group. Although these measures advanced our neurobiological understanding of impulsive aggression, their utility in the diagnosis of individual cases of intermittent explosive disorder and other disorders with impulsive aggression is yet to be demonstrated.

The second group of physical and laboratory findings is useful in the diagnosis of causes of impulsive aggression other than intermittent explosive disorder. The smell of alcohol on a patient's breath or a positive alcohol reading with a Breathalyzer may help reveal alcohol intoxication. Blood and urine toxicology screens may reveal the use of other substances, and track marks on the forearms may suggest intravenous drug use. Partial complex seizures and focal brain lesions may be evaluated by use of the EEG and brain imaging. In cases without a grossly abnormal neurological examination, magnetic resonance imaging may be more useful than computed tomography of the head. Magnetic resonance imaging can reveal mesiotemporal scarring, which may be the only evidence for a latent seizure disorder, sometimes in the presence of a normal or inconclusive EEG. Diffuse slowing on the EEG is a nonspecific finding that is probably more common in, but not diagnostic of, patients with impulsive aggression. Hypoglycemia, a rare cause of impulsive aggression, may be detected by blood chemistry screens.

### Differential Diagnosis

As discussed earlier, the differential diagnosis of intermittent explosive disorder covers the differential diagnosis of impulsivity and aggressive behavior in general. Aggression and impulsivity are defined as follows:

Aggression is defined as forceful physical or verbal action, which may be appropriate and self-protective or inappropriate as in hostile or destructive behavior. It may be directed against another person, against the environment, or toward the self. The psychiatric nosology of aggression is still preliminary. Impulsivity is defined as the tendency to act in a sudden, unpremeditated, and excessively spontaneous fashion.

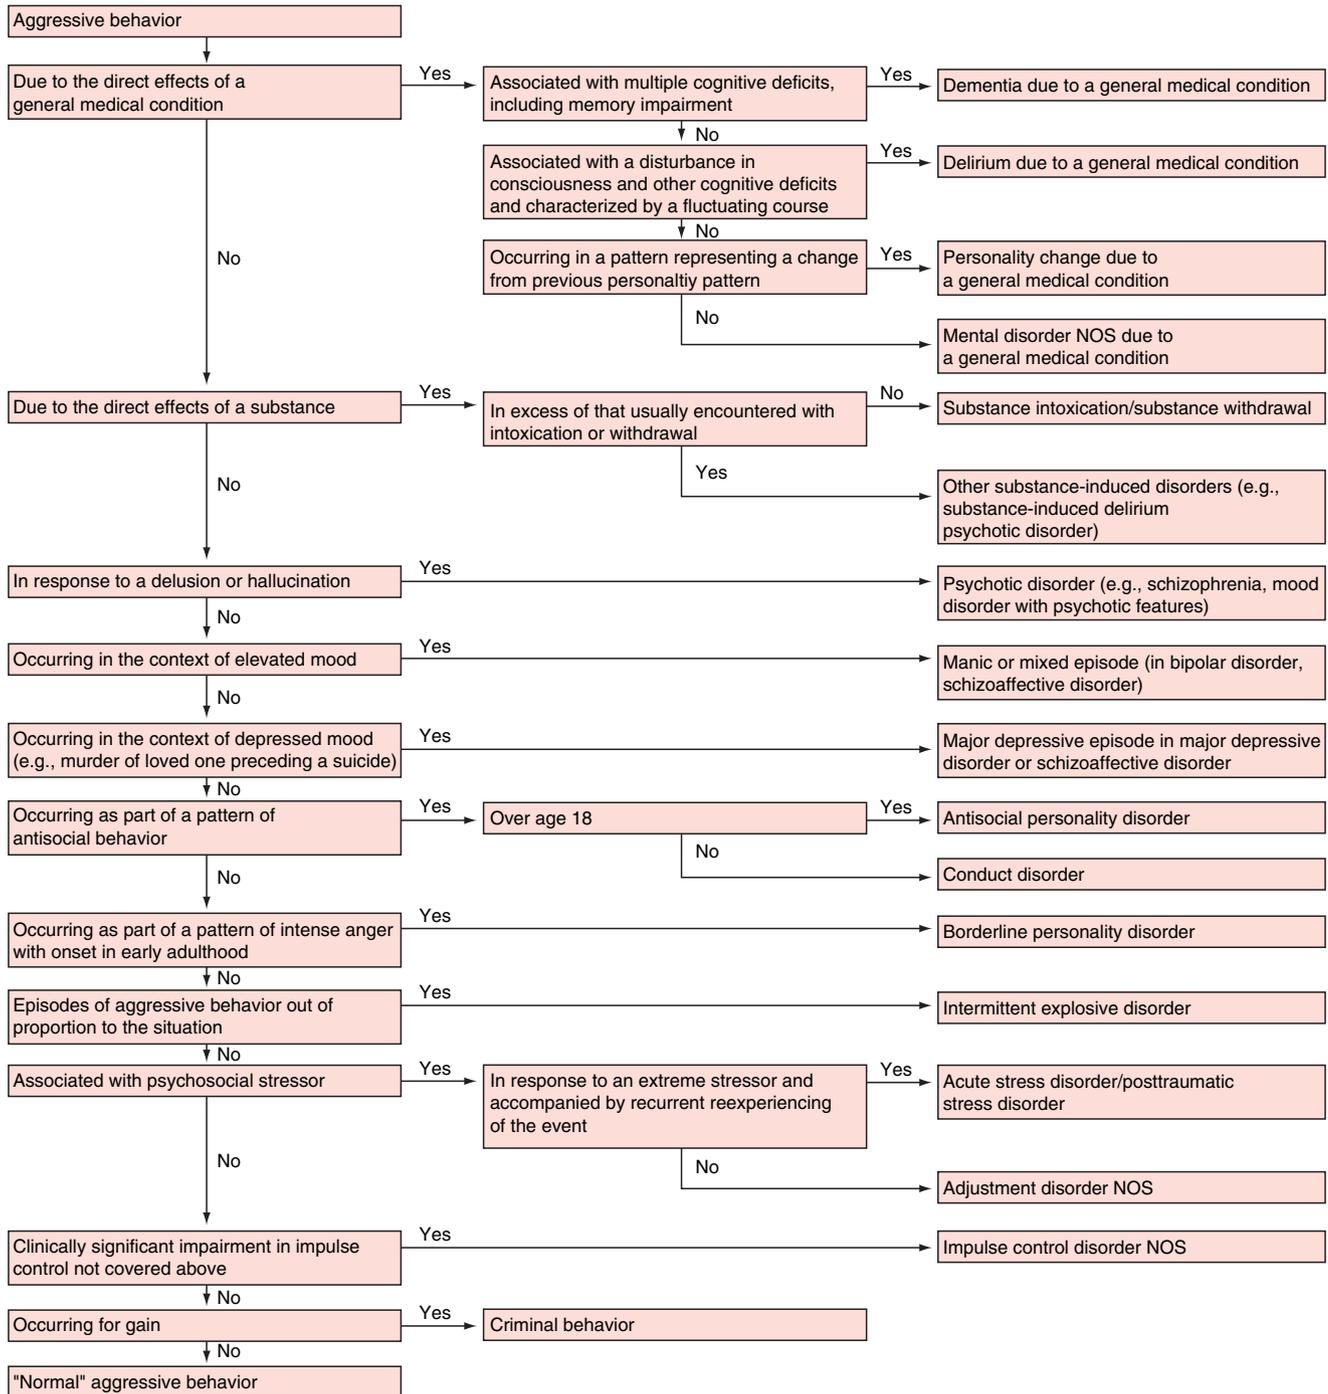

The diagnosis of intermittent explosive disorder should be considered only after all other disorders that are associated with impulsivity and aggression have been ruled out. Chronic impulsivity and aggression may occur as part of a cluster B personality disorder (antisocial and borderline); during the course of substance use disorders and substance intoxication; in the setting of a general medical (usually neurological) condition; and as part of disorders first diagnosed during childhood and adolescence such as conduct disorder, oppositional defiant disorder, attention-deficit/hyperactivity disorder and mental retardation. In addition, impulsive aggression may appear during the course of a mood disorder, especially during a manic episode, which precludes the diagnosis of intermittent explosive disorder, and during the

course of an agitated depressive episode. Impulsive aggression may also be an associated feature of schizophrenia, in which it may occur in response to hallucinations or delusions. Impulsive aggression may also appear in variants of OCD, which may present with concurrent impulsive and compulsive symptoms.

A special problem in the differential diagnosis of impulsive aggression, which may arise in forensic settings, is that it may rep-

resent purposeful behavior. Purposeful behavior is distinguished from intermittent explosive disorder by the presence of motivation and gain in the aggressive act, such as monetary gain, vengeance, or social dominance. Another diagnostic problem in forensic settings is malingering, in which individuals may claim to have intermittent explosive disorder to avoid legal responsibility for their acts.

Figure 60.2 presents the differential diagnosis of aggression.

**Figure 60.2** *Differential diagnosis of aggression. The psychiatric nosology of aggression has not been well worked out and requires much additional study. This is a particularly unfortunate state of affairs because the attribution (or misattribution) of aggression to a mental disorder is a frequent focus of forensic attention and can mean the difference between a life term in prison or a promotional tour for a bestseller. Because of the inherent difficulties in making these determinations, psychiatric testimony in this regard should be interpreted with caution. Other decision trees that may be of interest include those for catatonia; delusions; euphoria or irritability; disorganized, agitated, or unusual behavior; impulsivity; hallucinations; substance use and general medical condition.*

## Epidemiology

### Prevalence and Incidence

Intermittent explosive disorder has been subjected to little systematic study. The exclusionary criterion in the DSM-IV-TR definition (criterion C) reflects an ongoing debate over the boundaries of this disorder. In an early study of the prevalence of DSM-III-R intermittent explosive disorder among violent men, Felthous and colleagues (1991) found that of 443 subjects who complained of violence, only 15 (3.4%) met criteria for intermittent explosive disorder. However, the recently completed National Comorbidity Survey Replication (NCS-R) (Kessler *et al.*, 2005) found that intermittent explosive disorder (12 month prevalence 2.6%) was as nearly common as panic disorder (12 month prevalence 2.7%).

### Comorbidity

The DSM-IV-TR definition of intermittent explosive disorder allows signs of generalized impulsivity or aggressiveness to be present between episodes. It also allows the psychiatrist to give an additional diagnosis of intermittent explosive disorder in the presence of another disorder if the episodes are not better accounted for by the other disorder. The clinical reality is that most individuals who have intermittent episodes of aggressive behavior also have some impulsivity between episodes and often present with other past or current psychiatric disorders. There is minimal research-based data available regarding comorbidity. But the literature on the comorbidity of impulsive aggressive episodes suggests that it often occurs with three classes of disorders:

1. Personality disorders, especially antisocial personality disorder and borderline personality disorder. By definition, antisocial personality disorder and borderline personality disorder are chronic and include impulsive aggression as an essential feature. Therefore, their diagnosis effectively excludes the diagnosis of intermittent explosive disorder (Figure 60.2).
2. A history of substance use disorders, especially alcohol abuse. A concurrent diagnosis of substance intoxication excludes the diagnosis of intermittent explosive disorder. However, many patients with intermittent explosive disorder report past or family histories of substance abuse, and in particular alcohol abuse. In light of evidence linking personal and family history of alcohol abuse with impulsive aggression and the evidence (reviewed later) linking both with low central serotonergic function, this connection may be clinically relevant. Therefore, when there is evidence suggesting that alcohol abuse may be present, a systematic evaluation of intermittent explosive disorder is warranted, and vice versa.
3. Neurological disorders, especially severe head trauma, partial complex seizures, dementias and inborn errors of metabolism. Intermittent explosive disorder is not diagnosed if the aggressive episodes are a direct physiological consequence of a general medical condition. Such cases would be diagnosed as personality change due to a general medical condition, delirium, or dementia. However, individuals with intermittent explosive disorder often have nonspecific findings on neurological examination, such as reflex asymmetries, mild hand–eye coordination deficits, and childhood histories of head trauma with or without loss of consciousness. Their EEGs may show nonspecific changes. Such isolated findings are compatible with the diagnosis of intermittent explosive disorder and preempt the diagnosis only when they are indicative of a

definitely diagnosable general medical or neurological condition. Such “soft” neurological signs may be diagnosed by a full neurological examination and neuropsychological testing.

McElroy and coworkers (McElroy *et al.*, 1998; McElroy, 1999) studied 27 individuals who had symptoms that met criteria for intermittent explosive disorder (IED) and reported: “Twenty-five (93%) subjects had lifetime DSM-IV-TR diagnoses of mood disorders; 13 (48%), substance use disorders; 13 (48%), anxiety disorders; 6 (22%), eating disorders; and 12 (44%), an impulse control disorder other than intermittent explosive disorder. Subjects also displayed high rates of comorbid migraine headaches. First-degree relatives displayed high rates of mood, substance use, and impulse control disorders”.

Some children with Tourette’s disorder may be prone to rage attacks. The clinical manifestation of these rage attacks are similar to IED and may be more common among children with Tourette’s who have comorbid mood disorders. On the basis of these observations, the rage attacks of these children may flow from an underlying dysregulation of brain function (Budman *et al.*, 2000).

### Course, Natural History and Prognosis

Little systematic study has been done on the course of intermittent explosive disorder. The onset of the disorder appears to be from late adolescence to the third decade of life, and it may be abrupt and without a prodromal period. Intermittent explosive disorder is apparently chronic and may persist well into middle life unless treated successfully. In some cases, it may decrease in severity or remit completely with old age.

### Treatment

Given the rarity of pure intermittent explosive disorder, it is not surprising that few systematic data are available on its response to treatment and that some of the recommended treatment approaches to intermittent explosive disorder are based on treatment studies of impulsivity and aggression in the setting of other mental disorders and general medical conditions. Thus, no standard regimen for the treatment of intermittent explosive disorder can be recommended at this time.

### Psychological Treatment

Lion (1992) has described the major psychotherapeutic task of teaching individuals with intermittent explosive disorder how to recognize their own feeling states and especially the affective state of rage. Lack of awareness of their own mounting anger is presumed to lead to the build-up of intolerable rage that is then discharged suddenly and inappropriately in a temper outburst. Patients with intermittent explosive disorder are therefore taught how to first recognize and then verbalize their anger appropriately. In addition, during the course of insight-oriented psychotherapy, they are encouraged to identify and express the fantasies surrounding their rage. Group psychotherapy for temper-prone patients has also been described. The cognitive–behavioral model of psychological treatment may be usefully applied to problems with anger and rage management.

### Somatic Treatments

Several classes of medications have been used to treat intermittent explosive disorder. The same medications have also been used to treat impulsive aggression in the context of other disorders. These included beta-blockers (propranolol and metoprolol), anticonvulsants (carbamazepine and valproic acid),

lithium, antidepressants (tricyclic antidepressants and serotonin reuptake inhibitors) and anti-anxiety agents (lorazepam, alprazolam and buspirone). Mattes (1990) compared the effectiveness of two commonly used agents, carbamazepine and propranolol, for the treatment of rage outbursts in a heterogeneous group of patients. He found that although carbamazepine and propranolol were overall equally effective, carbamazepine was more effective in patients with intermittent explosive disorder and propranolol was more effective in patients with attention-deficit/hyperactivity disorder. A substantial body of evidence supports the use of propranolol – often in high doses – for impulsive aggression in patients with chronic psychotic disorders and mental retardation. Lithium has been shown to have anti-aggressive properties and may be used to control temper outbursts. In patients with comorbid major depressive disorder, OCD, or cluster B and C personality disorders, SSRIs may be useful. Overall, in the absence of more controlled clinical trials, the best approach may be to tailor the psychopharmacological agent to coexisting psychiatric comorbidity. In the absence of comorbid disorders, carbamazepine, titrated to antiepileptic blood levels, may be used empirically.

## Kleptomania

### Definition

Kleptomania shares with all other impulse control disorders the recurrent failure to resist impulses. Unfortunately, in the absence of epidemiological studies, little is known about kleptomania. Clinical case series and case reports are limited. Family, neurobiological, and genetic investigations are not available. There are no established treatments of choice. Therefore, in reading this section the reader must keep in mind that much of what is described is based on limited data or on anecdotal information.

### DSM-IV-TR Criteria 312.32

#### Kleptomania

- A. Recurrent failure to resist impulses to steal objects that are not needed for personal use or for their monetary value.
- B. Increasing sense of tension immediately before committing the theft.
- C. Pleasure, gratification, or relief at the time of committing the theft.
- D. The stealing is not committed to express anger or vengeance and is not in response to a delusion or a hallucination.
- E. The stealing is not better accounted for by conduct disorder, a manic episode, or antisocial personality disorder.

### Etiology and Pathophysiology

The etiology of kleptomania is essentially unknown, although various models have been proposed in an effort to conceptualize the disorder. The affective spectrum model suggests that

kleptomania and other impulse control disorders may share a common underlying biological diathesis with other disorders, such as depression, panic disorder, OCD and bulimia nervosa (McElroy *et al.*, 1992; Hudson and Pope, 1990). In some individuals, kleptomania responds to treatment with thymoleptic agents or electroconvulsive therapy. These observations are cited as support for an affective spectrum model.

Several lines of evidence support kleptomania as belonging to the obsessive-compulsive spectrum disorders. First, there are phenomenological similarities between the classical obsessions and compulsions of OCD and the irresistible impulses and repetitive actions characteristic of kleptomania. In addition, there appears to be a greater than chance occurrence of OCD in probands with kleptomania and in their relatives. In addition, both conditions have significant comorbidity with mood, anxiety, substance use and eating disorders. However, OCD rituals are more clearly associated with relief of anxiety and harm avoidance, whereas kleptomanic acts seem to be associated with gratification or pleasure. In addition, OCD is associated with a clear preferential response to SSRIs as opposed to general thymoleptics. The limited treatment literature does not support a similar response pattern in kleptomania. Unfortunately, the role of the serotonergic or of any other neurotransmitter system has not been investigated in kleptomania. Interestingly, a large study found subjects with mixed anorexia and bulimia nervosa to have a higher lifetime prevalence of kleptomania than those with either anorexia or bulimia nervosa alone (Herzog *et al.*, 1992). This could suggest a relationship between kleptomania and both the obsessive-compulsive (anorexic) and affective (bulimic) spectrum.

Alternatively, kleptomania could be conceptualized as an addictive disorder. The irresistible impulse to steal is reminiscent of the urge and the high associated with drinking or using drugs. Marks (1990) has proposed a constellation of behavioral (i.e., nonchemical) addictions encompassing OCD, compulsive spending, gambling, bingeing, hypersexuality and kleptomania. This model postulates certain concepts thought to be common in all these disorders, such as craving, mounting tension, “quick fixing”, withdrawal, external cuing and habituation. These components have not yet been well investigated in kleptomania.

It should be emphasized that the lack of neurobiological or prospective pharmacological treatment data for kleptomania limits any conclusions that can be drawn with regard to biological models.

A frequent theme, reported by numerous authors is that of kleptomania as an acting-out aimed at alleviating depressive symptoms. From a psychodynamic point of view, kleptomania has been viewed over the decades as a manifestation of a variety of unconscious conflicts, with sexual conflicts figuring prominently in the literature. Case reports have described conscious sexual gratification, sometimes accompanied by frank masturbation or orgasm during kleptomanic acts (Fishbain, 1987). Thus, it has been suggested, kleptomanic behavior serves to discharge a sexual drive that may have forbidden connotations similar to those of masturbation, and the stolen object itself may have unconscious symbolic or overt fetishistic significance. Although no systematic studies exist, there has long been an implication in the literature on kleptomania that those afflicted with kleptomania suffer disproportionately from a variety of sexual dysfunctions. Turnbull (1987) described six patients with a primary diagnosis of kleptomania, all of whom had dysfunctional sexual relationships with their partners, compulsive promiscuity, or anorgasmia.

Other cases of kleptomania have been understood as reflecting conflictual infantile needs and attempts at oral gratification, masochistic wishes to be caught and punished related to a harsh guilt-inducing superego or primitive aggressive strivings, penis envy or castration anxiety with the stolen object representing a penis, a defense against unwelcome passive homosexual longings, restitution of the self in the presence of narcissistic injuries, or the acquisition of transitional objects. One should probably conclude that the psychodynamics associated with kleptomania ought to be carefully tailored to the individual patient. The literature on kleptomania has frequently implicated disturbed childhoods, inadequate parenting and significant character disturbances in kleptomaniac patients. From this perspective kleptomania can be more effectively understood in the context of an individual's overall character. Unfortunately, no clinical studies exist that systematically explore Axis II psychopathology in these patients.

## Assessment and Differential Diagnosis

### Phenomenology and Presentation

At presentation, the typical patient suffering from kleptomania is a 35-year-old woman who has been stealing for about 15 years and may not mention kleptomania as the presenting complaint or in the initial history. The patient may complain instead of anxiety, depression, lability, dysphoria, or manifestations of character pathology. There is often a history of a tumultuous childhood and poor parenting, and in addition acute stressors may be present, such as marital or sexual conflicts. The patient experiences the urge to steal as irresistible, and the thefts are commonly associated with a thrill, a high, a sense of relief, or gratification. Generally, the behavior has been hard to control and has often gone undetected by others. The kleptomania may be restricted to specific settings or types of objects, and the patient may or may not be able to describe rationales for these preferences. Quite often, the objects taken are of inherently little financial value, or have meaningless financial value relative to the income of the person who has taken the object. Additionally, the object may never actually be used. These factors often help distinguish theft from kleptomania. The theft is followed by feelings of guilt or shame and, sometimes, attempts at atonement. The frequency of stealing episodes may greatly fluctuate in concordance with the degree of depression, anxiety, or stress. There may be periods of complete abstinence. The patient may have a past history of psychiatric treatments including hospitalizations or of arrests and convictions, whose impact on future kleptomaniac behavior can be variable.

### Assessment

Generally, the diagnosis of kleptomania is not a complicated one to make. However, kleptomania may frequently go undetected because the patient may not mention it spontaneously and the psychiatrist may fail to inquire about it as part of the routine history. The index of suspicion should rise in the presence of commonly associated symptoms such as chronic depression, other impulsive or compulsive behaviors, tumultuous backgrounds, or unexplained legal troubles. It could convincingly be argued that a cursory review of compulsivity and impulsivity, citing multiple examples for the patient, should be a part of any thorough and complete psychiatric evaluation. In addition, it is important to make a careful differential diagnosis and pay attention to the

various exclusion criteria before diagnosing theft as kleptomania. Possible diagnoses of sociopathy, mania, or psychosis should be carefully considered. In this regard, the psychiatrist must inquire about the affective state of the patient during the episodes, the presence of delusions or hallucinations associated with the occurrence of the behavior, the motivation behind the stealing, and the fate and subsequent use of the objects.

Although the typical patient may be a 35-year-old woman, it is important to remember that men, children and elderly persons may present with or engage in kleptomania. Interestingly, men may first present for evaluation 15 years later than women. Kleptomania occurs transculturally and has been described in various Western and Eastern cultures. Asian observers have also noted an overlap with eating disorders (Lee, 1994). Atypical presentations should raise a greater suspicion of an organic etiology, and a medical evaluation is then indicated. Medical conditions that have been associated with kleptomania include cortical atrophy, dementia, intracranial mass lesions, encephalitis, normal-pressure hydrocephalus, benzodiazepine withdrawal and temporal lobe epilepsy. A complete evaluation when such suspicions are present includes a physical and neurological examination, general serum chemistry and hematological panels, and an EEG with temporal leads or computed tomography of the brain.

## Epidemiology and Comorbidity

### Prevalence and Incidence

No epidemiological studies of kleptomania have been conducted, and thus its prevalence can be calculated only grossly and indirectly. Despite the lack of valid epidemiological data, there is general agreement that kleptomania is more common among women than among men. However, women generally seek psychiatric help more frequently than men, whereas men are more likely to become involved with the penal system. Consequently, this may not reflect true gender distribution.

### Comorbidity

Among individuals with kleptomania who present for treatment, there is a high incidence of comorbid mood, anxiety and eating disorders, when compared with rates in the general population. Comorbidity patterns among individuals who present for treatment may be greater than among random samples. More reliable comorbidity rates can be found in a prospective investigation of 20 individuals with kleptomania conducted by McElroy and coworkers (1991a). Lifetime DSM-III-R comorbidity rates were 40% major depressive disorder, 50% substance abuse, 40% panic disorder, 40% social phobia, 45% OCD, 30% anorexia nervosa, 60% bulimia nervosa and 40% other impulse control disorders. Dissociative symptoms, significant character pathology and trauma histories are commonly encountered among this group.

### Course

In two separate studies, the mean age at onset of kleptomania was reported to be 20 years (Goldman, 1991; McElroy *et al.*, 1991a). The subjects included individuals who had begun stealing as early as 5 to 7 years of age. The disorder appears to be chronic, lasting for decades, albeit with varying intensity. Fifteen or 16 years may elapse before treatment is sought. Onset in and beyond the fifth decade of life appears to be unusual, and in some of these cases remote histories of past kleptomania can be elicited.

At peak frequency, McElroy and colleagues (1991a) found a mean of 27 episodes a month, essentially daily stealing, with one patient reporting four acts daily. The majority of patients may eventually be apprehended for stealing once or more, and a minority may even be imprisoned; more often than not these repercussions do not result in more than a temporary remission of the behavior. Individuals with kleptomania may also have extensive histories of psychiatric treatments, including hospitalization for other conditions, most commonly depression or eating disorders. Because of the unavailability of longitudinal studies, the prognosis is not known. It appears, however, that without treatment the behavior may be likely to persist for decades, sometimes with significant associated morbidity. There may be transient periods of remission.

## Treatment

### Treatment Goals

The general goal of treatment is the eradication of kleptomaniac behavior. Treatment typically occurs in the outpatient setting, unless comorbid conditions such as severe depression, eating disturbances, or more dangerous impulsive behaviors dictate hospitalization. The interview must be conducted in a respectful climate that ensures confidentiality. Patients not only may experience considerable guilt or shame for stealing but also may be unrevealing because of the fear of legal repercussions. In the acute treatment phase, the aim is to decrease significantly or, ideally, eradicate episodes of stealing during a period of weeks to months. Concurrent conditions may compound the problem and require independently targeted treatment. The acute treatment of kleptomania has not been, to date, systematically investigated.

### Psychiatrist–Patient Relationship

As with any condition that may be associated with intense guilt or shame, kleptomania must be approached respectfully by the psychiatrist. Patients can be reassured and their negative feelings alleviated to some degree with proper initial psychoeducation. The treatment alliance can be strengthened by consistently maintaining a nonjudgmental and supportive stance. In addition, patients' fears regarding breaks of confidentiality and criminal repercussions must be addressed.

No treatments have been systematically shown to be effective for kleptomania. These treatment recommendations are supported by case reports and retrospective reviews only. In general, it appears that thymoleptic medications and behavioral therapy may be the most efficacious treatments for the short term, whereas long-term psychodynamic psychotherapy may be indicated and have good results for selected patients.

### Pharmacological and Somatic Treatments

Mixed results have been reported regarding the pharmacological treatment of kleptomania. In a literature review of 56 cases of kleptomania, McElroy and coworkers (1991b) noted that somatic treatments were described for eight patients. Significant improvement was reported for seven of these. Treatment included antidepressants alone, antidepressants combined with antipsychotics or stimulants, electroconvulsive therapy alone, or electroconvulsive therapy with antidepressants. It is still unclear whether kleptomania responds preferentially to serotonergic antidepressants, and this question awaits further study. Other agents reported to have

treated kleptomania successfully include nortriptyline and amitriptyline. In addition, it remains unclear if the antikleptomaniac effect of thymoleptics is dependent on or independent of their antidepressant effect.

A number of other medications have been employed to treat kleptomania. These include antipsychotics, stimulants, valproic acid, carbamazepine, clonazepam and lithium. Lithium augmentation may be of benefit when kleptomania does not respond to an antidepressant alone. Finally, there have been some reports of successful treatment of kleptomania with electroconvulsive therapy, which may have been administered for a concurrent mood disorder.

Although little is known about maintenance pharmacological treatment for kleptomania, there is a suggestion in the literature that symptoms tend to recur with cessation of thymoleptic treatment and again remit when treatment is reinstated.

### Psychosocial Treatments

Formal studies of psychosocial interventions for kleptomania have not been performed. However, a number of clinical reports have supported behavioral therapy for kleptomania. The available clinical literature suggests that for most patients this may be a more efficacious approach than insight-oriented psychotherapy. Different behavioral techniques have been employed with some success, including aversive conditioning, systematic desensitization, covert sensitization and behavior modification. In their review of 56 reported cases of kleptomania, McElroy and colleagues (1991a) noted that the eight patients who were treated with behavioral therapy – mostly aversive conditioning – showed significant improvement. We give here some specific examples of behavioral techniques that have been successfully employed and described. One patient was taught to hold her breath as a negative reinforcer whenever she experienced an impulse to steal. Another patient was taught to use systematic desensitization techniques to control the mounting anxiety associated with the impulse to steal. A patient treated by covert sensitization learned to associate images of nausea and vomiting with the desire to steal. A woman who experienced sexual excitement associated with shoplifting and would masturbate at the site of the act was instructed to practice masturbation at home, while fantasizing kleptomaniac acts. There is a suggestion in the literature that these techniques remain effective over the long term.

Finally, it appears that the most effective behavioral treatment of all may be complete abstinence, that is, the patient should no longer visit any of the stores or settings where kleptomaniac acts occur. A number of patients who never come to psychiatric attention apparently employ this technique successfully, and it may be an appropriate treatment goal if it does not result in excessive restrictions of activity and lifestyle.

The psychodynamic treatment of kleptomania centers on the exploration and working through of the underlying conflict or conflicts. There are case reports in the literature of successful psychodynamic treatment of kleptomania. Such treatment, possibly in combination with other approaches, may be indicated for patients for whom a clear conflictual basis for the behavior can be formulated, who also have the needed insight and motivation to undertake this type of treatment. In proposing such treatments, which may be long term, the psychiatrist should consider whether there are immediate risks that must be addressed, such as a high risk of legal consequences.

## Special Treatment Considerations

Little is known about treating kleptomania and therefore special treatment considerations have not been elucidated. However, it is clear that comorbid conditions, such as depression, bulimia nervosa, OCD, or substance abuse, must be addressed along with the kleptomania. In addition to the inherent suffering and morbidity of these other disorders, their course and severity could compound the kleptomaniac behavior. In the rare cases of a precipitating or exacerbating organic etiology, the underlying organic cause must be treated. In addition, the treatment of particular groups such as children or the elderly should take into account special contributing life stage or situational factors. The involvement of family or others on whom the patient is dependent may be indicated.

## Pyromania and Fire-setting Behavior

### Definition

The primary characteristics of pyromania are recurrent, deliberate fire-setting, the experience of tension or affective arousal before the fire-setting, an attraction or fascination with fire and its contexts, and a feeling of gratification or relief associated with the setting of a fire or its aftermath.

True pyromania is present in only a small subset of fire-setters. Multiple motivations are cited as causes for fire-setting behavior. These include arson for profit, crime concealment, revenge, vandalism and political expression. In addition, fire-setting may be associated with other psychiatric diagnoses. But true pyromania is rare.

Fire-setting behavior may be a focus of clinical attention, even when criteria for pyromania are not present. Because the large majority of fire-setting events are not associated with true pyromania, this section also addresses fire-setting behavior in general.

### Fire-setting as a Planned, Nonimpulsive Behavior

The following motivations have been suggested for intentional arson: financial reward, to conceal another crime, for political purposes, as a means of revenge, as a symptom of other (nonpyromania) psychiatric conditions (e.g., in response to a delusional belief), as attention-seeking behavior, as a means of deriving sexual satisfaction, and as an act of curiosity when committed by children. Revenge and anger appear to be the most common motivations for fire-setting.

### Etiology and Pathophysiology

Arson has been the subject of several investigations of altered neuroamine function. These findings include the observation that platelet monoamine oxidase is negatively correlated with fire-setting behavior of adults who had been diagnosed with attention-deficit disorder in childhood. Investigation of the function of serotonergic neurotransmission in individuals with aggressive and violent behaviors has included studies of CSF concentrations of 5-HIAA in individuals with a history of fire-setting. 5-HIAA is the primary metabolite of serotonin, and its concentration in the CSF is a valid marker of serotonin function in the brain. Virkkunen and colleagues (1994) demonstrated that impulsive fire-setting was associated with low CSF concentrations of 5-HIAA. This finding was consistent with other observations associating impulsive behaviors with low CSF 5-HIAA levels (such as impulsive violence and impulsive suicidal behavior). A history of suicide attempt strongly predicts recidivism of arson.

## DSM-IV-TR Criteria 312.33

### Pyromania

- A. Deliberate and purposeful fire-setting on more than one occasion.
- B. Tension or affective arousal before the act.
- C. Fascination with, interest in, curiosity about, or attraction to fire and its situational contexts (e.g., paraphernalia, uses, consequences).
- D. Pleasure, gratification, or relief when setting fires, or when witnessing or participating in their aftermath.
- E. The fire-setting is not done for monetary gain, as an expression of sociopathical ideology, to conceal criminal activity, to express anger or vengeance, to improve one's living circumstances, in response to a delusion or hallucination, or as a result of impaired judgment (e.g., in dementia, mental retardation, substance intoxication).
- F. The fire-setting is not better accounted for by conduct disorder, a manic episode, or antisocial personality disorder.

## Assessment and Differential Diagnosis

### Presentation

The diagnosis of pyromania emphasizes the affective arousal, thrill, or tension preceding the act, as well as the feeling of tension relief or pleasure in witnessing the outcome. This is useful in distinguishing between pyromania and fire-setting elicited by other motives (i.e., financial gain, concealment of other crimes, political, arson related to other mental illness, revenge, attention seeking, erotic pleasure, part of conduct disorder).

The onset of pyromania has been reported to occur as early as age 3 years, but the condition may initially present in adulthood. Because of the legal implications of fire-setting, individuals may not admit previous events, which may result in biased perceptions of the common age at onset. Men greatly outnumber women with the disorder. In children and adolescents, the most common elements are excitation caused by fires, enjoyment produced by fires, relief of frustration by fire-setting and expression of anger through fire-setting.

Fire-setting behavior may be common among more impaired psychiatric patients. In a study of 191 nongeriatric patients in a psychiatric hospital who were admitted for other reasons, 26 had some form of fire-setting behavior (including threats). Of these, 70% had actually set fires. None had a diagnosis of true pyromania (Soltys, 1992).

### The Psychiatric Interview

The interviewer must bear in mind that the circumstances of arson, whatever the motive, may pose legal and criminal problems for the individual. This may provide motivation to skew the reporting of events. Individuals who may be at risk for the legal consequences of fire-setting may be motivated to represent themselves as victims of psychiatric illness, hoping that a presumed

psychiatric basis of the behavior may attenuate legal penalties. Therefore, the interviewer must maintain a guarded view of the information presented.

## Epidemiology and Comorbidity

### Prevalence and Incidence

No data are available on the prevalence or incidence of pyromania, but it is apparently uncommon. Although pyromania is a rare event, fire-setting behavior is common in the histories of psychiatric patients. Among children with psychiatric conditions, fire-setting behavior is apparently quite common.

### Comorbidity

Limited data are available regarding individuals with pyromania. Reported data of comorbid diagnoses are generally derived from forensic samples and do not distinguish between criminally motivated fire-setters and compulsive fire-setters. Fire-setting behavior may be associated with other mental conditions. These include mental retardation, conduct disorder, alcohol and other substance use disorders, personality disorders and schizophrenia.

### Course

There are no data regarding the course of and prognosis for pyromania. However, the impulsive nature of the disorder suggests a repetitive pattern. Again, because legal consequences may occur, the individual may be motivated to represent the index episode as a unique event. Fire-setting for nonpsychiatric reasons may be more likely to be a single event.

## Treatment

### Treatment Goals

Because of the danger inherent in fire-setting behavior, the primary goal is elimination of the behavior. The treatment literature does not distinguish between pyromania and fire-setting behavior of other causes. Much of the literature is focused on controlling fire-setting behavior in children and adolescents.

### Psychiatrist–Patient Relationship

Because of the potential legal risks for individuals who acknowledge fire-setting behavior, the psychiatrist must take particular pains to ensure an environment of empathy and confidentiality. A corollary concern involves obligations that may be incumbent on the psychiatrist. Because of the legal implications of these behaviors and the potential for harm to another individual should fire-setting recur, the psychiatrist should be careful to consider both the ethical and the legal constraints that may follow from information learned in the course of treatment.

### Pharmacotherapy and Psychosocial Treatments

There are no reports of pharmacological treatment of pyromania. It has been estimated that up to 60% of childhood fire-setting is motivated by curiosity. Such behavior often responds to direct educational efforts. In children and adolescents, focus on interpersonal problems in the family and clarification of events preceding the behavior may help to control the behavior. The treatments described for fire-setting are largely behavioral or focused on intervening in family or intrapersonal stresses that may precipitate episode of fire-setting.

One technique combines overcorrection, satiation and negative practice with corrective consequences. The child is su-

pervised in constructing a controlled, small fire in a safe location. The fire is then extinguished by the child. Throughout the process, the parent verbally instructs the child in safety techniques.

The graphing technique has been used as the basis of several intervention programs with fire-setters. The psychiatrist and the patient agree on a goal of stopping the fire-setting behavior. The psychiatrist and the patient construct a graph that details the events, feelings and behaviors associated with fire-setting episodes. These factors are described on a chronological line graph. The graph is utilized to help the patient see the cause-and-effect relationships between personal events, feelings and subsequent behaviors. The specific intent is to educate patients so that they are able to identify the events that put them at risk for fire-setting. Then patients are equipped to label the feelings as a signal that may allow them to use alternative modes for discharging their feelings. This technique may help the individual curtail other maladaptive behaviors as well. Follow-up reports suggest that individuals who have successfully completed a graphing intervention may be at substantially lower risk for future fire-setting.

Relaxation training may be used (or added to graphing techniques) to assist in the development of alternative modes of dealing with the stress that may precede fire-setting. Principles of cognitive-behavioral therapy have been recently applied to childhood fire-setting.

## Pathological Gambling

### Definition

Gambling as a behavior is common. Current estimates suggest that approximately 80% of the adult population in the US gamble. The amount of money wagered legally in the USA grew from \$17 billion in 1974 to \$210 billion in 1988, an increase of more than 1200%, making gambling the fastest growing industry in America. DSM-IV-TR covertly recognized the ubiquity of gambling behavior and the desire to gamble by the careful wording of criterion A for pathological gambling: “Persistent and recurrent maladaptive gambling behavior as indicated by five (or more) of the following”. This definition of pathological gambling differs from some other definitions of impulse control disorders not elsewhere classified, which are worded as “Failure to resist an impulse to”. This difference implies that neither gambling behavior nor failure to resist an impulse to engage in it is viewed as pathological in and of itself. Rather, the maladaptive nature of the gambling behavior is the essential feature of pathological gambling and defines it as a disorder.

### Etiology and Pathophysiology

Pathological gambling has been included as a disorder of impulse control. Pathological gambling can also be viewed as an addictive disorder, an affective spectrum disorder and an obsessive-compulsive spectrum disorder. DSM-IV-TR maintains a close relationship between pathological gambling and addictive disorders in that several of the diagnostic criteria for pathological gambling were intentionally made to resemble criteria for substance dependence.

The parallels between pathological gambling and addictive disorders are manifold. Pathological gambling has been viewed as the “pure” addiction, because it involves several aspects of addictive behavior without the use of a chemical substance. The parallels between substance dependence, in particular alcohol dependence and pathological gambling have led to the successful

**DSM-IV-TR Criteria** 312.31**Pathological Gambling**

A. Persistent and recurrent maladaptive gambling behavior as indicated by five (or more) of the following:

- (1) is preoccupied with gambling (e.g., preoccupied with reliving past gambling experiences, handicapping or planning the next venture, or thinking of ways to get money with which to gamble)
- (2) needs to gamble with increasing amounts of money in order to achieve the desired excitement
- (3) has repeated unsuccessful efforts to control, cut back, or stop gambling
- (4) is restless or irritable when attempting to cut down or stop gambling
- (5) gambles as a way of escaping from problems or of relieving a dysphoric mood (e.g., feelings of helplessness, guilt, anxiety, depression)
- (6) after losing money gambling, often returns another day to get even (“chasing” one’s losses)
- (7) lies to family members, therapist, or others to conceal the extent of involvement with gambling
- (8) has committed illegal acts such as forgery, fraud, theft, or embezzlement to finance gambling
- (9) has jeopardized or lost a significant relationship, job, or educational or career opportunity because of gambling
- (10) relies on others to provide money to relieve a desperate financial situation caused by gambling

B. The gambling behavior is not better accounted for by a manic episode.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

adoption of the self-help group model of Alcoholics Anonymous to Gamblers Anonymous. Patterns of comorbidity also suggest a possible link between pathological gambling and addictions, in particular alcoholism. In addition to the comorbidity of pathological gambling and substance use disorders, family studies have demonstrated a familial clustering of alcoholism and pathological gambling. As high as 50% of patients with pathological gambling have a parent with alcoholism and a family history of substance dependence in patients with pathological gambling. There is also a greater prevalence of pathological gambling in parents of patients with pathological gambling.

The links between pathological gambling and affective disorders are also supported by family studies that demonstrate high rates of affective disorders in first-degree relatives of patients with pathological gambling as well as by high rates of comorbidity of pathological gambling and affective disorders. In addition, as noted by many authors and incorporated in the DSM-IV-TR criteria for pathological gambling, many patients with pathological gambling gamble as a way of relieving dysphoric moods

(criterion A5), and cessation of gambling may be associated with depressive episodes in the majority of recovering gamblers.

The links between pathological gambling and obsessive spectrum disorders are less clear. Although a popular name for pathological gambling is compulsive gambling, the vast majority of patients with pathological gambling do not experience the urge to gamble as egodystonic until late in the course of their illness, after they have suffered some of its consequences. The rates of comorbidity of pathological gambling and OCD and obsessive-compulsive personality disorder are not nearly as high as the rates of comorbidity of pathological gambling and affective and addictive disorders. Nevertheless, pathological gambling shares several characteristics with compulsions: it is repetitive, often has ritualized aspects, and is meant to relieve or reduce distress. Moreover, sporadic reports on the effectiveness of SSRIs in the treatment of pathological gambling suggest a possible link to obsessive spectrum disorders (Hollander *et al.*, 1992).

### Neurotransmitter Function in Pathological Gambling

The association between altered function of the serotonin neurotransmitter system and impulsive behaviors has focused attention on a potential role for serotonin function in the neurophysiology of pathological gambling. Several studies have provided data supporting such a link. However, direct measure of cerebrospinal fluid 5-HIAA in pathological gamblers has yielded mixed results. Preliminary data supports potential utility of serotonin reuptake inhibitor medications in the treatment of pathological gambling.

### Genetic Contribution

The incidence of pathological gambling among first degree family members of pathological gamblers appears to be approximately 20%. Inherited factors may explain 62% of variance in the diagnosis and some of these genetic factors may also contribute to the risk for conduct disorder, antisocial personality disorder and alcohol abuse (Eisen *et al.*, 2001). At this time, early molecular genetics studies of pathological gamblers point to possible associated polymorphisms in genes that code for both serotonergic and dopaminergic factors (Ibanez *et al.*, 2002).

### Psychodynamic Considerations

Psychoanalytic theories of gambling were the first systematic attempts to account for pathological gambling. Erotization of the fear, tension and aggression involved in gambling behavior, as well as themes of grandiosity and exhibitionism, were explored by several authors during the first quarter of the 20th century. Freud (1961), in his influential essay on Dostoyevsky, suggested that the pathological gambler actually gambled to lose, not to win, and traced the roots of the disorder to the ambivalence felt by the young man toward his father. The father, the object of his love, is not only loved but also hated, and this results in unconscious guilt. The gambler then loses to punish himself, in what Freud labeled “moral masochism”. Freud also spoke of “feminine masochism” in which losing is a way of gaining love from the father, who will somehow reward the loser for loyalty. To lose is to suffer, and for the feminine masochist, suffering equals love. Interestingly, in the later spirit of DSM-IV-TR, Freud also conceptualized pathological gambling as an addiction and included it in a triad with alcoholism and drug dependence. He saw all three as manifestations of that primary addiction, masturbation, or at least masturbatory fantasies. Like most researchers after him, Freud focused only on male gamblers.

Bergler, a psychoanalyst who actually treated many patients with pathological gambling, expanded on Freud's idea that the pathological gambler gambles to lose. He traced the roots of this desire to lose to the rebellion of gamblers against the authority of their parents and against the parents' intrusive introduction of the reality principle into their lives. The rebellion causes guilt, and the guilt creates the need for self-punishment. Bergler thought that the gambler's characteristic aggression is actually pseudoaggression, a craving for defeat and rejection. He saw the gambler as one who perpetuates an adversarial relationship with the world. The dealer in the casino, the gambler's opponents at the card table, the stock exchange and the roulette wheel are all unconsciously identified with the refusing mother or the rejecting father. Overall, psychoanalytic approaches to pathological gambling (Lesieur and Rosenthal, 1991) generally conceptualized it as either a compulsive neurosis (Freud, Bergler, Rosenthal) or an impulse disorder. Several published case reports documented the successful treatment of pathological gambling by psychoanalysis.

Learning theories of pathological gambling focus on the learned and conditioned aspects of gambling and use the quantifiable nature of the behavior to test specific hypotheses. One hypothesis was that patients with pathological gambling crave the excitement and tension associated with their gambling, as evidenced by the fact that they are much more likely to place last-second wagers than are low-frequency gamblers, to prolong their excitement. Higher wagers placed by patients with pathological gambling also produce greater excitement, and greater amounts of money are required to achieve the same "buzz" over time, an observation incorporated in the diagnostic criteria for pathological gambling (criterion A2).

### Assessment and Differential Diagnosis

It is not difficult to diagnose pathological gambling once one has the facts. It is much more of a challenge to elicit the facts, because the vast majority of patients with pathological gambling view their gambling behavior and gambling impulses as egosyntonic and may often lie about the extent of their gambling (criterion A7). Patients with pathological gambling may first seek medical or psychological attention because of comorbid disorders. Given the high prevalence of addictive disorders in pathological gambling and the increased prevalence of pathological gambling in those with alcoholism and other substance abuse, an investigation of gambling patterns and their consequences is warranted for any patient who presents with a substance abuse problem. Likewise, the high rates of comorbidity with mood disorders suggest the utility of investigating gambling patterns of patients presenting with an affective episode.

The spouses and significant others of patients with pathological gambling deserve special attention. Individuals with pathological gambling usually feel entitled to their behavior and often rely on their families to bail them out (criterion A10). As a consequence, it is often the spouse of the patient with pathological gambling who first realizes the need for treatment and who bears the consequences of the disorder. Lorenz (1981) conducted a survey of 103 wives of pathological gamblers who attended Gam-Anon meetings (for family members of patients with pathological gambling). She found that most spouses had to borrow money and were harassed or threatened by bill collectors. Most spouses physically assaulted the gambler, verbally abused their children, and experienced murderous or destructive impulses toward the gambler. Although the gamblers themselves

appeared less violent than the general population norms, their spouses were more violent, possibly because of desperation and anger. Eleven percent of the spouses of patients with pathological gambling admitted to having attempted suicide, and this result was replicated in a later study. These findings have two main implications for the assessment of pathological gambling: first, the spouse may be a valuable and motivated informant who should be questioned about the patient's behavior, and secondly, spouses should be specifically asked about the effects of the patient's illness on their own well-being and functioning and about suicidal ideation and attempts and the control of their own impulsivity.

An important and understudied area is the clinical presentation of pathological gambling in women. Women constitute a third of all patients with pathological gambling in epidemiological studies. However, they are extremely underrepresented in treatment populations, and most psychoanalytic theories of pathological gambling ignore them completely. Part of this bias may be due to the fact that gambling carries a greater social stigma for women, that women gamblers are more likely to live and to gamble alone, and that treatment programs for pathological gambling in the USA were first pioneered in Veterans Hospitals. Compared with men with pathological gambling, women with pathological gambling are more likely to be depressed and to gamble as an escape rather than because of a craving for action and excitement. Pathological gambling begins at a later age in female than in male gamblers, often after adult roles have been established. Big winning is usually less important than the need to impress. Women typically play less competitive forms of gambling in which luck is more important than skill, and they play alone. Their progression into the disorder is often more rapid, and the time between the onset of the disorder and the time they present for treatment is usually much shorter than for men (3 years compared with 20 years). The shorter duration makes for a better prognosis in treatment, but, unfortunately, few of the women with pathological gambling ever come to treatment.

The differential diagnosis of pathological gambling is relatively simple. Pathological gambling should be differentiated from professional gambling, social gambling and a manic episode. Social gambling, engaged in by the vast majority of adult Americans, typically occurs with friends or colleagues, lasts for a specified time, and is limited by predetermined acceptable losses. Professional gambling is practiced by highly skilled and disciplined individuals and involves carefully limited risks. Many individuals with pathological gambling may feel that they are actually professional gamblers. Chasing behavior and unplanned losses distinguish the pathological gamblers. Patients in a manic episode may exhibit a loss of judgment and excessive gambling resulting in financial disasters. A diagnosis of pathological gambling should be given only if a history of maladaptive gambling behavior exists at times other than during a manic episode. Problems with gambling may also occur in individuals with antisocial personality disorder. If criteria are met for both disorders, both can be diagnosed.

### Epidemiology and Comorbidity

#### Prevalence and Incidence

Pathological gambling is considered to be the most common of the impulse control disorders not elsewhere classified. The number of people whose gambling behavior meets criteria for pathological gambling in the USA is estimated to be between 2 million and 6 million. Surveys conducted between 1986 and 1990 in Maryland,

Massachusetts, New York, New Jersey and California estimated the prevalence of “probable pathological gamblers” among the adult population to be between 1.2 and 2.3%. These states have a broad range of legal wagering opportunities and a heterogeneous population. Similar surveys in Minnesota and Iowa, states with limited legal wagering opportunities and more homogeneous populations, yielded prevalence rates of 0.9 and 0.1%, respectively. It thus appears that availability of gambling opportunities as well as demographic make-up may influence the prevalence of pathological gambling. The combined total of “pathological gamblers” and “problem gamblers” is 5.5 million adult Americans. During the past 20 years, many states have turned to lotteries as a way of increasing their revenues without increasing taxes. At this time, some form of gambling is legal in 47 of the 50 states, as well as in more than 90 countries worldwide. From 1975 to 1999 revenues from legal gambling in the USA has risen from \$3 to 58 billion. (Given the dramatic increase in the amounts of money wagered in legal gambling activities during the past 20 years, the prevalence and incidence of pathological gambling are expected to increase.)

It is estimated that women make-up to one-third of all Americans with pathological gambling. Nevertheless, they are underrepresented in Gamblers Anonymous, in which only 2 to 4% of the members are women. The reason for this discrepancy was postulated to be the greater social stigma attached to pathological gambling in women and the characteristic pattern of solitary gambling in women. Nonwhites and those with less than a high school education are more highly represented among pathological gamblers than in the general population. The demographic make-up of patients in treatment for pathological gambling differs substantially from the demographics of all patients with pathological gambling. Jewish persons are overrepresented in treatment settings and in Gamblers Anonymous, whereas women, minorities and those younger than age 30 years are underrepresented in Gamblers Anonymous and in treatment.

### Comorbidity

Overall, patients with pathological gambling have high rates of comorbidity with several other psychiatric disorders and conditions. Individuals presenting for clinical treatment of pathological gambling apparently have impressive rates of comorbidity. Ibanez and coworkers (2001) reported 62.3% of one group seeking treatment had a comorbid psychiatric disorder. The most frequent diagnosis they found were personality disorders (42%), alcohol abuse or dependence (33.3%) and adjustment disorders (17.4%).

### Mood Disorders

There is evidence for extensive comorbidity of pathological gambling with major depressive disorder and with bipolar disorder. In several surveys, between 70 and 80% of all patients with pathological gambling also had mood symptoms that met criteria for a major depressive episode, a manic episode, or a hypomanic episode at some point in their life. More than 50% had recurrent major depressive episodes. A complicating factor is that recovering pathological gamblers may experience depressive episodes after cessation of gambling. In addition, some patients with pathological gambling may gamble to relieve feelings of depression (criterion A5). Despite criterion B for pathological gambling, which essentially precludes the diagnosis of pathological gambling if the behavior occurs exclusively during the course of a manic episode, many patients have a disturbance that meets criteria for both disorders because they gamble both during and

between manic and hypomanic episodes. Between 32 and 46% of patients with pathological gambling were reported also to have mood symptoms that meet criteria for bipolar disorder, bipolar II disorder, or cyclothymic disorder.

### Suicide

Although data is not yet conclusive, a meaningful association between problem gambling and suicidal behavior and/or ideation appears to exist. Between 12 and 24% of patients with pathological gambling in various settings have had a history of at least one suicide attempt. In one study, 80% of patients with pathological gambling had a history of either suicide attempts or suicidal ideation (Lesieur and Rosenthal, 1991).

### Substance Abuse and Dependence

Studies of prevalence of comorbid substance use disorders yield widely varying results; from 9.9% for alcohol and other substance dependence to 44% for alcohol dependence and 40% for illicit drug dependence. Using a structured instrument, between 5 and 25% of substance-abusing patients in several settings were found to meet criteria for pathological gambling and an additional 10 to 15% were considered to have “gambling problems” (Lesieur and Rosenthal, 1991). Among individuals with pathological gambling, individuals with higher socioeconomic status (SES) are more likely to have concurrent problems with alcohol abuse than are gamblers with lower SES.

### Other Disorders

Again, current data are inconclusive, but OCD, panic disorder, generalized anxiety disorder and eating disorders have all been reported present in higher rates in patients with pathological gambling than in the general population. The reported prevalence of OCD among pathological gamblers ranges from 0.9 to 16%. Narcissistic and antisocial personality disorders are believed to be overrepresented in patients with pathological gambling, and pathological narcissism is assumed by some psychoanalysts to underlie the entitlement displayed by many patients with pathological gambling. In addition, retrospective studies suggest that many patients with pathological gambling may have had symptoms that met criteria for attention-deficit/hyperactivity disorder as children. In addition to psychiatric disorders, patients with pathological gambling may manifest greater prevalences of stress-related medical conditions, like peptic ulcer disease, hypertension and migraine.

### Course

Pathological gambling usually begins in adolescence in men and later in life in women. The onset is usually insidious, although some individuals may be “hooked” by their first bet. There may be years of social gambling with minimal or no impairment followed by an abrupt onset of pathological gambling that may be precipitated by greater exposure to gambling or by a psychosocial stressor. The gambling pattern may be regular or episodic, and the course of the disorder tends to be chronic. Over time, there is usually a progression in the frequency of gambling, the amounts wagered, and the preoccupation with gambling and with obtaining money with which to gamble. The urge to gamble and gambling activity generally increase during periods of stress or depression, as an attempted escape or relief (criterion A5). Rosenthal (1992) described four typical phases in the course of a typical male patient with pathological gambling: winning, losing, desperation and hopelessness.

## Typical Phases

**Winning** Many male gamblers become involved with gambling because they are good at it and receive recognition for their early successes. Women with pathological gambling are less likely to have a winning phase. Traits that foster a winning phase and are typical of male patients with pathological gambling are competitiveness, high energy, ability with numbers and interest in the strategy of games. The early winnings lead to a state in which a large proportion of the gambler's self-esteem derives from gambling, with accompanying fantasies of winning and spectacular success.

**Losing** A string of bad luck or a feeling that losing is intolerable may be the precipitant of chasing behavior; previous gambling strategies are abandoned as the gambler attempts to win back everything all at once. The gambler experiences a state of urgency, and bets become more frequent and heavy. Debts accumulate, and only the most essential are paid. Covering up and lying about gambling become more frequent. As this is discovered, relationships with family members deteriorate. Losing gamblers use their own and their family's money, go through savings, take out loans and finally exhaust all legitimate sources. Eventually, they cannot borrow any more, and faced with threats from creditors or loss of a job or marriage, they go to their family and finally confess. This results in the "bailout": debts are paid in return for a promise to stop or cut down gambling. Any remission, if achieved at all, is short-lived. After the bailout there is an upsurge of omnipotence; the gambler believes that it is possible to get away with anything, bets more heavily and loses control altogether.

**Desperation** This stage is reached when the gambler begins to do things that would previously be inconceivable: writing bad checks, stealing from an employer, or other illegal activities. Done once, these behaviors are much more likely to be repeated. The behavior is rationalized as a short-term loan with an intention to pay it back as soon as the winning streak arrives. The gambler feels just one step away from winning and solving all the problems. Attention is increasingly taken up with illegal loans and various scams to make money. The gambler becomes irritable and quick tempered. When reminded of responsibilities or put in touch with guilt feelings, the gambler responds with anger and projective blame. Appetite and sleep deteriorate and life holds little pleasure. A common fantasy at this stage is of starting life over with a new name and identity, the ultimate "clean slate".

**Hopelessness** For some gamblers, there is a fourth stage in which they suddenly realize that they can never get even, but they no longer care. This is often a revelation, and the precise moment when it occurred is often remembered. From this point on, just playing is all that matters. Gamblers often acknowledge knowing in advance that they will lose and play sloppily so that they lose even if they have the right horse or a winning hand. They seek action or excitement for its own sake and gamble to the point of exhaustion.

Few gamblers seek help in the winning phase. Most seek help only during the later phases and only after a friend, family member, or employer has intervened. Two-thirds of the gamblers have committed illegal activities by then, and the risk of suicide increases as the gambler progresses through the phases of the illness.

## Prognosis

Without treatment, the prognosis of pathological gambling is poor. It tends to run a chronic course with increasing morbidity and comorbidity, gradual disruption of family and work roles and relationships, depletion of financial reserves, entanglement with criminals and the criminal justice system and, often, suicide attempts. In the hands of an experienced psychiatrist, it is an "extremely treatable disorder" with a favorable prognosis (Rosenthal, 1992). The difference between a poor and a good prognosis depends on treatment, and treatment depends on a diagnosis. As noted earlier, the diagnosis of pathological gambling is often missed in clinical settings because mental health professionals do not think to ask about it. Because most patients with pathological gambling do not see themselves as having a disorder and many of them do not even consider themselves as having a problem with gambling, collateral information from a family member may be extremely helpful.

## Treatment

### Overall Goals of Treatment

The goals of treatment of an individual with pathological gambling are the achievement of abstinence from gambling, rehabilitation of the damaged family and work roles and relationships, treatment of comorbid disorders and relapse prevention. This approach echoes the goals of treatment of an individual with substance dependence. Inpatient treatment in specialized programs may be considered if the gambler is unable to stop gambling, lacks significant family or peer support, or is suicidal, acutely depressed, multiply addicted, or contemplating some dangerous activity.

No standard treatment of pathological gambling has emerged. Despite many reports of behavioral and cognitive interventions for pathological gambling, there are minimal data available from well-designed or clearly detailed treatment studies. Pharmacologic treatments offer promise, but research-guided approaches are still insufficient to offer a standardized approach. Therefore, general approaches, based in clinical experience and available resources (such as Gamblers Anonymous or other support groups) should be considered.

The treatment of pathological gambling may consist of participation in Gamblers Anonymous, individual therapy, family therapy, treatment of comorbid disorders and medication treatment. As is the case for substance dependence, the gambler needs to be abstinent to be accessible to any or all of these treatment modalities. For many gamblers, participation in Gamblers Anonymous is sufficient, and it is an essential part of most treatment plans. Gamblers Anonymous is a 12-step group built on the same principles as Alcoholics Anonymous. It utilizes empathic confrontation by peers who struggle with the same impulses and a group approach. Gam-Anon is a peer support group for family members of patients with pathological gambling. Extensive data are lacking, but overall Gamblers Anonymous appears somewhat less effective than Alcoholics Anonymous in achieving and maintaining abstinence.

Individual therapy is often useful as an adjunct to Gamblers Anonymous. Rosenthal (1992) stressed that to maintain abstinence and use Gamblers Anonymous successfully, many gamblers need to understand why they gamble. Therapy involves confronting and teasing out the vicissitudes of the patient's sense of omnipotence and dealing with the various self-deceptions,

the defensive aspects of the patient's lying, boundary issues, and problems involving magical thinking and reality. Relapse prevention involves knowledge and avoidance of specific triggers. In addition to psychodynamic therapy, behavioral treatment of pathological gambling has been proposed, with imagined desensitization achieving better rates of remission than aversive conditioning.

The greatest differences between the treatment of pathological gambling and other addictions are in the area of family therapy. Because relapse may be difficult to detect (there is no substance to be smelled on the patient's breath, no dilated or constricted pupils, no slurred speech or staggered gait) and because of a long history of exploitative behavior by the patient, the spouse and other family members tend to be more suspicious of, and angry at, the patient with pathological gambling compared with families of alcoholic patients. Frequent family sessions are often essential to offer the gambler an opportunity to make amends, learn communication skills and deal with preexisting intimacy problems. In addition, the spouse and other family members have often acquired their own psychiatric illnesses during the course of the patient's pathological gambling and need individualized treatment to recover.

### Medication

Although research reports of the pharmacological treatment of pathological gambling have begun to emerge, there are still, as yet, insufficient data to come to any conclusions about the utility of medication. Small trials have reported on the use of SSRIs, mood stabilizers and naltrexone with the recommendation of dosing at the high end of usual treatment ranges.

## Trichotillomania

### Definition

The essential feature of trichotillomania is the recurrent failure to resist impulses to pull out one's own hair. Resulting hair loss may range in severity from mild (hair loss may be negligible) to severe (complete baldness and involving multiple sites on the scalp or body). Individuals with this condition do not want to engage in the behavior, but attempts to resist the urge result in great tension. Thus, hair-pulling is motivated by a desire to reduce this dysphoric state. In some cases, the hair-pulling results in a pleasurable sensation, in addition to the relief of tension. Tension may precede the act or may occur when attempting to stop. Distress over the symptom and the resultant hair loss may be severe.

### Etiology and Pathophysiology

The etiology of trichotillomania is unknown. The phenomenological similarities between trichotillomania and OCD have prompted speculations that the pathophysiology of the two conditions may be related. The apparent association between altered serotonergic function and OCD has guided attention toward the possible role of serotonergic function in the underlying cause of trichotillomania. Thus, interest has been spurred in examining serotonergic function in patients with trichotillomania. As yet, however, only limited laboratory investigations have emerged.

In summary, few data are available to support any particular model of the etiological pathophysiology of trichotillomania. Early studies point to some alteration of brain activity. Inconsistent support has been found in these early explorations for a relationship with OCD.

## DSM-IV-TR Criteria 312.39

### Trichotillomania

- A. Recurrent pulling out of one's hair resulting in noticeable hair loss.
- B. An increasing sense of tension immediately before pulling out the hair or when attempting to resist the behavior.
- C. Pleasure, gratification, or relief when pulling out the hair.
- D. The disturbance is not better accounted for by another mental disorder and is not due to a general medical condition (e.g., a dermatological condition).
- E. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

## Assessment and Differential Diagnosis

### Presentation

Typically, the person complaining of unwanted hair-pulling is a young adult or the parent of a child who has been seen pulling out hair. Hair-pulling tends to occur in small bursts that may last minutes to hours. Such episodes may occur once or many times each day. Hairs are pulled out individually and may be pulled out rapidly and indiscriminately. Often, however, the hand of the individual may roam the afflicted area of scalp or body, searching for a shaft of hair that may feel particularly coarse or thick. Satisfaction with having pulled out a complete hair (shaft and root) is frequently expressed. Occasionally the experience of hair-pulling is described as quite pleasurable. Some individuals experience an itch-like sensation in the scalp that is eased by the act of pulling. The person may then toss away the hair shaft or inspect it. A substantial number of people then chew or consume (trichophagia) the hair. Hair-pulling is most commonly limited to the eyebrows and eyelashes. The scalp is the next most frequently afflicted site. However, hairs in any location of the body may be the focus of hair-pulling urges, including facial, axillary, chest, pubic and even perineal hairs.

Anxiety is almost always associated with the act of hair-pulling. Such anxiety may occur in advance of the hair-pulling behavior. A state of tension may occur spontaneously, driving the person to pull out hair in an attempt to reduce dysphoric feelings. Varying lengths of time must pass before the tension abates. Consequently, the amount of hair that may be extracted in an episode varies from episode to episode and from person to person. Frequently, hair-pulling begins automatically and without conscious awareness. In such circumstances, individuals discover themselves pulling out hairs after some have already been pulled out. In these situations, dysphoric tension is associated with the attempt to stop the behavior.

Circumstances that seem to predispose to episodes of hair-pulling include both states of stress and, paradoxically, moments of particular relaxation. Frequently hair-pulling occurs

when at-risk individuals are engaged in a relaxing activity that promotes distraction and ease (e.g., watching television, reading, talking on the phone). It is common for hair-pullers to report that the behavior does not occur in the presence of other people. A frequent exception may be that many pull hair in the presence of members of the nuclear family.

Some individuals have urges to pull hairs from other people and may sometimes try to find opportunities to do so surreptitiously (such as initiating bouts of play fighting). There have been reports of affected individuals pulling hairs from pets, dolls, and other fibrous materials, such as sweaters or carpets.

The distress that usually accompanies trichotillomania varies in severity. Concerns tend to focus on the social and vocational consequences of the behavior. Themes of worry include fear of exposure, a feeling that “something is wrong with me”, anxiety about intimate relationships and sometimes inability to pursue a vocation. Because certain kinds of work, such as reading and writing at a desk, seem to precipitate episodes of hair-pulling, some afflicted individuals make career choices based on the avoidance of desk work. Leisure activities that may involve a risk of exposure (ranging from gymnastics class to sexual intimacy) may be avoided.

Patterns of hair-pulling behavior among children are less well described. Usually, the parent observes a child pulling out hair and may note patches of hair loss. Children may sometimes be unaware of the behavior or may, at times, deny it. Childhood trichotillomania has been reported to be frequently associated with thumb-sucking or nail-biting. It has been suggested that trichotillomania with onset in early childhood may occur frequently with spontaneous remissions. Consequently, some have recommended that trichotillomania in early childhood may be considered a benign habit with a self-limited course. However, many individuals who present with chronic trichotillomania in adulthood report onset in early childhood.

### Assessment

In general, the diagnosis of trichotillomania is not complicated. The essential symptom – recurrently pulling out hair in response to unwanted urges – is easily described by the patient. When the patient acknowledges the hair-pulling behavior and areas of patchy hair loss are evident, the diagnosis is not usually in doubt. Problems in diagnosis may arise when the diagnosis is suspected but the patient denies it. Such denial may occur in younger individuals and some adults. When the problem is suspected but denied by the patient, a skin biopsy from the affected area may aid in making the diagnosis.

### The Psychiatric Interview

The psychiatrist should carefully inquire into the nature of the distress and concerns that may be present in a person with this problem. Although the cosmetic impact may appear slight, distress may be severe. Concerns about disclosure, anticipation of social rejection and concerns about limitations in career choices are frequent and may result in chronic dysphoria. The psychiatrist should be aware of the embarrassment that may accompany inspection of the hair loss, particularly when located in regions of the body that are not usually accessible in the course of a standard psychiatric examination. Because of the apparent frequency of comorbid mood disorders (past or current), the interviewer should pay special attention to the presence of these features.

### Physical Examination and Laboratory Findings

Areas of hair loss can be marked by complete alopecia or can appear diffusely thinned or “ratty”. Altered scalp appearance can range from small areas of thinned hair to complete baldness. For unclear reasons, several patterns of scalp loss are typical. Frequently, coin-sized areas of alopecia are noted at the vertex or at temporal or occipital regions. Among more severely afflicted people a peculiar pattern, so-called tonsure trichotillomania, may appear: a completely bald head except for a narrow, circular fringe circumscribing the outer boundary of the scalp, producing a look reminiscent of medieval friars.

Despite the hair loss, most individuals with this condition have no overtly unusual appearance on cursory inspection. If the hair loss is not covered by clothing or accessories, artful combing of hair or use of eyeliner and false eyelashes may easily hide it. The ease with which the condition may often be hidden may explain the general underappreciation of its apparent frequency and potential associated distress.

### Associated Laboratory Findings

Histological findings are considered characteristic and may aid diagnosis when it is suspected despite denial by the individual. Biopsy samples from involved areas may have the following features. Short and broken hairs are present. The surface of the scalp usually shows no evidence of excoriation. On histological examination, normal and damaged follicles are found in the same area, as well as an increased number of catagen (i.e., nongrowing) hairs. Inflammation is usually minimal or absent. Some hair follicles may show signs of trauma (wrinkling of the outer root sheath). Involved follicles may be empty or contain a deeply pigmented keratinous material. The absence of inflammation distinguishes trichotillomania-induced alopecia from alopecia areata, the principal condition in the differential diagnosis.

### Specific Age-, Culture- and Gender-related Features

Secondary avoidance of intimate relationships, which occurs among some individuals with trichotillomania, may be exacerbated for women in cultures in which physical appearance is weighted differently for men and women. Avoidance of sports activities, in which disguised hair loss can be revealed, may also have gender-related effects in cultures in which athletic participation has different social meanings for men and women. Although culture-based expectations regarding appearance may make hair loss a greater burden for women, women may have a greater opportunity to hide hair loss through the use of wigs, hats and scarves. Reliable data regarding sex ratio in the general population are not yet available. For many women hair-pulling may worsen during the premenstrual phase.

### Differential Diagnosis

Among individuals presenting with alopecia who complain of hair-pulling urges, the diagnosis is not usually in doubt. When patients deny hair-pulling, other (dermatological) causes of alopecia should be considered. These include alopecia areata, male pattern hair loss, chronic discoid lupus erythematosus, lichen planopilaris, folliculitis decalvans, pseudopelade and alopecia mucinosa.

Trichotillomania is not diagnosed when hair-pulling occurs in response to a delusion or hallucination. Many people

twist and play with their hair. This may be exacerbated in states of heightened anxiety but does not qualify for a diagnosis of trichotillomania.

Some individuals may present with features of trichotillomania but hair damage may be so slight as to be virtually undetectable, even under close examination. In such conditions the disorder should be diagnosed only if it results in significant distress to the individual. Trichotillomania may have a short, self-limited course among children and may be considered a temporary habit. Therefore, among children the diagnosis should be reserved for situations in which the behavior has persisted during several months.

## Epidemiology and Comorbidity

### Prevalence and Incidence

Trichotillomania was long thought to be an uncommon condition, often accompanied by other psychiatric conditions. Although definitive studies of frequency rates in the general population are still lacking, three surveys of college-age samples support the emerging view that trichotillomania is quite common. In two of these samples, totaling approximately 3000 undergraduate students, a lifetime incidence of self-identified trichotillomania (reaching full symptom criteria as described in DSM-III-R) was present in about 1% of the respondents. Some features of the condition – but not meeting full criteria – were identified in an additional 1 to 2% (Rothbaum *et al.*, 1993).

In addition, because onset may occur later in life than the mean ages of individuals in these groups, the true lifetime incidence would probably be higher. Moreover, these samples consist of a selected population – largely first-year college students – and may not reflect the general population. Nonetheless, these studies indicate that the condition is likely to be far more common than previously assumed. But definitive, controlled studies of the prevalence of the condition have not yet been performed.

### Comorbidity

Individuals with trichotillomania have increased risk for mood disorders (major depressive disorder, dysthymic disorder) and anxiety symptoms. The frequency of specific anxiety disorders (such as generalized anxiety disorder and panic).

### Course

The age at onset typically ranges from early childhood to young adulthood. Peak ages at presentation may be bimodal, with an earlier peak about age 5 to 8 years among children in whom it has a self-limited course, whereas among patients who present to clinicians in adulthood the mean age at onset is approximately 13 years (Rothbaum *et al.*, 1993). Initial onset after young adulthood is apparently uncommon. There have been reports of onset as early as 14 months of age and as late as 61 years.

Trichotillomania may be one of the earliest occurring conditions in psychiatry. Some parents insist that their child began pulling hair before 1 year of age. When trichotillomania begins before age 6 years it tends to be a milder condition. It often responds to simple interventions and may be self-limited, with a duration of several weeks to several months, even if not treated. It often occurs in association with thumb-sucking. In some cases it remits spontaneously when therapeutic attention is directed at concurrent, severe thumb-sucking. It has been suggested that trichotillomania in childhood may be associated with severe intrapsychic or familial psychiatric conditions. But there is no

reliable evidence that supports such a conclusion. Indeed, some have suggested that because it may be common and frequently self-limiting, it should be considered a normal behavior among young children.

Some individuals have continuous symptoms for decades. For others, the disorder may come and go for weeks, months, or years at a time. Sites of hair-pulling may vary over time. Circumscribed periods of hair-pulling (weeks to months) followed by complete remission are reported among children.

Progression of the condition appears to be unpredictable. Waxing and waning of the severity of hair-pulling and number of hair-pulling sites occur in most individuals. It is not known which factors may predict a protracted and unremitting course.

## Prognosis

Because of the unavailability of longitudinal studies of trichotillomania, generalizations about prognosis cannot be made. Patients who present in research clinics typically have histories of many years (up to decades) of hair-pulling. Presentation after age 40 years appears to be far less common than in the previous three decades of life, suggesting that the condition may eventually remit spontaneously, even when untreated. It is likely that the persistent cases seen in research environments reflect the more severe end of the spectrum. As noted earlier, trichotillomania in children may often be a time-limited phenomenon.

## Treatment

### Treatment Goals

Treatment of trichotillomania typically occurs in an outpatient setting. Eradication of hair-pulling behavior is the general focus of treatment. Distress, avoidant behaviors and cosmetic impairment are secondary to the hair-pulling behavior and would be likely to remit if the hair-pulling behavior is controlled. However, if sufficient control of hair-pulling cannot be attained, treatment goals should emphasize these associated problems as well. Even if hair-pulling persists, therapeutic interventions may be targeted at reducing secondary avoidance and diminishing distress.

Treatment may be considered in three phases:

**Initial Contact** The diagnosis is made and the patient and psychiatrist agree on a strategy that may incorporate both pharmacological and psychological interventions. If distress is severe, supportive interventions should be immediately considered in anticipation of incomplete treatment response or of a delay of weeks to months before interventions may be beneficial.

**Acute Treatment** Even when treatment of hair-pulling behavior is optimally successful, there may be a delay of several weeks to months before adequate control is attained. Therefore, the acute treatment phase may be prolonged.

**Maintenance** It is not known how long patients must maintain active treatment interventions to prevent relapse. It should be anticipated that a substantial number of patients require ongoing treatment for an extended time. Pharmacological treatments may need to be maintained for open-ended periods. Behavioral or hypnotic intervention may require periodic “booster shots” to support continuation of benefits.

### Psychiatrist–Patient Relationship

It is important to bear in mind the particular nature of embarrassment that often accompanies this condition. Several factors contribute to feelings of shame for many people with trichotillomania. When hair-pulling has had its onset in childhood or

adolescence, there is often a history of the hair-pulling being treated as a family secret. Patients have been frequently castigated by parents or spouses for lack of self-control. In addition, there may be a feeling that the problem is largely cosmetic, causing some individuals to fear they do not have the “right” to utilize health resources for its treatment. This may also be manifest as fears of having their problem minimized or of being derided for seeking help. It is helpful for the psychiatrist to share with patients an understanding that the problem pervades their daily life and may result in meaningful distress and functional inhibition.

A variety of treatment approaches have been advocated for trichotillomania. However, there have, as yet, been few controlled studies of the efficacy of any treatment approach. A number of investigations of the use of antidepressants with specific inhibition of serotonin reuptake (i.e., fluoxetine and clomipramine) have yielded mixed results. A multimodal approach, simultaneously utilizing several complementary treatment options, may turn out to be the most effective approach for most patients. While a number of treatment options can be currently offered to individuals with trichotillomania, the durability of long-term outcomes is unclear.

### Stress Management

Before embarking on a course of treatment, the psychiatrist and the patient should first consider the course and severity of the individual's condition. Because early remission may occur in cases of recent onset, mild trichotillomania of short duration does not necessarily require immediate intervention. In particular, if the hair-pulling first occurred during a period of stress, the behavior may spontaneously diminish as the stressful circumstances abate. In such circumstances, therapeutic attention may best be directed toward examining and seeking to diminish the basis for stress. Teaching alternative stress reduction methods may be useful in reducing recent-onset trichotillomania. However, when individuals with trichotillomania present to the psychiatrist, it is often likely to have been a persistent condition and may have been present for many years or decades. Among such patients, stress reduction may also be useful in reducing trichotillomania but complete remission is less likely.

### Pharmacotherapy

A variety of medications have been used in the treatment of trichotillomania. Initial reports appeared demonstrating the apparent benefits of fluoxetine and clomipramine. Clomipramine was found to be superior to desipramine (and fluoxetine was reported beneficial in open treatment. Although reports for more than 60 patients have subsequently added support for the use of these medications, the two double-blind studies in which fluoxetine has been compared with placebo did not demonstrate any improvement compared with placebo. Fluvoxamine, citalopram and venlafaxine have been reported to be efficacious in open trials. Although further controlled studies of SSRIs are needed, the use of such medications would be a prudent first step if a pharmacological approach has been agreed upon.

Initial evidence of improvement is usually first reported by the patient as greater awareness of the inclination to pull hair. This is usually followed by an ability to abort hair-pulling episodes more quickly than in the past. The ability to resist the urge follows. In cases with a good outcome, the inclination to pull diminishes and may eventually disappear. Patients who pull from several sites may find that the rate of improvement varies from site to site.

There have been conflicting reports of early relapse of symptoms in some patients treated with clomipramine or fluoxetine. Although good maintenance of benefit has been reported for some patients 6 months and longer after the initiation of treatment, early relapse after several weeks to months has been reported as well. Keuthen and coworkers (2001) have provided long-term data on maintenance of response over time. Following a group of individuals who had varying forms of treatment (pharmacologic and psychological) for several years after an index evaluation, the authors concluded that initial improvement was common, but over time there was an increase in symptom scores and self-esteem scores worsened in the group over time. This problem remains to be further evaluated in long-term treatment studies. If early relapse does turn out to be common, it would distinguish trichotillomania from depression and OCD, in which, once established, medication benefits are often well maintained as long as medication is continued. Optimal duration of treatment for well-treated individuals is also still unknown. In accordance with standards developed for the treatment of other conditions, it would be reasonable to continue medication for at least 6 months before tapering. Reinitiation of treatment may be necessary.

### Other Medications

There have been reports of successful treatment with lithium. Adjunctive treatment with pimozide, a neuroleptic agent, has been advocated for some patients who are refractory to other medications. The potential benefits of neuroleptics has been reported and individuals have been described for whom SSRIs provided insufficient benefits. The addition of atypical neuroleptics much improved their outcomes. The greater margin of safety and tolerability associated with atypical neuroleptics have made this a more viable treatment option.

Van Ameringen and colleagues (1999) described the use of haloperidol in nine patients with trichotillomania. Six had previously failed treatment with SSRIs. Eight of nine patients responded to the haloperidol. The possible superiority of neuroleptics prompted these authors to speculate that trichotillomania may be similar to Tourette's syndrome (TS), which responds preferentially to neuroleptics.

### Psychosocial Treatments

**Behavioral Treatment** Various behavioral techniques have been tried. The most successful technique, habit reversal, is based on designing competitive behaviors that should inhibit the behavior of hair-pulling. For example, if hair-pulling requires raising the arm to the scalp and contracting the muscles of the hand to grasp a hair, the behaviorist may design a behavioral program in which the patient is taught to lower the arm and extend the muscles of the hand. As with behavioral techniques in general, these interventions are most successful when the patient is strongly motivated and compliant. In addition, the treating psychiatrist should be experienced in the use of such techniques. If necessary, a referral should be made to such an experienced individual. Modified behavioral approaches have been described for children and adolescents.

**Cognitive Behavioral Therapy (CBT)** CBT has been developed for, and applied to, individuals with trichotillomania. At this time, the potential for the efficacy of this treatment approach appears good. Ninan and colleagues (2000) compared CBT with clomipramine in the treatment of trichotillomania. The authors reported that CBT had a dramatic effect in reducing symptoms

of trichotillomania and was significantly more effective than clomipramine ( $P = 0.016$ ) or placebo ( $P = 0.026$ ). Clomipramine resulted in symptom reduction greater than that with placebo, but the difference fell short of statistical significance. Placebo response was minimal.

**Hypnotherapy** There are no formal studies of the use of hypnosis for trichotillomania, but there are many published reports of beneficial treatment. Benefits may be variable. Some patients may have dramatic improvement. For some who improve, the benefits may be short-lived. As with behavioral interventions, the benefits of this approach are sometimes dependent on a highly motivated patient who can regularly carry out self-hypnotic measures as instructed by the psychiatrist. Some patients who have obtained partial benefits from either hypnosis or medication do well when both treatments are combined. Successful use of hypnotherapy for children with trichotillomania has also been reported.

**Dynamic Psychotherapy** Many psychoanalytically oriented descriptions of individuals with trichotillomania have been published. These reports generally describe the psychodynamic formulations of individual cases and should not be the basis for generalizations about most individuals with trichotillomania. Although patients with trichotillomania may benefit from exploration and attempts to reduce intrapsychic conflict, the literature does not provide persuasive evidence of the efficacy of this approach in reducing hair-pulling.

**Self-help and Other Groups** Self-help groups for patients with trichotillomania have appeared. Some are based in the structure of other 12-step programs. Some patients appear to experience meaningful reduction in hair-pulling symptoms after beginning participation in such a group. Although the efficacy of such groups in reducing symptoms remains to be established, most patients with trichotillomania can benefit from meeting other individuals with similar symptoms. Because of the lack of general awareness of trichotillomania, these individuals frequently believe that they are “oddball” individuals with a behavior that is unique. Many have experienced parental condemnation for the behavior and have been frequently castigated for a “habit” that may be viewed by others as under their voluntary control. The experience of meeting others with the condition is extremely supportive for such individuals and may help to reduce the attendant stress while supporting self-esteem. Where programs specifically oriented toward trichotillomania may not be generally available, these individuals may benefit from groups oriented toward OCD.

### Treatment of Comorbid Conditions

Depression, dysthymic disorder and anxiety symptoms occur frequently in patients with trichotillomania. Successful treatment of depression may not be associated with reduction in trichotillomania. If depression or dysthymic disorder is present and independently provides an indication for medication, one of the antidepressants discussed earlier should be chosen. If fluoxetine is used, the psychiatrist should be aware that a dose that is sufficient for reduction of the depressive symptoms may not be sufficient for reduction of trichotillomania. If panic disorder is present, either medication may still be used, but fluoxetine may initially exacerbate panic attacks in such patients and initiation of treatment at low doses (2.5–5 mg/day) should be considered. With slow titration upward, the patient should generally be able to tolerate usual doses with concomitant amelioration of the

panic disorder. Combined treatment with anxiolytics may be useful for some and may contribute to the reduction in symptoms of trichotillomania. Other conditions that may be present, such as OCD or eating disorders, may require special attention. Although fluoxetine may be useful for patients with eating disorders, medication treatment alone is unlikely to be adequate and the usual multimodal approaches for the treatment of bulimia nervosa or anorexia are appropriate. OCD may respond to treatment directed at trichotillomania, but adjunctive behavioral treatment of symptoms of OCD may be desirable.

### Demographical Features

When trichotillomania presents in early childhood, the condition may be likely to be inherently self-limited. Often, all that may be necessary is to draw the child's attention to the behavior in some systematic way and to clarify for the child that the behavior is undesirable. Such methods include daily application of a nonmedicinal ointment to the affected region and reminding the child that the purpose is elimination of the hair-pulling habit. Some suggest that the child be given the responsibility of applying the ointment with parental supervision. Others suggest that parents should monitor the child as much as possible and respond with reminders that the hair should not be pulled and rewards with verbal encouragement for ceasing to pull hair. There have been no systematic studies of the benefits of such interventions, but dermatologists who specialize in the treatment of children have noted that hair-pulling behavior may frequently disappear within a few weeks of initiating such an approach. In circumstances in which childhood trichotillomania is more persistent, the parent and psychiatrist are faced with a dilemma. More elaborate behavioral interventions, such as habit reversal, should be tried. This, however, may be difficult with a child. Hypnosis has been also used in the treatment of habit disorders in children. Medication should be cautiously considered in the treatment of childhood trichotillomania. Although medication may be useful, the absence of data supporting the benefits of such treatments in children indicates a conservative approach. If medication is considered, the use of medication in the treatment of childhood OCD should serve as a guideline.

Should the psychiatrist be presented with trichotillomania in a person of advanced age, special attention should be paid to usual concerns regarding the use of these medications in the elderly. Lower doses of medication should be considered because of potential altered pharmacokinetics in older persons. Medications with anticholinergic side effects (such as clomipramine) may present greater hazards for the older person. Sedative-hypnotic anxiolytics should be used sparingly because of greater vulnerability to cognitive side effects and the increased risk of falling.

Women of childbearing potential (perhaps the majority of individuals who may present for treatment) should be advised regarding the potential risks of these medications to a developing fetus. If the patient is pregnant or considering pregnancy, behavioral treatments may be favored.

The psychiatrist should be sensitive to the interaction between cultural values and trichotillomania. Women of certain cultures may be more prone to distress if trichotillomania is perceived as a hindrance to achieving valued goals, such as marriage. It should also be noted that in some communities, wigs and other hair accessories are generally acceptable and may present a comfortable means of diminishing the cosmetic impact of hair loss. In other communities, such accoutrements may themselves draw undesired attention.

## Comparison of DSM-IV/ICD-10 Diagnostic Criteria

The ICD-10 Diagnostic Criteria for Research do not include diagnostic criteria for intermittent explosive disorder. It is included in ICD-10 as an “other habit and Impulse Control Disorder”.

The ICD-10 Diagnostic Criteria for Research and the DSM-IV-TR criteria for kleptomania, pyromania and trichotillomania are essentially equivalent.

Finally, the ICD-10 Diagnostic Criteria for Research for pathological gambling are monothetic (i.e., A plus B plus C plus D are required) whereas the DSM-IV-TR criteria set is polythetic (i.e., five out of 10 required) with different items. Furthermore, the ICD-10 criteria specify “two or more episodes of gambling over a period of at least 1 year”, whereas DSM-IV-TR does not specify a duration.

**Definition**

The *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR) states that the essential feature of adjustment disorder (AD) is the development of clinically significant emotional or behavioral symptoms in response to an identifiable psychosocial stressor (American Psychiatric Association, 2000). The symptoms must develop within 3 months after the onset of the stressor (criterion A). The clinical significance of the reaction is indicated either by marked distress that is in excess of what would be expected given the nature of the stressor or by significant impairment in social or occupational (academic) functioning (criterion B). This disorder should not be used if the emotional and cognitive disturbances meet the criteria for another specific Axis I disorder (e.g., a specific anxiety or mood disorder) or are merely an exacerbation of a preexisting Axis I or Axis II disorder (criterion C). AD may be diagnosed if other Axis I or II disorders are present, but do not account for the pattern of symptoms that have occurred in response to the stressor. The diagnosis of AD does not apply when the symptoms represent bereavement (criterion D). By definition, AD must resolve within 6 months of the termination of the stressor or its consequences (criterion E). However, the symptoms may persist for a prolonged period (i.e., longer than 6 months) if they occur in response to a chronic stressor (e.g., a chronic, disabling general medical condition) or to a stressor that has enduring consequences (e.g., the financial and emotional difficulties resulting from a divorce) (American Psychiatric Association, 2000).

Although the above definition provides a certain structure for identifying and describing AD, there is still uncertainty as to when the impairment in functioning or the severity of the psychiatric symptoms that develop in response to a stressor are sufficient to warrant a diagnosis of AD. The DSM-IV-TR describes the boundary issues between conditions that may be a focus of clinical attention (V codes), **subthreshold** disorders (NOS disorders) and the specific mental disorders (American Psychiatric Association, 2000). A compelling literature documents that there is much “physical” in mental disorders and much “mental” in physical disorders. No definition adequately specifies precise boundaries for the concept of a “mental disorder”. “The concept... lacks a consistent operational definition that covers all situations. Whatever its original cause, it must currently be considered a manifestation of a behavioral, psychological, or biological dysfunction in the individual”. The issue of defining boundaries is especially problematic in the **subthreshold** diagnoses, for example, the AD, in which there are no symptom checklists, algorithms, or guidelines for the “quantification of attributes”.

The symptoms of AD are defined in terms of their being a maladaptive response to a psychosocial stressor. There are, in

**DSM-IV-TR Criteria 309.xx****Adjustment Disorders**

- A. The development of emotional or behavioral symptoms in response to an identifiable stressor(s) occurring within 3 months of the onset of the stressor(s).
- B. These symptoms or behaviors are clinically significant as evidenced by either of the following:
  - (1) marked distress that is in excess of what would be expected from exposure to the stressor.
  - (2) significant impairment in social or occupational (academic) functioning.
- C. The stress-related disturbance does not meet the criteria for another specific Axis I disorder and is not merely an exacerbation of a preexisting Axis I or Axis II disorder.
- D. The symptoms do not represent bereavement.
- E. Once the stressor (or its consequences) has terminated, the symptoms do not persist for more than an additional 6 months.

*Specify if:*

**Acute:** if the disturbance lasts less than 6 months

**Chronic:** if the disturbance lasts for 6 months or longer

Adjustment disorders are coded based on the subtype, which is selected according to the predominant symptoms. The specific stressor(s) can be specified on Axis IV.

**With 309.0 depressed mood**

**With 309.24 anxiety**

**With 309.28 mixed anxiety and depressed mood**

**With 309.3 disturbance of conduct**

**With 309.4 mixed disturbance of emotions and conduct**

**Unspecified 309.9.**

fact, no specific symptoms of AD; any combination of behavioral or emotional symptoms that occur in association with a stressor may qualify. The lack of specific symptoms or quantifiable

criteria of the AD permits the labeling of early or temporary mental states when the clinical picture does not meet full evidence for a more specific mental disorder, but the morbid state is more than expected in a normal reaction and treatment or intervention may be indicated. AD are an essential “linchpin” in the psychiatric–taxonomic spectrum-hierarchy: 1) disorders with specific diagnostic criteria; 2) disorders not otherwise specified (NOS); 3) adjustment disorders; 4) other conditions that may be a focus of clinical attention (V codes) (American Psychiatric Association, 2000); and 5) normal fluctuations of mental states.

Disorders that do not fulfill the criteria for a specific mental disorder may be accorded a lesser interest by mental health care workers, research institutes and third-party payers, even though they present with serious (or incipient) symptoms that require intervention or treatment. Given this concept, the AD are formulated as a means of classifying psychiatric morbidity that is clinically significant; when the symptom profile is as yet insufficient to meet the more specifically operationalized criteria for another mental disorder; when the symptoms, disturbance of mood, and vocational or interpersonal dysfunction are in excess of a normal reaction to the stressors in question; and for which treatment is indicated. For example, a diagnosis of AD is not given when the clinical picture is a psychosocial problem (V code) requiring clinical attention, such as noncompliance, phase of life problem, bereavement, or occupational (academic) problem. Their etiological and dynamic attributes make the AD a fascinating group of disorders that serve as a fulcrum between normality and more specific mental disorders (Figure 61.1).

Attention to less severe mental symptoms (and psychiatric morbidity) may forestall the evolution to more serious disorders and allow remediation before relationships, work and functioning are so impaired that they are disrupted or permanently sundered.

**Figure 61.1** *Descending order of depressive states, from most serious to least depressed mood, as a state of being for an occurrence of the moment.*

Yet, in the gray area in which early diagnosis may have enormous value with modest therapeutic investment, guidelines are the most tenuous. It is the professionals at the “front door” – primary care physicians, triage personnel, emergency department staff, walk-in clinic staff – who need assistance in making this difficult call: Is there sufficient psychiatric morbidity to warrant mental health intervention?

Because AD is a nonpejorative psychiatric condition it may have been overdiagnosed in youths to protect them from feared adversities of major psychiatric nomenclature. An early study observed that 25% of a sample of adolescents with AD had attempted suicide and that 17% probably “would have met DSM-III criteria for major depressive disorder” because they had the required symptoms. Nevertheless, in psychological autopsy studies of adolescent suicide completers, approximately 20% do not meet the criteria for any single psychiatric diagnosis, although they present with significant functional impairment and life-threatening behavior.

How to diagnose individuals with suicidal behavior who do not meet criteria for a specific mental is a challenge. Runeson and colleagues (1996) observed from psychological autopsy methods that there was a very short median interval between first suicidal communication and suicide in AD (less than 1 month) compared with major depressive disorder (3 months), borderline personality disorder (30 months), or schizophrenia (47 months).

Recent life events, which would constitute an acute stress, were commonly found to correlate with suicidal behavior in a group that included those with AD (Isometsa *et al.*, 1996). The assessment of suicidal behavior is an important tool in differentiating major depressive disorder, dysthymic disorder and AD. Furthermore, AD patients appear to be among the most common recipients of a deliberate self-harm (DSH) diagnosis, with the majority involving self-poisoning. Thus, DSH with all its variants, e.g., reckless driving, is more common in AD patients, whereas the percentage of completed suicidal behavior *per se* was found to be higher in depressed patients (Spalletta *et al.*, 1996). Of note, biological findings in suicidal patients with AD suggest characteristic patterns of monoamine oxidase (MAO) and noradrenaline turnover. Clearly, what is regarded, as a subthreshold diagnosis – AD – does not necessarily imply the presence of subthreshold symptomatology.

## Epidemiology

AD has principally been studied in clinical samples. Epidemiological data in adults are not available. The AD diagnosis was not included in the Epidemiologic Catchment Area Study and there are only a few studies in children and adolescents. Prevalence rates for AD range from 2.3% of walk in clinic patients who had no other Axis I or II disorders to 20% when comorbid axis I and II diagnoses were present. In a Pittsburgh sample, 16% of the children and adolescents younger than 18 years were diagnosed with AD (Fabrega *et al.*, 1986). In adults, women predominated over men by approximately 2:1. The sex ratio was more equal in children and adolescents, although there was still a slight excess of female patients.

Prevalence estimates of AD in other clinical populations have been characterized by considerable variability. In general hospital inpatient and psychiatric consultation populations, AD was diagnosed in 21.5 and 11.5%, respectively (Popkin *et al.*, 1988; Snyder and Strain, 1990). Consultation–liaison data from seven university teaching hospitals in the USA, Canada and Australia revealed that AD was diagnosed in 125 patients (12.0%); as the sole diagnosis in 81 (7.8%); and comorbidly with other Axis I and II diagnoses in 44 (4.2%) (Strain *et al.*, 1998). It had been

considered as a “rule-out” diagnosis in an additional 110 (10.6%). AD with depressed mood, anxious mood, or mixed emotions were the most common subcategories used. AD was diagnosed comorbidly most frequently with personality disorder and organic mental disorder. Sixty-seven (6.4%) were assigned a V code diagnosis only. Patients with AD compared with other diagnostic categories were referred significantly more often for problems of anxiety, coping and depression; had less past psychiatric illness; and were rated as functioning better – all consistent with the construct of AD as a maladaptation to a psychosocial stressor. Interventions employed for this general hospital inpatient cohort were similar to those for other Axis I and II diagnoses, in particular, the prescription of antidepressant medications. Patients with AD required a similar amount of clinical time and resident supervision.

Oxman and coworkers (1994) observed that 50.7% of elderly patients (aged 55+ years) receiving elective surgery for coronary artery disease developed AD related to the stress of surgery. Thirty percent had symptomatic and functional impairment 6 months following surgery. It is reported that more than 25% of elderly patients examined 5 to 9 days following a cerebral vascular accident had symptoms that fulfilled the criteria for AD. Spiegel (1996) observed that half of all cancer patients have a psychiatric disorder, usually an AD with depression. Since patients treated for their mental states had longer survival time, treatment of depression in cancer patients should be considered integral to their medical treatment. AD is a frequently made diagnosis in patients with head and neck surgery (16.8%), patients with HIV dementia (73%) and cancer patients (27%). AD is seen in dermatology patients and suicide attempters examined in an emergency department. Other studies include diagnosis of AD in more than 60% of inpatients being treated for severe burns, 20% of patients in early stages of multiple sclerosis and 40% of poststroke patients.

There are two published epidemiological studies in populations of children and adolescents that included AD. One determined the prevalence rate of AD was 7.6% if an upper limit of 70 on the Children’s Global Assessment Scale (CGAS) is applied. However, if an upper limit of 60 is imposed (corresponding to “moderate” impairment on the CGAS), the prevalence of AD dropped to 4.2%. This indicates that up to 40% of AD diagnosed patients have only mild impairment, more than for any other diagnosis.

The relationship between family functioning and AD was evaluated by administering the Family Assessment Devise (FAD) to families who had a member with one of seven mental disorders: schizophrenia, bipolar disorder, major depression, anxiety disorder, eating disorder, substance abuse and adjustment disorder (Friedmann *et al.*, 1997). Regardless of which specific psychiatric diagnosis was present in the family member, having a family member in an acute phase of any of these psychiatric disorders – even a subthreshold diagnosis such as AD, was a risk factor for poor family functioning. AD in a family member was a significant family stressor.

## Etiology

By definition, the ADs are stress-related phenomena in which a psychosocial stressor results in the development of maladaptive states and psychiatric symptoms. The condition is presumed to be time limited, that is, a transitory reaction; symptoms recede when the stressor is removed or a new state of adaptation is defined.

That the relationship between stress and the occurrence of a psychiatric disorder is both complex and uncertain has caused many to question the theoretical basis of AD. The linear model

of stress–disease interaction, which serves as the model for AD, has been questioned as well. The linear model presupposes that a direct and clearly identifiable pathological reaction may follow a stressful event, a scenario that no doubt occurs in some individuals with AD but may not accurately characterize others. For example, there may be multiple stressors, insidious or chronic, as opposed to discrete events. Furthermore, relatively minor precipitating events may generate a disturbance in an individual who has previously been sensitized to stress.

Several authors have criticized the stressor criterion in AD because stressors are difficult to specify and measure, and their clinical implications and impact are uncertain. Questions pertain to whether patients with AD are unusually sensitive to psychosocial events not likely to cause disturbance in others. Are there individuals who have been exposed to high levels of stress, the severity or accumulation of which would probably produce negative consequences in most people?

Diverse variables and modifiers are involved in the presentation of AD after exposure to a stress. Cohen (1981) argued that acute stresses are different from chronic ones in both psychological and physiological terms; that the meaning of the stress is affected by “modifiers” – ego strengths, support systems, prior mastery – and that one must differentiate manifest and latent meaning of the stressors (e.g., loss of a job may be a relief or a catastrophe). An objectively overwhelming stress could have little impact on one individual, whereas another individual could regard a minor one as cataclysmic. A recent minor stress superimposed on a previous underlying (major) stress (which had no observable effect on its own) may have a significant impact, not operating independently but by its additive effect: the concatenation of events (Hamburg, personal communication).

Despite variable findings suggesting a correlation between the acknowledgment of stress and the assignment of an AD diagnosis, stress is not universally related to the development of psychiatric illness, and this has implications for understanding the meaning of stressors in AD. Specific types of stressful events and individual patterns of stress response appear to be preferentially related to the development of psychiatric symptoms in vulnerable individuals.

## Diagnosis and Differential Diagnosis

Each of the diagnostic constructs required for the diagnosis of AD is difficult to assess and measure: 1) the stressor, 2) the maladaptive reaction to the stressor, and 3) the time and relationship between the stressor and the psychological response. None of these three components has been operationalized for a diagnostic decision tree, which consequently plagues the AD diagnosis with limited reliability.

In contrast to other DSM-IV-TR disorders, the diagnostic criteria for AD include no clear and specific symptoms (or checklist) that collectively compose a psychiatric (medical) syndrome or disorder.

First, with regard to the maladaptive reaction, it is unclear how this concept can or should be operationalized. The social, vocational and relationship dysfunctions, which are unspecified qualitatively or quantitatively, do not lend themselves to reliable or to valid assessment. The elements of culture (i.e., the expectable reactions within a specific cultural environment), differences in gender responses, developmental level differences and differences in the “meaning” of events and reactions to them by a specific individual further confound it.

The concepts of “average expectable environment” (e.g., the expectation of adequate food in a household in an industrial society) and “patient’s explanatory belief model” are examples of an attempt to weigh cultural and subjective differences in the assessment of an individual’s mental state and reaction. Such individual cultural–social considerations often require an understanding on the part of the psychiatrist and thereby often render the assessment of whether a reaction is excessive or maladaptive a judgment call.

The criterion and predictive validity of the diagnosis of AD in 92 children who had new onset insulin-dependent diabetes mellitus were examined. DSM-III criteria were employed plus requiring four clinically significant signs or symptoms, and the time frame extended to 6 months (instead of the 3 months specified in the definition) after the diagnosis of diabetes. Thirty-three percent of the cohort developed AD (mean 29 days after the medical diagnosis) and the average episode length was 3 months with a recovery rate of 100%. The five-year cumulative probability of a new psychiatric disorder was 0.48 in comparison to 0.16 for the nonAD subjects. The findings support the criterion validity of the AD diagnosis using the criterion of predicting the future development of psychiatric disorder.

### Maladaptation

Although the diagnosis of AD requires evidence of maladaptation, it is notable that no specific requirement for functional impairment has been included (e.g., there is no requirement for a certain decrement in the Global Assessment of Functioning Scale score in order to make the diagnosis). Fabrega and colleagues (1986) stated that both subjective symptoms and decrement in social function can be considered maladaptive and that the severity of either of these is subject to great individual variation. However, they could not conclude that the level of severity of psychiatric illness observed correlates with impaired functioning in three areas: occupational status, family, or other individuals.

The psychiatrist needs to examine the patient’s behavior to see whether it is beyond what is expected in a particular situation, and for that patient. In order to do this, the psychiatrist needs to take into account the patient’s cultural beliefs and practices, his or her developmental age and the transient nature of the behavior. If the behavior lasts a few moments or is an impulsive outburst, it would not qualify for a maladaptive response to justify the diagnosis of AD. The behavior in question should be maladaptive for that patient, in his/her culture and sufficiently persistent to qualify for the maladaptation attribute of the AD diagnosis.

### Stresses

No criteria or guidelines are offered in DSM-IV-TR to quantify the degree of stress required for the diagnosis of AD or assess its effect or meaning for a particular individual at a given time. Many of the statements regarding the problem of assessing maladaptation described above apply equally well to the assessment of stressors. The measurement of the severity of the stressor and its temporal and causal relationship to demonstrable symptoms are often uncertain.

According to DSM-IV-TR, even if a specific and presumably causal stressor is identified, if enough symptoms develop so that diagnostic criteria are met for a specific disorder, then that diagnosis should be made instead of a diagnosis of AD (American Psychiatric Association, 1980, 1987, 2000). Therefore, the presence of stressors does not automatically signify a diagnosis of

AD, and conversely, a diagnosis of a specific disorder (e.g., major depressive or anxiety disorder) does not imply the absence of concomitant or concurrent stressful events.

### Assessment of the Subtypes of Adjustment Disorder, Comorbidity and Diagnostic Boundaries

The diagnostic criteria for AD define the contextual and temporal characteristics of a subthreshold response to a psychosocial stressor; the specific quality and nature of the resultant psychological morbidity have been used as a means of subtyping.

DSM-IV-TR identifies six AD subtypes; two of the subtypes define discrete disturbances of mood (e.g., depressed, anxious); two describe mixed clinical presentations (e.g., mixed emotional features, mixed disturbance of emotions and conduct); one specifies disturbance of conduct; and the final subtype, unspecified, is a residual category.

Significant occurrence of comorbidity has been reported in studies of AD using structured diagnostic instruments. In a cohort of children, adolescents and adults, approximately 70% of AD patients had at least one additional Axis I diagnosis. In the study of correlates of depressive disorders in children, 45% of those with AD with depressed mood had another disorder. However, comorbidity in AD was less than in dysthymic disorder or major depressive disorder, suggesting a “purer” or more encapsulated disturbance in AD.

Several studies reported an association of suicidal behavior in adolescents and young adults with AD. These studies underscore the seriousness of AD in a subset of individuals and suggest that although the diagnosis may be **subthreshold**, its morbidity can be serious and at times even fatal.

The issue of boundaries between the specific mood and anxiety disorders, depressive disorder or anxiety disorder NOS, and the AD remains problematic. The specific mood and anxiety disorders are often associated with and even precipitated by stress. Therefore, it is not always possible to say one group of diagnoses is accompanied by stress (the AD) and another (e.g., major depressive disorder) is not. Stress may accompany many of the psychiatric diagnoses, but it is not an essential component to make certain diagnoses (e.g., major depressive disorder).

More research is needed carefully to demarcate the boundaries or the meaning of these boundaries among the problem-level, subthreshold and threshold disorders, in particular with regard to the role of stressors as etiological precipitants, concomitants, or factors essentially unrelated to the occurrence of a particular psychiatric diagnosis. In reviewing the diagnosis of AD for DSM-IV, one issue emerges as fundamental. The effect of the imprecision of this diagnosis on reliability and validity, because of the lack of behavioral or operational criteria, must be determined.

Snyder and Strain (1989) observed that in the acute care inpatient hospital setting, many of the psychiatric consultation patients initially thought to have an AD did not maintain that diagnosis at the time of discharge. These same authors also observed that many patients initially diagnosed as having major depressive disorder were reclassified to AD at discharge. It remains to be seen if either the major depressive disorder or the AD diagnosis is significantly altered at a 6-week follow-up and, in particular, when the patient has left the hospital. This evolution of psychiatric morbidity within the acute care general medical

setting cautions the psychiatrist to go slowly with treatment until there is a level of certainty to justify an intervention, in particular with a chemotherapeutic modality.

Attempting to diagnose disorders in an early state or before there is a full-blown syndrome or disorder often means that a patient will qualify for the AD criteria or the subsyndromal condition. Just as it is difficult to know when a patient has crossed the diagnostic line (threshold) from normal to disturbed behavior, it is difficult to know how quickly the symptoms will remit with a remission of the stressor, which for the general medical–surgical inpatient include 1) acute hospitalization, 2) uncertain medical diagnosis, 3) pain, 4) medications, 5) separation and 6) lack of ability to function or contain emotions. The AD must be looked at as a **transitory state** for most patients, in that it may subside, respond with treatment, evolve to another diagnosis, or be maintained as the stressor continues.

Furthermore, Monroe and associates (1992) pointed out that “stress does not credit a more favorable treatment course for patients with recurrent depression”. For these patients, stress occurring before treatment entry suggests the likelihood of a poorer early treatment response and a longer time to attain relief. Psychiatrists working with recurrent depression should not expect more rapid recovery from patients reporting these types of stress and should not become discouraged if treatment progress is slower or more erratic than usual. The severity of the stressor should be studied as well as its recurrence and its meaning to the patient, all in conjunction with treatment outcome in those with AD.

### Clinical Vignette 1

A 35-year-old married woman, mother of three children, was desperate when she learned she had cancer and would need mastectomy followed by chemotherapy and radiation. She was convinced that she would not recover, that her body would be forever distorted and ugly, that her husband would no longer find her attractive, and that her children would be ashamed of her baldness and the fact that she had cancer. She wondered whether anyone would ever want to touch her again. Because her mother and sister had also experienced breast cancer, the patient felt she was fated to an empty future. Despite several sessions dealing with her feelings, the patient’s dysphoria remained profound. It was decided to add antidepressant medication (fluoxetine, 20 mg/day) to her psychotherapy to decrease the patient’s continuing unpleasant symptoms. Two weeks later, the patient reported that she was feeling less despondent and less concerned about the future and that she had a desire to start resuming her former activities with her family. As the patient came to terms with the overwhelming stressor and, assisted with antidepressant agents, her depressed mood improved, more adequate coping strategies to handle her serious medical illness were mobilized.

Although it is uncommon to use psychotropic medication for the majority of the adjustment disorders, this clinical vignette illustrates the effective use of antidepressant therapy in a patient who was not responding to counseling and psychotherapy; she never had symptoms that met the DSM-IV criteria for a major depressive disorder. It has been found that the addition of a psychotropic medication in adjustment disorder, on the basis of the mood disturbance, may assist those patients who continue to

experience disordered mood and adjustment to the stressor despite treatment with verbal therapies. The antidepressant medications have also been found helpful in the terminally ill who exhibit adjustment disorder with depressed mood and who have not responded to counseling alone.

## Treatment

There are no reported randomized controlled trials regarding the psychological, social, or pharmacological treatment of AD. In lieu of any substantive randomized controlled trials to guide treatment, the choice of intervention remains a clinical decision.

There are two approaches to treatment. One is based on the understanding that this disorder emanates from a psychological reaction to a stressor. The stressor needs to be identified, described and shared with the patient; plans must be made to mitigate it, if possible. The abnormal response may be attenuated if the stressor can be eliminated or reduced. Popkin and coworkers (1990) have shown that, in the medically ill, the most common stressor is the medical illness itself; and the AD may remit when the medical illness improves or a new level of adaptation is reached. The other approach to treatment is to provide intervention for the symptomatic presentation, despite the fact that it does not reach threshold level for a specific disorder, on the premise that it is associated with impairment and that treatments that are effective for more pronounced presentations of similar pathology are likely to be effective. This may include psychotherapy, pharmacotherapy, or a combination of the two.

## Psychotherapy

Psychotherapeutic intervention in AD is intended to reduce the effects of the stressor, enhance coping to the stressor that cannot be reduced or removed, and establish a mental state and support system to maximize adaptation. Psychotherapy can involve any one of several approaches: cognitive–behavioral treatment, interpersonal therapy, psychodynamic efforts, or counseling.

The first goal of these psychotherapies is to analyze the nature of the stressors affecting the patient to see whether they may be avoided or minimized (e.g., assuming excessive responsibility out of keeping with realistic goals; putting oneself at risk, such as dietary indiscretions for a type I diabetic). It is necessary to clarify and interpret the meaning of the stressor for the patient. For example, an amputation of the leg may have devastated a patient’s feelings about himself or herself, especially if the individual was a runner. It is necessary to clarify that the patient still has enormous residual capacity; that he or she can engage in much meaningful work, does not have to lose valued relationships, and can still be sexually active; and that it does not necessarily mean that further body parts will be lost. (However, it will also involve redirecting the physical activity to another pastime.) Otherwise, the patient’s pernicious fantasies (“all is lost”) may take over in response to the stressor (i.e., amputation), make the patient dysfunctional (at work, sex) and precipitate a painful dysphoria or anxiety reaction.

Some stressors may elicit an overreaction (e.g., the patient’s attempted suicide or homicide after the abandonment by a lover). In such instances of overreaction with feelings, emotions, or behaviors, the therapist would help the patient put his or her feelings and rage into words rather than into destructive actions and gain some perspective. The role of verbalization and

the joining of affects and conflicts cannot be overestimated in an attempt to reduce the pressure of the stressor and enhance coping. Drugs and alcohol are to be discouraged.

Psychotherapy, medical crisis counseling, crisis intervention, family therapy, group treatment, cognitive-behavioral treatment and interpersonal therapy all encourage the patient to express affects, fears, anxiety, rage, helplessness and hopelessness to the stressors imposed. They also assist the patient to reassess reality in the service of adaptation. Following the example given above, the loss of a leg is not the loss of one's life. But it is a major loss. Sifneos (1989) believed that patients with AD could profit most from brief psychotherapy. The psychotherapy should attempt to reframe the meaning of the stress, find ways to minimize it, and diminish the psychological deficit due to its occurrence. The treatment should expose the concerns and conflicts that the patient is experiencing; help the patient gain perspective on the adversity; and encourage the patient to establish relationships and to attend support groups or self-help groups for assistance in the management of the stressor and the self.

Wise (1988), drawing from his experience in military psychiatry, emphasized the variables of brevity, immediacy, centrality, expectance, proximity and simplicity (BICEPS principles). The treatment structure encompasses a simple straightforward approach dealing with the immediate situation at hand which is troubling the patient. The treatment approach is brief, usually no more than 72 hours.

In another sample, interpersonal psychotherapy was applied to depressed outpatients with human immunodeficiency virus, (HIV), infection and found to be useful (Markowitz *et al.*, 1992). Some of the attributes of interpersonal psychotherapy are psychoeducation regarding the sick role; using a here-and-now framework; formulation of the problems from an interpersonal perspective; exploration of options for changing dysfunctional behavior patterns; and identification of focused interpersonal problem areas. Lazarus (1992) described a seven-pronged approach in the treatment of minor depression. The therapy includes assertiveness training, enjoyable events, coping, imagery, time projection, cognitive disputation, role-playing, desensitization, family therapy and biological prophylaxis.

Support groups have been demonstrated to help patients adjust and enhance their coping mechanisms, and they may prolong life as well although the data is conflicting regarding the latter.

## Pharmacotherapy

Stewart and colleagues (1992) emphasized the need to consider psychopharmacological interventions as well as psychotherapy for the treatment of minor depression, and this recommendation might be extrapolated to other subthreshold disorders. This group recommends antidepressant therapy if there is no benefit from 3 months of psychotherapy or other supportive measures. Although psychotherapy is the first choice treatment, psychotherapy combined with benzodiazepines may be helpful, especially for patients with severe life stress(es) and a significant anxious component. Tricyclic antidepressants or buspirone are appropriate in place of benzodiazepines for patients with current or past heavy alcohol use because of the greater risk of dependence in these patients.

Psychotropic medication has been used in the medically ill, in the terminally ill and in patients who have been refractory to verbal therapies. Amphetamine derivatives appear helpful in the treatment of these groups of patients. Whether methylphenidate is similarly useful in AD with depressed mood remains

to be examined. Bereavement-related syndromal depression also appears to respond to antidepressant medication. The medication chosen should reflect the nature of the predominant mood that accompanies the AD (e.g., benzodiazepines for AD with anxious mood; antidepressants for AD with depressed mood). The degree to which pharmacotherapy is used for AD has remained elusive.

Some have begun to examine the effect of homeopathic treatments. From a 25-week multicenter randomized placebo-controlled double-blind trial, a special extract from kava-kava was reported to be effective in AD with anxiety and without the adverse side-effect profile associated with tricyclics and benzodiazepines (Volz and Kieser, 1997). Tianeptine, alprazolam and mianserin were found to be equally effective in symptom improvement in patients with AD and anxious mood. In a random double-blind study trazodone was more effective than clorazepate in cancer patients for the relief of anxious and depressed symptoms. Similar findings were observed in HIV positive patients with AD.

## Refractory Patients and Nonresponse to Initial Treatment

Those patients who do not respond to counseling or the various modes of psychotherapy that have been outlined and to a trial of antidepressant or anxiolytic medications should be regarded as treatment nonresponders. It is essential to reevaluate the patient to ensure that the diagnostic impression has not altered and, in particular, that the patient has not developed a major mental disorder, which would require a more aggressive treatment, often biological. The psychiatrist must also consider that an Axis II disorder might be interfering with the patient's resolution of the AD. Finally, if the stressor continues and cannot be removed (e.g., the continuation of a seriously impairing chronic illness), additional support and management strategies need to be employed to assist the patient in optimally adapting to the stressor that she or he is confronting (e.g., experiencing the progression of HIV infection).

DSM-IV allows the use of the diagnosis of AD even after 6 months, and then it is described as AD, chronic. With such a contingency (e.g., AD lasting a few years), it is necessary to ensure that the patient is not experiencing dysthymic disorder or an unremitting depressive disorder. However, these diagnoses have a symptom profile that should distinguish them from the AD.

## Conclusion

Appropriate and timely treatment is essential for patients with AD so that their symptoms do not worsen; do not further impair their important relationships; and do not compromise their capacity to work, study, or be active in their interpersonal pursuits. Treatment must attempt to forestall further erosion of the patient's capacity to function that could ultimately have grave and untoward consequences. Maladaptation may so impede the patient that irreversible losses in important sectors of his or her life occur. Although this diagnosis lacks rigorous specificity, its treatment is no less challenging or less important. AD's lack of a designated symptom profile results in this diagnosis having insufficient specificity. However, it is this lack of specificity, which permits the psychiatrist to have a "diagnosis" to use when the patient is presenting with early, vague, nonconcrete symptomatology, which should be noted, identified and followed. This is similar to the situation with early fever, or fever of unknown origin, which, by the way, may never go on to a specific medical diagnosis, but be at discharge simply diagnosed as a "fever

of unknown origin". Unspecified chest pain is another example where the patient may never have a specific diagnosis even over time. Spitzer has described the ADs as a "wild card" in the psychiatric lexicon that allows a place for an uncertain, early, not completely developed diagnosis to be housed until it disappears, develops into a full blown category, persists in a subsyndromal state, or disappears. As said above, this is not uncommon with physical or mental subsyndromal states.

DSM-III-R has been described as "medical illness and age unfair" (i.e., it does not sufficiently take into account the issues of age and/or medical illness. DSM-IV-TR has tried to take this into account with considerable effort placed on those psychological interface disorders that border between physical and mental phenomena, for example, the somatoform disorders, AD, dissociation and so on. However, in addition to enhancing reliability and validity, the psychiatric taxonomy needs to consider the impact of developmental epochs (e.g., children and youth, adults, young elderly and "old" elderly) and medical illness on symptomatology. With regard to the latter issue, Endicott (1984) has described replacing vegetative with ideational symptoms when evaluating depressed patients with medical illness. Rapp and Vrana (1989) confirmed Endicott's proposed changes in the diagnostic criteria for depression in medically ill elderly persons and observed maintenance of specificity and sensitivity, respectively, when substituting ideational for vegetative symptoms. Recent studies found AD patients to be significantly younger compared with patients who have a major psychiatric diagnosis. Zarb's (1996) study suggests that cognitively impaired elderly, when evaluated using individual items of the Geriatric Depression Scale exhibited AD rather than major depressive disorder. In addition, Despland and colleagues (1995) reported that the patients' group with AD with depressive or mixed symptoms included more women, thus exhibiting a sex ratio resembling that for major depressive disorder or dysthymic disorder. Therefore, future editions of DSM may be able to take into account the differences encountered in symptom profiles for gender, various developmental epochs, and medical and psychiatric comorbidity. Finally, longitudinal observations would describe the outcome of AD over time. Their resolution, evolution to another diagnosis, their response to a variety of treatments would augment our understanding and approach to this important sub-threshold diagnosis.

### Comparison of DSM-IV/ICD-10 Diagnostic Criteria

In contrast to DSM-IV-TR (which requires the onset of symptoms within 3 months of the stressor), the ICD-10 Diagnostic Criteria for Research specify an onset within 1 month. Furthermore, ICD-10 excludes stressors of "unusual or catastrophic type". In contrast, DSM-IV-TR allows extreme stressors so long as the criteria are not met for post traumatic or acute stress disorder. ICD-10 also provides for several different subtypes, including "brief depressive reaction" (depressive state lasting 1 month or less) and "prolonged depressive reaction" (depressive state lasting up to 2 years).

Personality traits have long been the focus of considerable research. Their heritability, cross-situational consistency, temporal stability, functional relevance to work, well-being, marital stability and even physical health have been well established across many studies. Everybody has a personality, or a characteristic manner of thinking, feeling, behaving and relating to others. Some persons are typically introverted and withdrawn, others are more extraverted and outgoing. Some persons are invariably conscientious and efficient, whereas other persons might be consistently undependable and negligent. Some persons are characteristically anxious and apprehensive, whereas others are typically relaxed and unconcerned. These personality traits are often felt to be integral to each person's sense of self, as they involve what persons value, what they do, and their innate tendencies and preferences.

It is "when personality traits are inflexible and maladaptive and cause significant functional impairment or subjective distress [that] they constitute Personality Disorders" (American Psychiatric Association, 2000, p. 686). The *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR) (American Psychiatric Association, 2000) provides the diagnostic criteria for 10 personality disorders. Two additional diagnoses are placed within an appendix to DSM-IV for criteria sets provided for further study (passive-aggressive and depressive). This chapter begins with a discussion of the definition, etiology, assessment, epidemiology, course and treatment of personality disorders in general, followed by a discussion of these issues for the 12 individual personality disorders.

## Personality Disorder

### Definition

A personality disorder is defined in DSM-IV-TR as "an enduring pattern of inner experience and behavior that deviates markedly from the expectations of the individual's culture, is pervasive and inflexible, has an onset in adolescence or early adulthood, is stable over time, and leads to distress or impairment" (American Psychiatric Association, 2000, p. 686). The DSM-IV-TR general diagnostic criteria for a personality disorder are provided below.

Personality disorder is the only class of mental disorders in DSM-IV-TR for which an explicit definition and criterion set are provided. A general definition and criterion set can be useful to psychiatrists because the most common personality disorder diagnosis in clinical practice is often the diagnosis "not otherwise specified" (NOS) (Clark *et al.*, 1995). Psychiatrists provide the NOS diagnosis when they determine that a personality disorder

is present but the symptomatology fails to meet the criterion set for one of the 10 specific personality disorders. A general definition of what is meant by a personality disorder is therefore helpful when determining whether the NOS diagnosis should in fact be provided. Points worth emphasizing with respect to the general criterion set are presented in the following discussion of the assessment, differential diagnosis, epidemiology and course of personality disorders.

### DSM-IV-TR Criteria

#### General Diagnostic Criteria for Personality Disorder

- A. An enduring pattern of inner experience and behavior that deviates markedly from the expectations of the individual's culture. This pattern is manifested in two (or more) of the following areas:
  1. cognition (i.e., ways of perceiving and interpreting self, other people, and events)
  2. affectivity (i.e., the range, intensity, lability, and appropriateness of emotional response)
  3. interpersonal functioning
  4. impulse control
- B. The enduring pattern is inflexible and pervasive across a broad range of personal and social situations.
- C. The enduring pattern leads to clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- D. The pattern is stable and of long duration and its onset can be traced back at least to adolescence or early adulthood.
- E. The enduring pattern is not better accounted for as a manifestation or consequence of another mental disorder.
- F. The enduring pattern is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., head trauma).

## Etiology and Pathophysiology

A primary purpose of a diagnosis is to lead to scientific knowledge concerning the etiology for a patient's condition and the identification of a specific pathology for which a particular treatment (e.g., medication) would ameliorate the condition. However, many of the mental disorders in DSM-IV-TR, including the personality disorders, may not in fact have single etiologies or even specific pathologies. The DSM-IV-TR personality disorders might be, for the most part, constellations of maladaptive personality traits that are the result of multiple genetic dispositions interacting with a variety of detrimental environmental experiences. The DSM-IV-TR personality disorder diagnoses do provide the clinician with a substantial amount of important information concerning the etiology and pathology for a patient's particular personality syndrome, but there are likely to be alternative pathways to the development of maladaptive personality traits and alternative neurophysiological, cognitive-behavioral, interpersonal and psychodynamic models for their pathology (Livesley, 2001).

## Assessment and Differential Diagnosis

Since 1980, the multiaxial system appears to have been successful in encouraging psychiatrists no longer to make arbitrary distinctions between personality disorders and other mental disorders. Ironically, however, the placement of the personality disorders on a separate axis may have also contributed to the development of false assumptions and misleading expectations concerning the distinctions between personality disorders and other mental disorders with respect to etiology, pathology, or treatment. It has been difficult to provide a brief list of specific diagnostic criteria for the broad and complex behavior patterns that constitute a personality disorder. The only personality disorder to be diagnosed reliably in general clinical practice has been antisocial and the validity of this diagnosis has been questioned precisely because of its emphasis on overt and behaviorally specific acts of criminality, irresponsibility and delinquency.

There are assessment instruments, however, that will help psychiatrists obtain more reliable and valid personality disorder diagnoses. Semi-structured interviews will obtain reliable diagnoses of personality disorders and are therefore the preferred method for the assessment of personality disorders in clinical settings. Semi-structured interviews provide a researched set of required and recommended interview queries and observations to assess each of the personality disorder diagnostic criteria. Psychiatrists can find the administration of a semi-structured interview to be constraining but a major strength of semi-structured interviews is their assurance through an explicit structure that each relevant diagnostic criterion has in fact been systematically assessed. Idiosyncratic and subjective interviewing techniques are much more likely to result in gender- and culturally-biased assessments relative to unstructured clinical interviews. The manuals that accompany a semi-structured interview also provide useful information for understanding the rationale of each diagnostic criterion, for interpreting vague or inconsistent symptomatology, and for resolving diagnostic ambiguities. There are currently five semi-structured interviews for the assessment of the DSM-IV-TR (American Psychiatric Association, 2000) personality disorder diagnostic criteria: 1) Diagnostic Interview for Personality Disorders (Zanarini *et al.*, 1995); 2) International Personality Disorder Examination (Loranger, 1999); 3) Personality Disorder Interview-IV (Widiger *et al.*, 1995); 4) Structured Clinical Interview for DSM-IV-TR Axis II Personality

Disorders (First *et al.*, 1997); and 5) Structured Interview for DSM-IV-TR Personality Disorders (Pfohl *et al.*, 1997). The particular advantages and disadvantages of each particular interview have been discussed extensively (Widiger and Coker, 2002).

The administration of an entire personality disorder semi-structured interview can take 2 hours, an amount of time that is impractical for routine clinical practice. However, this time can be reduced substantially by first administering a self-report questionnaire that screens for the presence of the DSM-IV-TR personality disorders (Widiger and Coker, 2002). A psychiatrist can then confine the interview to the few personality disorders that the self-report inventory suggested would be present. Self-report inventories are useful in ensuring that all of the personality disorders were systematically considered and in alerting the clinician to the presence of maladaptive personality traits that might otherwise have been missed. There are a number of alternative self-report inventories that can be used and the advantages and disadvantages of each of them have been discussed extensively (Widiger and Coker, 2002).

Gender and cultural biases are one potential source of inaccurate personality disorder diagnosis that are worth noting in particular. One of the general diagnostic criteria for personality disorder is that the personality trait must deviate markedly from the expectations of a person's culture (see DSM-IV-TR general diagnostic criteria for personality disorders). The purpose of this cultural deviation requirement is to compel clinicians to consider the cultural background of the patient. A behavior pattern that appears to be aberrant from the perspective of one's own culture (e.g., submissiveness or emotionality) could be quite normative and adaptive within another culture. The cultural expectations or norms of the psychiatrist might not be relevant or applicable to a patient from a different cultural background. However, one should not infer from this requirement that a personality disorder is primarily or simply a deviation from a cultural norm. Deviation from the expectations of one's culture is not necessarily maladaptive, nor is conformity to one's culture necessarily healthy. Many of the personality disorders may even represent (in part) extreme or excessive variants of behavior patterns that are valued or encouraged within a particular culture. For example, it is usually adaptive to be confident but not to be arrogant, to be agreeable but not to be submissive, or to be conscientious but not to be perfectionistic. Gender and cultural biases of particular relevance to individual personality disorders will be discussed further in the chapter.

## Epidemiology and Comorbidity

Virtually all patients must have had a characteristic manner of thinking, feeling, behaving and relating to others prior to the onset of an Axis I disorder that could have an important impact on the course and treatment of the respective mental disorder and many of these persons would be diagnosed with a DSM-IV-TR personality disorder. Estimates of the prevalence of personality disorder within clinical settings is typically above 50%. As many as 60% of inpatients within some clinical settings would be diagnosed with borderline personality disorder and as many as 50% of inmates within a correctional setting could be diagnosed with antisocial personality disorder. Although the comorbid presence of a personality disorder is likely to have an important impact on the course and treatment of an Axis I disorder the prevalence of personality disorder is generally underestimated in clinical practice due in part to the failure to provide systematic or

comprehensive assessments of personality disorder symptomatology and perhaps as well to the lack of funding for the treatment of personality disorders.

Approximately 10 to 15% of the general population would be diagnosed with one of the 10 DSM-IV-TR personality disorders, excluding PDNOS. However the studies of community populations have important limitations that qualify their results. For example, many of the studies sampled persons who would probably have less personality disorder pathology than a randomly selected sample (e.g., some studies have sampled persons without any history of Axis I psychopathology) and the studies have used either the DSM-III (American Psychiatric Association, 1980) or DSM-III-R (American Psychiatric Association, 1987) criterion sets rather than DSM-IV-TR (American Psychiatric Association, 2000). Nevertheless, the prevalence estimates are generally close to those provided in DSM-IV-TR. Prevalence rates for individual personality disorders will be discussed later in this chapter.

There is also considerable personality disorder diagnostic cooccurrence (Table 62.1). Patients who meet the DSM-IV diagnostic criteria for one personality disorder are likely to meet the diagnostic criteria for another DSM-IV instructs psychiatrists that all diagnoses should be recorded because it can be important to consider (for example) the presence of antisocial traits in someone with a borderline personality disorder or the presence of paranoid traits in someone with a dependent personality disorder. However, the extent of diagnostic cooccurrence is at times so extensive that most researchers prefer a more dimensional description of personality. Diagnostic categories provide clear, vivid descriptions of discrete personality types but the personality structure of actual patients might be more accurately described by a constellation of maladaptive personality traits.

Alternative dimensional models of personality disorder are being developed. One such model, based on a theory of temperament and character, consists of seven dimensions. Cloninger (2000) proposes that there are four temperaments (reward dependence, harm avoidance, novelty seeking and persistence), each governed by a particular neurotransmitter system, and three character dimensions (self-directedness, cooperativeness and self-transcendence). The presence of a personality disorder is said to be determined primarily by the four temperaments and

the particular form or manner of the personality disorder by the three character dimensions.

Alternative dimensional models of personality disorder are being developed. One such model, based on a theory of temperament and character, consists of seven dimensions. Cloninger (2000) proposes that there are four temperaments (reward dependence, harm avoidance, novelty seeking and persistence), each governed by a particular neurotransmitter system, and three character dimensions (self-directedness, cooperativeness and self-transcendence). The presence of a personality disorder is said to be determined primarily by the four temperaments and the particular form or manner of the personality disorder by the three character dimensions. Another approach has been to apply the predominant model of general personality functioning to the study of personality disorders. Five broad domains of personality functioning have been identified empirically through the study of the languages of a number of different cultures. Language can be understood as a sedimentary deposit of the observations of persons over the thousands of years of the language's development and transformation. The most important domains of personality functioning would be those with the greatest number of terms to describe and differentiate their various manifestations and nuances, and the structure of personality will be evident by the empirical relationship among the trait terms. Such lexical analyses of languages have typically identified five fundamental dimensions of personality: neuroticism (or negative affectivity) versus emotional stability, introversion versus extraversion, conscientiousness versus undependability, antagonism versus agreeableness, and closedness versus openness to experience (Costa and McCrae, 1992). Each of these five broad domains can be differentiated further in terms of underlying facets. For example, the facets of antagonism versus agreeableness include suspiciousness versus trusting gullibility, tough-mindedness versus tender-mindedness, confidence and arrogance versus modesty and meekness, exploitation versus altruism and sacrifice, oppositionalism and aggression versus compliance, and deception and manipulation versus straightforwardness and honesty. Each of the DSM-IV-TR personality disorders can be understood as maladaptive variants of these personality traits that are evident in all persons to varying degrees.

Table 62.2 provides a description of the DSM-IV-TR personality disorders in terms of this five-factor model. For example, the schizoid personality disorder may represent an extreme variant of introversion, avoidant may represent extreme neuroticism and introversion, and antisocial personality disorder an extreme variant of antagonism and undependability. Advantages of understanding personality disorders in terms of this dimensional model are the provision of more specific descriptions of individual patients (including adaptive as well as maladaptive personality functioning) and the avoidance of arbitrary categorical distinctions. An additional factor is the ability to bring to bear on an understanding of personality disorders the extensive amount of research on the heritability, temperament, development and course of general personality functioning.

### Course

Personality disorders must be evident since adolescence or young adulthood and have been relatively chronic and stable throughout adult life (see DSM-IV-TR criteria for personality disorders). The World Health Organization's (WHO) *International Classification of Diseases*, 10th Revision (ICD-10, World Health Organization, 1992) does recognize the existence of personality change second-

ary to catastrophic experiences and to brain injury or disease, but only the latter is included within DSM-IV-TR (American Psychiatric Association, 2000). A 75-year-old man can be diagnosed with a DSM-IV-TR dependent personality disorder but the symptoms must have been present throughout the duration of his adulthood (e.g., since the age of 18 years) unless the dependent behavior was a direct, explicit expression of a neurochemical disease or lesion.

The requirement that a personality disorder be evident since late adolescence and be relatively chronic thereafter has been a traditional means with which to distinguish a personality disorder from an Axis I disorder. Mood, anxiety, psychotic, sexual and other mental disorders have traditionally been conceptualized as conditions that arise at some point during a person's life and that are relatively limited or circumscribed in their expression and duration. Personality disorders, in contrast, are conditions that are evident as early as late adolescence (and in some instances prior to that time), are evident in everyday functioning, and are stable throughout adulthood. However, the consistency of this distinction across disorders in the classification has been decreasing with each edition of the DSM, as early-onset and chronic variants of Axis I disorders are

being added to the diagnostic manual (e.g., early-onset dysthymia and generalized social phobia). Some researchers have in fact suggested abandoning the concept of personality disorders and replacing them with early-onset and chronic variants of existing Axis I disorders. For example, avoidant personality disorder could become generalized social phobia, obsessive-compulsive personality disorder could become an early-onset variant of obsessive-compulsive anxiety disorder, and borderline personality disorder could become an early-onset and chronic mood dyscontrol.

## Treatment

One of the mistaken assumptions or expectations of Axis II is that personality disorders are untreatable. In fact, maladaptive personality traits are often the focus of clinical attention. Personality disorders are among the more difficult of mental disorders to treat as they involve entrenched behavior patterns, some of which will be integral to a patient's self-image. Nevertheless, there is compelling empirical support to indicate that meaningful responsiveness to psychosocial and pharmacologic treatment does occur. Treatment of a personality disorder is unlikely to result in the development of a fully healthy or ideal personality structure, but clinically and socially meaningful change to personality structure and functioning does occur. In fact, given the considerable social, occupational, medical and other costs that are engendered by such personality disorders as the antisocial and borderline, even marginal reductions in symptomatology can represent quite significant and meaningful public health care, social and clinical benefits.

DSM-IV-TR includes 10 individual personality disorder diagnoses that are organized into three clusters: 1) paranoid, schizoid and schizotypal (placed within an odd-eccentric cluster); 2) antisocial, borderline, histrionic and narcissistic (dramatic-emotional-erratic cluster); and 3) avoidant, dependent and obsessive-compulsive (anxious-fearful cluster) (American Psychiatric Association, 2000). Each of these personality disorders, along with the two that are included in the appendix to DSM-IV-TR for disorders needing further study (i.e., passive-aggressive and depressive), will be discussed in turn.

## Paranoid Personality Disorder

### Definition

Paranoid personality disorder (PPD) involves a pervasive and continuous distrust and suspiciousness of the motives of others) but the disorder is more than just suspiciousness. Persons with this disorder are also hypersensitive to criticism, they respond with anger to threats to their autonomy, they incessantly seek out confirmations of their suspicions, and they tend to be quite rigid in their beliefs and perceptions of others. The presence of PPD is indicated by four or more of the seven diagnostic criteria presented in the DSM-IV criteria for PPD.

### Etiology and Pathology

Research has indicated a genetic contribution to the development of suspiciousness and mistrust. There is some support for a genetic relationship of PPD with schizophrenia but these findings have not always been replicated and the findings may have been due to the overlap of PPD with the schizotypal personality disorder

## DSM-IV-TR Criteria 301.0

### Paranoid Personality Disorder

- A. A pervasive distrust and suspiciousness of others such that their motives are interpreted as malevolent, beginning by early adulthood, and present in a variety of contexts, as indicated by four (or more) of the following:
- (1) suspects, without sufficient basis, that others are exploiting, harming, or deceiving him or her
  - (2) is preoccupied with unjustified doubts about the loyalty or trustworthiness of friends or associates
  - (3) is reluctant to confide in others because of unwarranted fear that the information will be used maliciously against him or her
  - (4) reads hidden demeaning or threatening meanings into benign remarks or events
  - (5) persistently bears grudges, i.e. is unforgiving of insults, injuries, or slights
  - (6) perceives attacks on his or her character or reputation that are not apparent to others and is quick to react angrily or to counterattack
  - (7) has recurrent suspicions, without justification, regarding fidelity of spouse or sexual partner
- B. Does not occur exclusively during the course of schizophrenia, a mood disorder with psychotic features, or another psychotic disorder, and is not due to the direct physiological effects of a general medical condition.

**Note:** if criteria are met prior to the onset of schizophrenia, add "premorbid", e.g., paranoid personality disorder (premorbid).

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

There are no systematic studies on possible psychosocial contributions to the development of PPD. There is some support for the contribution of excessive parental criticism and rejection but there has not yet been adequate prospective longitudinal studies. Paranoid belief systems could develop through parental modeling, a history of discriminatory exploitation or abandonment, or the projection of anger, resentment and bitterness onto a group that is external to, and distinct from, oneself. Mistrust and suspicion is often evident in members of minority groups, immigrants, refugees and other groups for whom such distrust can be a realistic and appropriate response to the social environment. It is conceivable that a comparably sustained experience through childhood and adolescence could contribute to the development of excessive paranoid beliefs that are eventually applied inflexibly and inappropriately to a wide variety of persons, but it can be very difficult to determine what is excessive or unrealistic suspicion and mistrust within a member of an oppressed minority. Paranoid suspiciousness could in fact be more closely associated with prejudicial attitudes, wherein a particular minority group in society becomes the inappropriate target of one's anger, blame and resentment.

There has been little consideration given to the neurophysiological concomitants of nonpsychotic paranoid personality traits. More attention has been given to cognitive, interpersonal and object-relational models of pathology. Paranoid beliefs do appear to have a self-perpetuating tendency resulting from the narrow and limited focus on signs and evidence for malicious intentions. The pathology of PPD, from this perspective, is inherent to the irrationality of the person's belief systems and is sustained by the biased information processing. There may also be an underlying motivation or need to perceive threats in others and to externalize blame that help to sustain the accusations and distortions.

### Differential Diagnosis

PPD paranoid ideation is inconsistent with reality and is resistant to contrary evidence but the ideation is not psychotic, absurd, inconceivable, or bizarre. PPD also lacks other features of psychotic and delusional disorders (e.g., hallucinations) and is evident since early adulthood, whereas a psychotic disorder becomes evident later within a person's life or remits after a much briefer period of time. Persons with PPD can develop psychotic disorders but to diagnose PPD in such cases the paranoid personality traits must be evident prior to and persist after the psychotic episode. If PPD precedes the onset of schizophrenia, then it should be noted that it is premorbid to the schizophrenia (American Psychiatric Association, 2000). However, it may not be meaningful to diagnose a person with both PPD and schizophrenia, as the premorbid paranoid traits may in some cases have simply represented a prodromal phase of the schizophrenic pathology.

### Epidemiology and Comorbidity

Trust versus mistrust is a fundamental personality trait along which all persons vary. Thirteen percent of the adult male population and 6% of the adult female population may be characteristically mistrustful of others (Costa and McCrae, 1992). However, only 0.5 to 2.5% of the population are likely to meet the DSM-IV-TR diagnostic criteria for a PPD. It is suggested in DSM-IV-TR that approximately 10 to 30% of persons within inpatient settings and 2 to 10% within outpatient settings have this disorder (American Psychiatric Association, 2000) but the lower end of these rates may represent the more accurate estimate. It does appear that more males than females have the disorder.

Paranoid personality traits are evident in other personality disorders. Persons with avoidant personality disorder are socially withdrawn and apprehensive of others; borderline, antisocial and narcissistic persons may be impatient, irritable and antagonistic; and schizotypal persons may display paranoid ideation. The diagnosis of PPD often cooccurs with these other personality disorder diagnoses. Persons with PPD are prone to develop a variety of Axis I disorders, including substance-related, obsessive-compulsive anxiety, agoraphobia and depressive disorders (American Psychiatric Association, 2000).

### Course

Premorbid traits of PPD may be evident prior to adolescence in the form of social isolation, hypersensitivity, hypervigilance, social anxiety, peculiar thoughts, angry hostility and idiosyncratic fantasies (American Psychiatric Association, 2000). As children, they may appear odd and peculiar to their peers and they may not have achieved to their capacity in school. Their adjustment as adults is particularly poor with respect to interpersonal relationships. They may become socially isolated or fanatic members of groups that

encourage or at least accept their paranoid ideation. They might maintain a steady employment but are difficult coworkers, as they tend to be rigid, controlling, critical, blaming and prejudicial. They are likely to become involved in lengthy, acrimonious and litigious disputes that are difficult, if not impossible, to resolve.

### Treatment

Persons with PPD rarely seek treatment for their feelings of suspiciousness and distrust. They experience these traits as simply accurate perceptions of a malevolent and dangerous world (i.e., egosyntonic). They may not consider the paranoid attributions to be at all problematic, disruptive, or maladaptive. They are not delusional but they also fail to be reflective, insightful, or self-critical. They may recognize only that they have difficulty controlling their anger and getting along with others. They might be in treatment for an anxiety, mood, or substance-related disorder or for various marital, familial, occupational, or social (or legal) conflicts that are secondary to their personality disorder but they also externalize the responsibility for their problems and have substantial difficulty recognizing their own contribution to their internal dysphoria and external conflicts. They consider their problems to be due to what others are doing to them, not to how they perceive, react, or relate to others.

The presence of paranoid personality traits complicate the treatment of an Axis I disorder or a relationship problem. Trust is central to the development of an adequate therapeutic alliance, yet it is precisely the absence of trust that is central to this disorder. It can be tempting to be less than forthright and open in the treatment of excessively suspicious persons because they distort, exaggerate, or escalate minor errors, misunderstandings, or inconsistent statements. However, therapists find that they weave an increasingly tangled web as they walk gingerly around the truth. Also, persons with PPD seize upon any kernel of deception to confirm their suspicion that the therapist is not to be trusted. It is preferable to be especially forthright and precise with paranoid patients. Details that are inconsequential and of no interest to most patients can be important to provide to persons with PPD so that they are ensured that nothing is being withheld or hidden from them.

Clinicians agree on several general principles in the treatment of paranoid personality. It is usually pointless and often harmful to rapport or to confront (or argue with) the paranoid beliefs. Such efforts may only alienate the patient and confirm his or her suspicions. The therapist should maintain a sincere and consistent respect for their autonomy and for their right to make their own decisions. However, one should not attempt to ingratiate oneself by being overly acquiescent and compliant. This can appear to be obviously patronizing, insincere, or manipulative. The goal is to develop, in a nonthreatening way, more self-reflection and self-awareness (e.g., recognition of the contribution of the paranoid traits and behaviors to the difficulties they are experiencing within their lives). A useful approach can be to communicate a sincere and respectful willingness to explore the implications, logic and reality of the suspicions. Whenever one appears to be endangering rapport by moving too quickly, one should retreat to a more neutral and accepting position.

One must also be careful to avoid defensive reactions to the inevitable accusations. Any one of the conflicts they have had with others can develop within the therapeutic relationship and persons with PPD have a tendency to be contentious, rigid, accusatory, suspicious and litigious that can tax the empathy and patience of the therapist. One must attempt to maintain an

empathic concern for their feelings of betrayal, and reassure them in an understanding, forthright manner that is neither patronizing nor disrespectful. Termination of treatment may at times be necessary if continuation would only result in further acrimony.

The suspicions, accusations and acrimony often makes the person with PPD a poor candidate for group therapies. There is the potential to learn much about themselves within a group, but it is usually very difficult for them to develop the feelings of trust, respect and security that are necessary for successful group therapy. Their propensity to make unfair hostile accusations alienate them from other group members, and they may quickly become a scapegoat for difficulties and conflicts that develop within the group.

There have been a variety of studies on the pharmacologic treatment of psychotic paranoid ideation and of schizotypal PD (which often includes paranoid personality traits) but little to no research on the pharmacologic responsiveness of the nonpsychotic suspiciousness and egosyntonic paranoid ideation of PPD. Persons with PPD may also perceive the use of a medication to represent an effort simply to suppress or control their accusations and suspicions rather than respectfully to consider and address them. However, they may be receptive and responsive to the benefits of a medication to help control feelings of anxiousness or depression that are secondary to their personality disorder.

### DSM-IV-TR Criteria 301.20

#### Schizoid Personality Disorder

- A. A pervasive pattern of detachment from social relationships and a restricted range of expression of emotions in interpersonal settings, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:
- (1) neither desires nor enjoys close relationships, including being part of a family
  - (2) almost always chooses solitary activities
  - (3) has little, if any, interest in having sexual experiences with another person
  - (4) takes pleasure in few, if any, activities
  - (5) lacks close friends or confidants other than first-degree relatives
  - (6) appears indifferent to the praise or criticism of others
  - (7) emotional coldness, detachment, or flattened affectivity
- B. Does not occur exclusively during the course of schizophrenia, a mood disorder with psychotic features, another psychotic disorder, or a pervasive developmental disorder, and is not due to the direct physiological effects of a general medical condition.

**Note:** if criteria are met prior to the onset of schizophrenia, add “premorbid”, e.g., schizoid personality disorder (premorbid).

## Schizoid Personality Disorder

### Definition

The schizoid personality disorder (SZPD) is a pervasive pattern of social detachment and restricted emotional expression. Introversion (versus extraversion) is one of the fundamental dimensions of general personality functioning. Facets of introversion include low warmth (e.g., cold, detached, impersonal), low gregariousness (socially isolated, withdrawn) and low positive emotions (reserved, constricted or flat affect, anhedonic), which define well the central symptoms of SZPD (see Table 62.1). The presence of SZPD is indicated by four or more of the seven diagnostic criteria presented in the DSM-IV criteria for SZPD.

### Etiology and Pathology

A fundamental distinction for schizophrenic symptomatology is between positive and negative symptoms. Positive symptoms include hallucinations, delusions, inappropriate affect and loose associations; negative symptoms include flattened affect, alogia, anhedonia and avolition. SZPD has been conceptualized as representing subthreshold negative symptoms, comparable to the subthreshold positive symptoms (cognitive–perceptual aberrations) that predominate schizotypal personality disorder (STPD). However, a genetic link of SZPD to schizophrenia that cannot be accounted for by comorbid STPD symptomatology has not been well established. Research has supported heritability for the personality dimension of introversion–extraversion and for the association of SZPD with introversion. The central pathology of SZPD does appear to be anhedonic deficits, or an excessively low ability to experience positive affect. Psychosocial models for the etiology of SZPD are lacking. It is possible that a sustained history of isolation during infancy and childhood, with an encouragement and modeling by parental figures of interpersonal withdrawal, indifference and detachment could contribute to the development of schizoid personality traits.

### Differential Diagnosis

SZPD can be confused with the schizotypal and avoidant personality disorders as both involve social isolation and withdrawal. Schizotypal personality disorder, however, also includes an intense social anxiety and cognitive–perceptual aberrations. The major distinction with avoidant personality disorder is the absence of an intense desire for intimate social relationships. Avoidant persons will also exhibit substantial insecurity and inhibition, whereas the schizoid person is largely indifferent toward the reactions or opinions of others.

The presence of premorbid schizoid traits can have prognostic significance for the course and treatment of schizophrenia but, more importantly, it might not be meaningful to suggest that a person has a schizoid personality disorder that is independent of or unrelated to a comorbid schizophrenia. The negative, prodromal and residual symptoms of schizophrenia resemble closely the features of SZPD. Once a person develops schizophrenia, a diagnosis of SZPD can become rather pointless as all of the schizoid symptoms can then be understood as (prodromal or residual) symptoms of schizophrenia.

### Epidemiology and Comorbidity

Approximately half of the general population will exhibit an introversion within the normal range of functioning. However, only a small minority of the population would be diagnosed with a schizoid personality disorder. Estimates of the prevalence of

SZPD within the general population have been less than 1% and SZPD is among the least frequently diagnosed personality disorders within clinical settings. Many of the persons who were diagnosed with SZPD prior to DSM-III are probably now diagnosed with either the avoidant or the schizotypal personality disorders and prototypic (pure) cases of SZPD are likely to be quite rare within the population.

### Course

Persons with SZPD are socially isolated and withdrawn as children. They may not have been accepted well by their peers, and may have even borne the brunt of some ostracism (American Psychiatric Association, 2000). As adults, they have few friendships. The friendships that do occur are likely to be initiated by their peers or colleagues. They have few sexual relationships and may never marry. Relationships fail to the extent to which the other person desires or needs emotional support, warmth and intimacy. Persons with SZPD may do well and even excel within an occupation, as long as substantial social interaction is not required. They prefer to work in isolation. They may eventually find employment and a relationship that is relatively comfortable, but they could also drift from one job to another and remain isolated throughout much of their life. If they do eventually become a parent, they have considerable difficulty providing warmth and emotional support, and they may appear neglectful, detached and disinterested.

### Treatment

Prototypic cases of SZPD rarely present for treatment, whether it is for their schizoid traits or a concomitant Axis I disorder. They feel little need for treatment, as their isolation is often egosyntonic. Their social isolation is of more concern to their relatives, colleagues, or friends than to themselves. Their disinterest in and withdrawal from intimate or intense interpersonal contact is also a substantial barrier to treatment. They at times appear depressed but one must be careful not to confuse their anhedonic detachment, withdrawal and flat affect with symptoms of depression.

If persons with SZPD are seen for treatment for a concomitant Axis I disorder (e.g., a sexual arousal disorder or a substance dependence) it is advisable to work within the confines and limitations of the schizoid personality traits. Charismatic, engaging, emotional, or intimate therapists can be very uncomfortable, foreign and even threatening to persons with SZPD. A more business-like approach can be more successful.

It is also important not to presume that persons with SZPD are simply inhibited, shy, or insecure. Such persons are more appropriately diagnosed with the avoidant personality disorder. Persons with SZPD are perhaps best treated with a supportive psychotherapy that emphasizes education and feedback concerning interpersonal skills and communication. One may not be able to increase the desire for social involvements but one can increase the ability to relate to, communicate with and get along with others. Persons with SZPD may not want to develop intimate relationships but they will often want to interact and relate more effectively and comfortably with others. The use of role playing and videotaped interactions can at times be useful in this respect. Persons with SZPD can have tremendous difficulty understanding how they are perceived by others or how their behavior is unresponsive to and perceived as rejecting by others.

Group therapy is often useful as a setting in which the patient can gradually develop self-disclosure, experience the interest of others, and practice social interactions with immediate and supportive

feedback. However, persons with SZPD are prone to being rejected by a group due to their detachment, flat affect and indifference to the feelings of others. If the group is patient and accepting, they can benefit from the experience.

There have been many studies on the pharmacologic treatment of the schizotypal PD but no comparable studies on SZPD. The schizotypal and schizoid PDs share many features, but the responsiveness of the schizotypal PD to pharmacotherapy will usually reflect schizotypal social anxiety and cognitive-perceptual aberrations that are not seen in prototypic, pure cases of SZPD.

## Schizotypal Personality Disorder

### Definition

Schizotypal PD (STPD) is a pervasive pattern of interpersonal deficits, cognitive and perceptual aberrations, and eccentricities of behavior (American Psychiatric Association, 2000). The interpersonal deficits are characterized in large part by an acute discomfort with and reduced capacity for close relationships. The symptomatology of STPD has been differentiated further into components of positive (cognitive, perceptual aberrations) and negative (social aversion and withdrawal) symptoms comparable to the distinctions made for schizophrenia. The presence of STPD is indicated by five or more of the nine diagnostic criteria listed in the DSM-IV criteria for STPD.

### Etiology and Pathology

There is substantial empirical support for a genetic association of STPD with schizophrenia which is not surprising given that the diagnostic criteria were obtained from the observations of biological relatives of persons with schizophrenia. Research has indicated further that the positive and negative symptoms may even have a distinct genetic relationship with the comparable symptoms of schizophrenia. This suggests that the influence of familial etiological factors determining the expression of these symptom dimensions reaches across the boundary of psychotic illness to phenomena currently classified under the rubric of personality.

A predominant model for the psychopathology of STPD is deficits or defects in the attention and selection processes that organize a person's cognitive-perceptual evaluation of and relatedness to his or her environment. These defects may lead to discomfort within social situations, misperceptions and suspicions, and to a coping strategy of social isolation. Correlates of central nervous system dysfunction seen in persons with schizophrenia have been observed in laboratory tests of persons with STPD, including performance on tests of visual and auditory attention (e.g., backward masking and sensory gating tests) and smooth pursuit eye movement. This dysfunction may be the result of dysregulation along dopaminergic pathways, which could be serving to modulate the expression of an underlying schizotypal genotype.

### Differential Diagnosis

Avoidant personality disorder and STPD share the features of social anxiety and introversion, but the social anxiety of STPD does not diminish with familiarity, whereas the anxiety of avoidant PD (AVPD) is concerned primarily with the initiation of a relationship. STPD is also a more severe disorder that includes a variety of cognitive and perceptual aberrations that are not seen in persons with AVPD.

**DSM-IV-TR Criteria** 301.22**Schizotypal Personality Disorder**

- A. A pervasive pattern of social and interpersonal deficits marked by acute discomfort with, and reduced capacity for, close relationships as well as by cognitive or perceptual distortions and eccentricities of behavior, beginning by early adulthood, and present in a variety of contexts, as indicated by five (or more) of the following:
- (1) ideas of reference (excluding delusions of reference)
  - (2) odd beliefs or magical thinking that influences behavior and is inconsistent with subcultural norms (e.g., superstitiousness, belief in clairvoyance, telepathy, or “sixth sense”; in children and adolescents, bizarre fantasies or preoccupations)
  - (3) unusual perceptual experiences, including bodily illusions
  - (4) odd thinking and speech (e.g., vague, circumstantial, metaphorical, overelaborate, or stereotyped)
  - (5) suspiciousness or paranoid ideation
  - (6) inappropriate or constricted affect
  - (7) behavior or appearance that is odd, eccentric, or peculiar
  - (8) lacks close friends or confidants other than first-degree relatives
  - (9) excessive social anxiety that does not diminish with familiarity and tends to be associated with paranoid fears rather than negative judgments about self
- B. Does not occur exclusively during the course of schizophrenia, a mood disorder with psychotic features, another psychotic disorder, or a pervasive developmental disorder.

**Note:** if criteria are met prior to the onset of schizophrenia, add “premorbid”; e.g., schizotypal personality disorder (premorbid).

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

An initial concern of many clinicians when confronted with a person with STPD is whether the more appropriate diagnosis is schizophrenia. Persons with STPD closely resemble persons within the prodromal or residual phases of schizophrenia. This differentiation is determined largely by the absence of a deterioration in functioning. It is indicated in DSM-IV that one should note that STPD is “premorbid” if the schizotypal symptoms were present prior to the onset of schizophrenia (American Psychiatric Association, 2000). Premorbid schizotypal traits will have prognostic significance for the course and treatment of schizophrenia and such traits should then be noted. However, as discussed for SZPD, in most of these cases the schizotypal PD symptoms could then be readily understood as prodromal symptoms of schizophrenia.

**Epidemiology and Comorbidity**

STPD may occur in as much as 3% of the general population although most studies with semistructured interviews have suggested a somewhat lower percentage. STPD might occur somewhat more often in males. STPD cooccurs most often with the schizoid, borderline, avoidant and paranoid personality disorders. Common Axis I disorders are major depressive disorder, brief psychotic disorder and generalized social phobia.

**Course**

STPD is classified within the same diagnostic grouping as schizophrenia in ICD-10 (World Health Organization, 1992) because of its close relationship in phenomenology, etiology and pathology. However, it is classified as a personality disorder in DSM-IV-TR (American Psychiatric Association, 2000) because its course and phenomenology are more consistent with a disorder of personality (i.e., early onset, evident in everyday functioning, characteristic of long-term functioning and egosyntonic). Persons with STPD are likely to be rather isolated in childhood. They may have appeared peculiar and odd to their peers, and may have been teased or ostracized. Achievement in school is usually impaired, and they may have been heavily involved in esoteric fantasies and peculiar interests, particularly those that do not involve peers. As adults, they may drift toward esoteric–fringe groups that support their magical thinking and aberrant beliefs. These activities can provide structure for some persons with STPD, but they can also contribute to a further loosening and deterioration if there is an encouragement of aberrant experiences. Only a small proportion of persons with STPD develop schizophrenia. The symptomatology of STPD does not appear to remit with age. The course appears to be relatively stable, with some proportion of schizotypal persons remaining marginally employed, withdrawn, and transient throughout their lives.

**Treatment**

Persons with STPD may seek treatment for their feelings of anxiousness, perceptual disturbances, or depression. Treatment of persons with STPD should be cognitive, behavioral, supportive and/or pharmacologic, as they will often find the intimacy and emotionality of reflective, exploratory psychotherapy to be too stressful and they have the potential for psychotic decompensation.

Persons with STPD will often fail to consider their social isolation and aberrant cognitions and perceptions to be particularly problematic or maladaptive. They may consider themselves to be simply eccentric, creative, or nonconformist. Rapport can be difficult to develop as increasing familiarity and intimacy may only increase their level of discomfort and anxiety. They are unlikely to be responsive to informality or playful humor. The sessions should be well-structured to avoid loose and tangential ideation.

Practical advice is usually helpful and often necessary. The therapist should serve as the patient’s counselor, guide, or “auxiliary ego” to more adaptive decisions with respect to everyday problems (e.g., finding an apartment, interviewing for a job and personal appearance). Persons with STPD should also receive social skills training directed at their awkward and odd behavior, mannerisms, dress and speech. Specific, concrete discussions on what to expect and do in various social situations (e.g., formal meetings, casual encounters and dates) should be provided. The rate of progress will tend to be slow, and it is helpful if there remains a continuity in the therapeutic relationship.

Most of the systematic empirical research on the treatment of STPD has been confined to pharmacologic interventions. Low doses of neuroleptic medications (e.g., thiothixene) have shown some effectiveness in the treatment of schizotypal symptoms, particularly the perceptual aberrations and social anxiousness. Group therapy has also been recommended for persons with STPD but only when the group is highly structured and supportive. The emotional intensity and intimacy of unstructured groups will usually be too stressful. Schizotypal patients with predominant paranoid symptoms may even have difficulty in highly structured groups.

## Antisocial Personality Disorder

### Definition

Antisocial PD (ASPD) is a pervasive pattern of disregard for and violation of the rights of others (American Psychiatric Association, 2000). Persons with ASPD will also be irresponsible and exploitative in their sexual relationships, and irresponsible as employees and parents. They may display a lack of empathy, an inflated or arrogant self-appraisal, a callous, cynical and contemptuous response to the suffering of others, and a glib, superficial charm. This disorder has also been referred to as psychopathy, sociopathy, or dissociative personality disorder. The presence of ASPD is indicated by the occurrence of a conduct disorder prior to age 15 years and by three of the seven adult diagnostic criteria presented in DSM-IV Criteria for ASPD.

### Etiology and Pathology

There is considerable support from twin, family and adoption studies for a genetic contribution to the etiology of the criminal, delinquent tendencies of persons with ASPD. The genetic disposition may be somewhat stronger in ASPD females due perhaps to a greater social pressure on females against aggressive, exploitative and criminal behavior. What is inherited by persons with ASPD, however, is unclear; it could be impulsivity, antagonistic callousness, or abnormally low anxiousness.

A predominant theory for the etiology of ASPD is that it results from abnormally low levels of behavioral inhibition and high levels of behavioral activation systems that are important for normal, adaptive functioning. The behavioral inhibition system (BIS) is responsible for inhibiting behavior in response to punishment and acts in opposition to the behavioral activation system (BAS) that activates behavior in response to reward. The BIS has input into the reticular activating system providing experiences of anxiety or arousal. The clinical symptoms of ASPD might be manifestations of a weak or deficient BIS in combination with a normal or strong BAS that reduce normal sensitivity and anxiety in response to threatening and stressful situations. Activities that the average person would find stimulating, antisocial persons would find dull, impelling them to engage in risky, reckless, prohibited and impulsive activities. Low arousal would also help minimize feelings of anxiety, guilt, or remorse and help resist aversive conditioning. Studies have indicated an electrodermal response hyporeactivity in psychopathic persons. This hyporeactivity may be particularly associated with a deficit in anticipatory anxiety and worrying, while not impairing the alarm reactions of flight versus fight. Abnormally low levels of behavioral inhibition may be mediated by the septohippocampal system (and the neurotransmitter serotonin). Deficiencies in response modulation (difficulties suspending a dominant set in

## DSM-IV-TR Criteria 301.7

### Antisocial Personality Disorder

- A. There is a pervasive pattern of disregard for and violation of the rights of others (occurring since age 15 years), as indicated by three (or more) of the following:
- (1) failure to conform to social norms with respect to lawful behaviors as indicated by repeatedly performing acts that are grounds for arrest
  - (2) deceitfulness, as indicated by repeated lying, use of aliases, or conning others for personal profit or pleasure
  - (3) impulsivity or failure to plan ahead
  - (4) irritability and aggressiveness, as indicated by repeated physical fights or assaults
  - (5) reckless disregard for safety of self or others
  - (6) consistent irresponsibility, as indicated by repeated failure to sustain consistent work behavior or honor financial obligations
  - (7) lack of remorse, as indicated by being indifferent to or rationalizing having hurt, mistreated, or stolen from another
- B. The individual is at least age 18 years.
- C. Evidence of conduct disorder with onset before age 15 years.
- D. The occurrence of antisocial behavior is not exclusively during the course of schizophrenia or a manic episode.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

response to negative feedback) are apparent in animals with septohippocampal dysfunction.

There are also substantial data to support the contribution of family, peer, and other environmental factors. No single environmental factor appears to be specific to its development. Modeling by parental figures and peers, excessively harsh, lenient, or erratic discipline, and a tough, harsh environment in which feelings of empathy and warmth are discouraged (if not punished) and tough-mindedness, aggressiveness and exploitation are encouraged (if not rewarded) have all been associated with the development of ASPD. For example, ASPD in some cases could be the result of an interaction of early experiences of physical or sexual abuse, exposure to aggressive parental models and erratic discipline that develop a view of the world as a hostile environment, which is further affirmed over time through selective attention on cues for antagonism, encouragement and modeling of aggression by peers, and the immediate benefits that result from aggressive, exploitative behavior. Persons with ASPD may have had their feelings of anxiety, guilt and remorse extinguished through progressive and cumulative experiences of harsh aggression, violence, abuse and exploitation.

The development of adequate guilt, conscience and shame may also require a degree of distress-proneness (anxiousness or neuroticism) and attentional self-regulation (constraint). Normal

levels of neuroticism will promote the internalization of a conscience (the introjection of the family's moral values) by associating distress and anxiety with wrongdoing, and the temperament of self-regulation will help modulate impulses into a socially acceptable manner. Studies have indicated that high levels of arousal at age 15 years serve as a protective factor against criminal activities at age 30 years in persons at high risk for becoming criminals. Additional factors may also help to avoid the development of ASPD, such as high intelligence which may contribute to the availability of alternative life paths, while other factors may exacerbate or escalate its development, such as drug or alcohol dependence. In sum, ASPD appears to be the result of a constellation of factors, including genetic predisposition, experiences within the family and sociological factors, coupled with the absence of preventive factors.

### Assessment and Differential Diagnosis

All of the DSM-IV-TR assessment instruments described earlier include the assessment of ASPD. However, an instrument that is focused on the assessment of ASPD is the Psychopathy Checklist – Revised (PCL-R, Hare, 1991). The PCL-R is commonly used within forensic and prison settings and is particularly well suited for the assessment of this disorder within settings that are heavily populated by persons with a criminal history. The PCL-R includes the assessment of psychopathic traits that are relatively more specific to ASPD within prison settings, such as lack of empathy, glib charm and arrogance. However, as suggested by its title, it is perhaps better described as a checklist than as a semistructured interview. Many of its items are scored primarily (if not solely) on the basis of a person's legal, criminal record rather than on the basis of interview questions. The availability of a detailed criminal history within prison settings has contributed to the PCL-R's excellent interrater reliability and predictive validity, but an application of the PCL-R within most other clinical settings will need to rely more heavily on PCL-R interview questions, the administration and scoring of which will be unclear for some PCL-R items.

ASPD will at times be difficult to differentiate from a substance dependence disorder in young adults because many persons with ASPD develop a substance-related disorder and many persons with a substance dependence engage in antisocial acts. The requirement that the ASPD features be evident prior to the age of 15 years will usually assure the onset of ASPD prior to the onset of a substance-related disorder. If both are evident prior to the age of 15 years, then it is likely that both disorders are in fact present and both diagnoses should then be made. ASPD and substance dependence will often interact, exacerbating and escalating each other's development.

Antisocial acts will also be evident in the histrionic and borderline personality disorders, as persons with these disorders will display impulsivity, sensation-seeking, self-centeredness, manipulateness and a low frustration tolerance. Females with antisocial PD are often misdiagnosed with histrionic personality disorder. Prototypic cases of ASPD might be distinguished from other personality disorders by the presence of the childhood history of conduct disorder and the cold, calculated exploitation, abuse and aggression. Persons with narcissistic personality disorder are also characterized by a lack of empathy and may often exploit and use others. In fact, many of the traits of narcissistic personality disorder are evident in psychopathy, including a lack of empathy, glib and superficial charm and arrogant self-appraisal.

### Epidemiology and Comorbidity

The National Institute of Mental Health Epidemiologic Catchment Area (ECA) study indicated that approximately 3% of males and 1% of females have ASPD (Robins *et al.*, 1991). This rate has been replicated in subsequent studies, but it has also been suggested that the ECA finding may have underestimated the prevalence in males due to the failure to consider the full range of ASPD features. Other estimates have been as high as 6% in males (Kessler *et al.*, 1994; Robins *et al.*, 1991). The rate of ASPD within prison and forensic settings has been estimated at 50% but the ASPD criteria may exaggerate the rate within such settings due to the emphasis given to overt acts of criminality, delinquency and irresponsibility that are common to the persons within these settings. More specific criteria for psychopathy provide a more conservative estimate of 20 to 30% of male prisoners with ASPD.

ASPD is much more common in males than in females. A sociobiological explanation for the differential sex prevalence is the presence of a genetic advantage for social irresponsibility, infidelity, superficial charm and deceit in males that contributes to a higher likelihood of developing features of ASPD. It has also been suggested that ASPD and histrionic personality disorder share a biogenetic disposition (perhaps towards impulsivity or sensation-seeking) that is mediated by gender-specific biogenetic and sociological factors toward respective gender variants.

Persons with ASPD are at a high risk for developing substance-related and impulse dyscontrol disorders. They are also likely to display borderline, narcissistic and paranoid personality traits. Females with ASPD will also display histrionic personality traits.

### Course

ASPD is evident in childhood in the form of a conduct disorder. Evidence of a conduct disorder prior to the age of 15 years is in fact required for a DSM-IV ASPD diagnosis (American Psychiatric Association, 2000). The continuation into adulthood is particularly likely to occur if multiple delinquent behaviors are evident prior to the age of 10 years. As adults, persons with ASPD are unlikely to maintain steady employment and they may even become impoverished, homeless, or spend years within penal institutions. However, some persons with ASPD characterized by high rather than low levels of conscientiousness may express their psychopathic tendencies within a socially acceptable or at least legitimate profession. They may in fact be quite successful as long as their tendency to bend or violate the norms or rules of their profession and exploit, deceive and manipulate others, contribute to a career advancement. Their success, however, may at some point unravel when their psychopathic behaviors become problematic or evident to others. The same pattern may also occur within sexual and marital relationships. They may at first appear to be charming, engaging and sincere, but most relationships will end due to a lack of empathy, responsibility and fidelity.

There does tend to be a gradual remission of antisocial behaviors, particularly overt criminal acts, as the person ages. Persons with ASPD, however, are more likely than the general population to have died prematurely by violent means (e.g., accidents or homicides) and to engage in quite dangerous, high-risk behavior.

### Treatment

The presence of ASPD is important to recognize in the treatment of any Axis I disorder, as their tendency to be manipulative,

dishonest, exploitative, aggressive and irresponsible will often disrupt and sabotage treatment. It is also very easy to be seduced by psychopathic charm. Persons with ASPD can be seductive in their engaging friendliness, expressions of remorse, avowed commitment to change, and apparent response to or even fascination with the success, skills, and talents of the therapist, none of which will be sincere or reliable.

The extent to which ASPD is untreatable has at times been overstated and exaggerated. Nevertheless, ASPD is the most difficult personality disorder to treat. Persons with ASPD will often lack a motivation or commitment to change. They might see only the advantages of their antisocial traits and not the costs (e.g., risks of arrest and failure to sustain lasting or meaningful relationships). They are prone to manipulate, abuse, or exploit their fellow patients and the staff. The immediate motivation for treatment is often provided by an external source, such as a court order or the demands of an employer or relative. Motivation may last only as long as an external pressure remains.

The most effective treatment is likely to be prevention through an identification and intervention early in childhood. In adulthood, the most effective treatment may at times be simply some form of sustained incarceration (e.g., imprisonment), as many antisocial behaviors do tend to dissipate (or burnout) with time. The tendency to rationalize irresponsibility, minimize the consequences of acts, and manipulate others needs to be confronted on a daily and immediate basis. Community residential or wilderness programs that provide a firm structure, close supervision and intense confrontation by peers have been recommended. The involvement of family members in the treatment has been shown to be helpful, but there are also data to suggest that interventions with little professional input are less successful and are times counterproductive.

There is some research to suggest that the ability to form a therapeutic alliance is an important indicator of treatment success. Factors to consider are the demographic similarity of the therapist and patient, the quality of the patient's past relationships and the therapist's positive regard for the patient. Many psychiatrists may also experience strong feelings of animosity and distaste for antisocial persons who have a history of abusive and exploitative acts. Rational, utilitarian approaches that help the person consider the long-term consequences of behavior can be useful. This approach does not attempt to develop a sense of conscience, guilt, or even regret for past actions, but focuses instead on the material value and future advantages to be gained by a more prosocial behavior pattern. There are data to suggest the use of pharmacotherapy in the treatment of impulsive aggression but it is unclear whether these findings would generalize to the full spectrum of ASPD psychopathology.

## Borderline Personality Disorder

### Definition

Borderline personality disorder (BPD) is a pervasive pattern of impulsivity and instability in interpersonal relationships and self-image (American Psychiatric Association, 2000). A broad domain of general personality functioning is neuroticism or emotional instability, characterized by facets of angry hostility, anxiousness, depressiveness, impulsivity and vulnerability; BPD is essentially the most extreme and highly maladaptive variant of

emotional instability. This disorder is indicated by the presence of five or more of the nine diagnostic criteria presented in the DSM-IV-TR criteria for BPD.

### Etiology and Pathology

There are studies to indicate that BPD may breed true but most research has suggested an association with mood and impulse dyscontrol disorders. There is also consistent empirical support for a childhood history of physical and/or sexual abuse, as well as parental conflict, loss and neglect. It appears that past traumatic events are important in many if not most cases of BPD, contributing to the overlap and association with post traumatic stress and dissociative disorders but the nature and age at which these events have occurred will vary. BPD may involve the interaction of a genetic disposition towards dyscontrol of mood and impulses (i.e., emotionally unstable temperament), with a cumulative and evolving series of intensely pathogenic relationships.

### DSM-IV-TR Criteria 301.83

#### Borderline Personality Disorder

A pervasive pattern of instability of interpersonal relationships, self-image, and affects, and marked impulsivity beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

- (1) frantic efforts to avoid real or imagined abandonment.  
**Note:** do not include suicidal or self-mutilating behavior covered in criterion 5
- (2) a pattern of unstable and intense interpersonal relationships characterized by alternating between extremes of idealization and devaluation
- (3) identity disturbance: markedly and persistently unstable self-image or sense of self
- (4) impulsivity in at least two areas that are potentially self-damaging (e.g., spending, sex, substance abuse, reckless driving, binge eating). **Note:** do not include suicidal or self-mutilating behavior covered in criterion 5
- (5) recurrent suicidal behavior, gestures, or threats, or self-mutilating behavior
- (6) affective instability due to a marked reactivity of mood (e.g., intense episodic dysphoria, irritability, or anxiety usually lasting a few hours and only rarely more than a few days)
- (7) chronic feelings of emptiness
- (8) inappropriate, intense anger or difficulty controlling anger (e.g., frequent displays of temper, constant anger, recurrent physical fights)
- (9) transient, stress-related paranoid ideation or severe dissociative symptoms

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

There are numerous theories regarding the pathogenic mechanisms of BPD, most concern issues regarding abandonment, separation, and/or exploitative abuse, which is one of the reasons that frantic efforts to avoid abandonment is the first item in the DSM-IV-TR diagnostic criterion set. Persons with BPD have quite intense, disturbed, and/or abusive relationships with the significant persons of their past, including their parents, contributing to the development of malevolent perceptions and expectations of others. These expectations, along with an impairment in the ability to regulate affect and impulses may contribute to the perpetuation of intense, angry and unstable relationships. Neurochemical dysregulation is evident in persons with BPD but it is unclear whether this dysregulation is a result, cause, or correlate of prior interpersonal traumas.

### Assessment and Differential Diagnosis

All of the DSM-IV assessment instruments described earlier include the assessment of BPD. However, an instrument that is focused on the assessment of BPD is the Diagnostic Interview for Borderlines-Revised (DIB-R; Zanarini *et al.*, 1989). The DIB-R provides a more thorough assessment of components of BPD (e.g., impulsivity, affective dysregulation and cognitive-perceptual aberrations) than is provided by more general DSM-IV-TR personality disorder semi-structured interviews, but psychiatrists might find it impractical to devote up to 2 hours to assess one particular personality disorder, especially when it is likely that other maladaptive personality traits not covered by the DIB-R are also likely to be present.

Most persons with BPD develop mood disorders and it is at times difficult to differentiate BPD from a mood disorder if the assessment is confined to the current symptomatology. A diagnosis of BPD requires that the borderline symptomatology be evident since adolescence, which should differentiate BPD from a mood disorder in all cases other than a chronic mood disorder. If there is a chronic mood disorder, then the additional features of transient, stress-related paranoid ideation, dissociative experiences, impulsivity and anger dyscontrol that are evident in BPD should be emphasized in the diagnosis (Gunderson, 2001).

### Epidemiology and Comorbidity

Approximately 1 to 2% of the general population would meet the DSM-IV criteria for BPD. BPD is the most prevalent personality disorder within maximum clinical settings. Approximately 15% of all inpatients (51% of inpatients with a personality disorder) and 8% of all outpatients (27% of outpatients with a personality disorder) have a borderline personality disorder. Approximately 75% of persons with BPD will be female. Persons with BPD meet DSM-IV-TR criteria for at least one Axis I disorder. The range of potential Axis I comorbid psychopathology includes mood (major depressive disorder), anxiety (post traumatic stress disorder), eating (bulimia nervosa), substance (alcohol dependence), dissociative (dissociative identity disorder), and psychotic (brief psychotic) disorders (Gunderson, 2001). Persons with BPD also meet DSM-IV-TR criteria for at least one other personality disorder, particularly histrionic, dependent, antisocial, schizotypal, or passive-aggressive. Researchers and clinicians have at times responded to this extensive cooccurrence by imposing a diagnostic hierarchy whereby other disorders are not diagnosed in the presence of BPD because BPD is generally the most severely dysfunctional disorder (Gunderson *et al.*, 2000). A potential limitation of this approach is that it resolves the complexity of personality by largely ignoring it. This approach may fail to rec-

ognize the presence of maladaptive personality traits that could be important for understanding a patient's dysfunctions and for developing an optimal treatment plan.

### Course

As children, persons with BPD are likely to have been emotionally unstable, impulsive and angry or hostile. Their chaotic impulsivity and intense affectivity may contribute to involvement within rebellious groups as a child or adolescent, along with a variety of Axis I disorders, including eating, substance use and mood disorders. BPD is often diagnosed in children and adolescents but considerable caution should be used when doing so as some of the symptoms of BPD (e.g., identity disturbance and unstable relationships) could be confused with a normal adolescent rebellion or identity crisis. As adults, persons with BPD may require numerous hospitalizations due to their affect and impulse dyscontrol, psychotic-like and dissociative symptomatology and risk of suicide. Minor problems quickly become crises as the intensity of affect and impulsivity result in disastrous decisions. They are at a high risk for developing depressive, substance-related, bulimic and post traumatic stress disorders. The potential for suicide increases with a comorbid mood and substance-related disorder. Approximately 3 to 10% commit suicide by the age of 30 years. Relationships tend to be very unstable and explosive and employment history is poor. Affectivity and impulsivity, however, may begin to diminish as the person reaches the age of 30 years, or earlier if the person becomes involved with a supportive and patient sexual partner. Some, however, may obtain stability by abandoning the effort to obtain a relationship, opting instead for a lonelier but less volatile life. The mellowing of the symptomatology, however, can be easily disrupted by the occurrence of a severe stressor (e.g., divorce by or death of a significant other) that results in a brief psychotic, dissociative, or mood disorder episode.

### Treatment

Persons with BPD often develop intense, dependent, hostile, unstable and manipulative relationships with their therapists as they do with their peers. At one time they might be very compliant, responsive and even idealizing, but later angry, accusatory and devaluing. Their tendency to be manipulatively as well as impulsively self-destructive is often very stressful and difficult to treat (Stone, 2000).

Persons with BPD are often highly motivated for treatment. Psychotherapeutic approaches tend to be both supportive and exploratory. Therapists should provide a safe, secure environment in which anger can be expressed and actively addressed without destroying the therapeutic relationship. The historical roots of current bitterness, anger and depression within past familial relationships should eventually be explored, but immediate, current issues and conflicts must also be explicitly addressed. Suicidal behavior should be confronted and contained, by hospitalization when necessary. Patients with BPD can be very difficult to treat because the focus of the patient's love and wrath will often be shifted toward the therapist, and the treatment may itself become the patient's latest unstable, intense relationship. Immediate and ongoing consultation with colleagues is often necessary, as it is not unusual for therapists to be unaware of the extent to which they are developing or expressing feelings of anger, attraction, annoyance, or intolerance toward their borderline patient.

A particular form of cognitive-behavioral therapy, dialectical behavior therapy, has been shown empirically to be effective in the treatment of BPD (Linehan, 2000). Part of the strategy entails

keeping patients focused initially on the priorities of reducing suicidal threats and gestures, behaviors that can disrupt or resist treatment, and behaviors that affect the immediate quality of life (e.g., bulimia, substance abuse, or unemployment). Once these goals are achieved, the focus can then shift to a mastery of new coping skills, management of reactions to stress and other individualized goals. Individual therapy is augmented by skills-training groups that may be highly structured (e.g., comparable to a classroom format). Patients are taught skills for coping with identity diffusion, tolerating distress, improving interpersonal relationships, controlling emotions and resolving interpersonal crises. Patients are given homework assignments to practice these skills that are further addressed and reinforced within individual sessions. Negative affect is also addressed through a mindful meditation that contributes to an acceptance and tolerance of past abusive experiences and current stress. The dialectical component of the therapy is that “the dialectical therapist helps the patient achieve synthesis of oppositions, rather than focusing on verifying either side of an oppositional argument” (Linehan, 1993, p. 204). An illustrative list of dialectical strategies is presented in Table 62.3.

DBT, however, also includes more general principles of treatment that are important to emphasize in all forms of therapy for BPD (Linehan, 1993; Stone, 1993, 2000), some of which are presented in Table 62.4. For example, exasperated therapists may unjustly experience and even accuse borderline patients of being unmotivated or unwilling to work. It is important to appreciate that they do want to improve and are doing the best that they can. One should not make the therapy personal, but instead identify the sources of the inhibition or interference to their motivation to change. One should take seriously their complaints that their lives are indeed unbearable but not absolve them of their responsibility to solve their own problems. They are unlikely to change simply through a passive reception of insight, nurturance, support and

**Table 62.3 Dialectical Behavior Therapy Strategies**

Alternate between acceptance and change strategies  
 Balance nurturing with demands for self-help  
 Balance persistence and stability with flexibility  
 Balance capabilities with limitations and deficits  
 Move with speed, keeping the patient slightly off balance  
 Take positions whole-heartedly  
 Look for what is not included in patient’s own points of view  
 Provide developmental descriptions of change  
 Question intransigence of boundary conditions of the problem  
 Highlight importance of interrelationships in identity  
 Advocate a middle path  
 Highlight paradoxical contradictions in patient’s own behavior, in the therapeutic process, and in life in general  
 Speak in metaphors and tell parables and stories  
 Play the devil’s advocate  
 Extend the seriousness or implications of patient’s statements  
 Add intuitive knowing to emotional experience and logical analysis  
 Turn problems into assets  
 Allow natural changes in therapy  
 Assess the patient, therapist and process dialectically

medication. They will need to work actively on changing their lives. Therapists will often be tempted to rescue their patients, particularly when they are within a crisis. However, it is precisely at such times that there will be the best opportunity to develop and learn new coping strategies. Failures can occur, and it is a failure of the therapy that should be conscientiously and effectively addressed by the therapist. Finally, therapists need honestly to recognize their own limitations. All therapists have their own flaws and limits and patients with BPD invariably strain and overwhelm these limits. Therapists need to be open and receptive to outside support, advice and criticism.

Pharmacologic treatment of patients with BPD is varied, as it depends primarily on the predominant Axis I symptomatology. Persons with BPD can display a wide variety of Axis I symptoms, including anxiety, depression, hallucinations, delusions and dissociations. It is important in their pharmacologic treatment not to be unduly influenced by transient symptoms or by symptoms that are readily addressed through exploratory or supportive techniques. On the other hand, it is equally important to be flexible in the use of medications and not to be unduly resistant to their use. Relying solely upon one’s own psychotherapeutic skills can be unnecessary and even irresponsible.

## Histrionic Personality Disorder

### Definition

Histrionic personality disorder (HPD) is a pervasive pattern of excessive emotionality and attention-seeking (American Psychiatric Association, 2000). Histrionic persons tend to be emotionally manipulative and intolerant of delayed gratification. HPD is indicated by the presence of five or more of the eight diagnostic criteria presented in DSM-IV criteria for HPD.

### Etiology and Pathology

There is little research on the etiology of HPD. There is a suggestion that HPD may share a genetic disposition toward impulsivity or sensation-seeking with the antisocial personality. It has also been suggested that HPD is (in part) a severe, maladaptive variant of the personality dimensions of extraversion and neuroticism. Extraversion includes the facets of excitement seeking, gregariousness and positive emotionality, and neuroticism includes the facets of angry hostility, self-consciousness and vulnerability that are all characteristic of persons with HPD

**DSM-IV-TR Criteria 301.50****Histrionic Personality Disorder**

A pervasive pattern of excessive emotionality and attention seeking, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

- (1) is uncomfortable in situations in which he or she is not the center of attention
- (2) interaction with others is often characterized by inappropriate sexually seductive or provocative behavior
- (3) displays rapidly shifting and shallow expression of emotions
- (4) consistently uses physical appearance to draw attention to self
- (5) has a style of speech that is excessively impressionistic and lacking in detail
- (6) shows self-dramatization, theatricality, and exaggerated expression of emotion
- (7) is suggestible, i.e. easily influenced by others or circumstances
- (8) considers relationships to be more intimate than they actually are

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000, American Psychiatric Association.

and there is considerable empirical support for the heritability of these personality dimensions.

Environmental and social-cultural factors, however, may also play a significant role in the development of HPD. There is some speculation that the fathers of females with HPD combine early sexual seductiveness with subsequent authoritarian puritanical attitudes, while the mother tends to be domineering, controlling and intrusive. Such a history may indeed occur in some cases of HPD but there is unlikely to be a specific, common pattern to all cases. The tendency of a family to emphasize, value, or reinforce attention-seeking in a person with a genetic disposition toward emotionality may represent a more general pathway toward HPD.

Affective instability is an important feature of HPD, which may be associated with a hyperresponsiveness of the noradrenergic system. This instability in the catecholamine functioning may contribute to a pronounced emotional reactivity to rejection and loss. However, the attention-seeking of HPD can be as important to the disorder as the emotionality. The purpose of the exaggerated emotionality is often to evoke the attention and maintain the interest of others. Persons with HPD are intensely insecure regarding the extent to which others appreciate, desire, or want their company. They need to be the center of attention to reassure themselves that they are valued, desired, attractive, or wanted.

**Assessment and Differential Diagnosis**

HPD involves to some extent maladaptive variants of stereotypically feminine traits. The DSM-IV-TR diagnostic criteria for HPD are sufficiently severe that a normal woman would not

meet these criteria, but studies have indicated that clinicians will at times diagnose HPD in females who in fact have antisocial traits. Both of these disorders can involve impulsivity, sensation-seeking, low frustration tolerance and manipulativeness, and the presence of a female gender may at times contribute to a false presumption of HPD. It is therefore important to adhere closely to the DSM-IV-TR diagnostic criteria when confronted with histrionic and antisocial symptoms in female patients.

Persons with HPD will often have borderline, dependent, or narcissistic personality traits. Prototypic cases of HPD can be distinguished from other personality disorders. For example, the prototypic narcissistic person ultimately desires admiration whereas the histrionic person desires whatever attention, interest, or concern can be obtained. As a result, the histrionic person will at times seek attention through melodramatic helplessness and emotional outbursts that could be experienced as denigrating and humiliating to the narcissistic person. However, most cases will not be prototypic and the most accurate description of a patient's constellation of maladaptive personality traits will be the provision of multiple diagnoses.

**Epidemiology and Comorbidity**

Approximately 1 to 3% of the general population may be diagnosed with HPD. A controversial issue is its differential sex prevalence. It is stated in DSM-IV-TR that the sex ratio for HPD is "not significantly different than the sex ratio of females within the respective clinical setting" (American Psychiatric Association, 2000, p. 712). However, this should not be interpreted as indicating that the prevalence is the same for males and females. It has typically been found that at least two-thirds of persons with HPD are female, although there have been a few exceptions. Whether or not the rate will be significantly higher than the rate of women within a particular clinical setting depends upon many factors that are independent of the differential sex prevalence for HPD.

**Course**

Little is known about the premorbid behavior pattern of persons with HPD. During adolescence they are likely to be flamboyant, flirtatious and attention-seeking. As adults, persons with HPD readily form new relationships but have difficulty sustaining them. They may fall in love quite quickly, but just as rapidly become attracted to another person. They are unlikely to be reliable or responsible. Relationships with persons of the same sexual orientation are often be strained due to their competitive sexual flirtatiousness. Employment history is likely to be erratic, and may be complicated by the tendency to become romantically or sexually involved with colleagues, by their affective instability and by their suggestibility. Persons with HPD may become devoted converts to faddish belief systems. They have a tendency to make impulsive decisions that will have a dramatic (or melodramatic) effect on their lives. The severity of the symptomatology may diminish somewhat as the person ages.

**Treatment**

Persons with HPD readily develop rapport but it is often superficial and unreliable. Therapists may also fail to appreciate the extent of influence they can have on the highly suggestible HPD patient. Persons with HPD can readily become converts to whatever the therapist may suggest or encourage. The transformation to the theoretical model or belief system of the psychiatrist is unlikely to be sustained.

A key task in treating the patient with HPD is countering their global and diffuse cognitive style by insisting on attending to structure and detail within sessions and to the practical, immediate problems encountered in daily life. It is also important to explore within treatment the historical source for their needs for attention and involvement. Persons with HPD are prone to superficial and transient insights but they will benefit from a carefully reasoned and documented exploration of their current and past relationships.

Many clinicians recommend the use of group therapy for persons with HPD. It is quite easy for them to become involved within a group, which may then be very useful in helping them recognize and explore their attention-seeking, suggestibility and manipulation, as well as develop alternative ways to develop more meaningful and sustained relationships. However, it is also important to monitor closely their involvements within the group, as they are prone to dominate and control sessions and they may escalate their attention-seeking to the point of suicidal gestures. The intense affectivity of persons with HPD may also be responsive to antidepressant treatment, particularly those patients with substantial mood reactivity, hypersomnia and rejection sensitivity.

## Narcissistic Personality Disorder

### Definition

Narcissistic PD (NPD) is a pervasive pattern of grandiosity, need for admiration and lack of empathy (American Psychiatric Association, 2000). Persons with NPD can be very vulnerable to threats to their self-esteem. They may react defensively with rage, disdain, or indifference but are in fact struggling with feelings of shock, humiliation and shame. NPD is indicated by the presence of five or more of the nine diagnostic criteria presented in the DSM-IV-TR Criteria for NPD.

### Etiology and Pathology

There are no data on the heritability of the narcissistic PD, although there are data on the heritability of arrogance, modesty and conceit. The etiological theories have been primarily sociological, psychodynamic and interpersonal. For example, it has been suggested that current Western society has become overly self-centered with the decreasing importance of familial bonds, traditional social, religious and political values or ideals, and rising materialism.

Narcissism may also develop through unempathic, neglectful and/or devaluing parental figures (Kernberg, 1991). The child may develop the belief that a sense of worth, value, or meaning is contingent upon accomplishment or achievement. Kohut (1977) has suggested that the parents failed adequately to mirror an infant's natural need for idealization. Benjamin (1993) and Millon and colleagues (1996) suggest that narcissistic persons received excessive idealization by parental figures, which they incorporated into their self-image. The irrationality of this idealization, or its being coupled with inconsistent indications of an actual disinterest and devaluation, may contribute to the eventual difficulties and conflicts surrounding self-image.

Conflicts and deficits with respect to self-esteem have been shown empirically to be central to the pathology of NPD. Narcissistic persons must continually seek and obtain signs and symbols of recognition to compensate for feelings of inadequacy.

## DSM-IV-TR Criteria 301.81

### Narcissistic Personality Disorder

A pervasive pattern of grandiosity (in fantasy or behavior), need for admiration, and lack of empathy, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

- (1) has a grandiose sense of self-importance (e.g. exaggerates achievements and talents, expects to be recognized as superior without commensurate achievements)
- (2) is preoccupied with fantasies of unlimited success, power, brilliance, beauty, or ideal love
- (3) believes that he or she is "special" and unique and can only be understood by, or should associate with, other special or high-status people (or institutions)
- (4) requires excessive admiration
- (5) has a sense of entitlement, i.e. unreasonable expectations of especially favorable treatment or automatic compliance with his or her expectations
- (6) is interpersonally exploitative, i.e., takes advantage of others to achieve his or her own ends
- (7) lacks empathy: is unwilling to recognize or identify with the feelings and needs of others
- (8) is often envious of others or believes that others are envious of him or her
- (9) shows arrogant, haughty behaviors or attitudes

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

They are not persons who feel valued for their own sake. Value is contingent upon a success, accomplishment, or status. Their feelings of insecurity may be masked by a disdainful indifference towards rebuke and by overt expressions of arrogance, conceit and even grandiosity. However, the psychopathology is still evident in such cases by the excessive reliance and importance that is continually placed upon status and recognition. Some narcissistic persons may in fact envy those who are truly indifferent to success and who can enjoy a modest, simple and unassuming life.

### Assessment and Differential Diagnosis

All of the semi-structured interviews and self-report inventories described earlier include scales for the assessment of NPD. There is also a semi-structured interview devoted to the assessment of narcissism (Diagnostic Interview for Narcissism [DIN]; Gunderson *et al.*, 1990), the research with which was highly influential in the development of the DSM-IV-TR diagnostic criteria. There are also a number of self-report inventories devoted to the assessment of narcissistic personality traits, including the Narcissistic Personality Inventory (NPI) that has been used in a number of informative personality and social-psychological studies of narcissism

(Rhodewalt and Morf, 1995). The DIN and NPI have the useful feature of subscales for the assessment of various components of narcissism (e.g., NPI scales for superiority, vanity, leadership, authority, entitlement, exploitativeness and exhibitionism).

Individuals with narcissistic PD may often appear relatively high functioning. Exaggerated self-confidence may in fact contribute to success in a variety of professions and narcissistic traits will at times be seen in highly successful persons. A diagnosis of NPD requires the additional presence of interpersonal exploitation, lack of empathy, a sense of entitlement, and other symptoms beyond simply arrogance and grandiosity.

Both narcissistic and antisocial persons may exploit, deceive and manipulate others for personal gain, and both may demonstrate a lack of empathy or remorse. As indicated above, many of the traits of narcissism, such as arrogance and glib charm, are seen in psychopathic persons. Prototypic cases can be distinguished, as the motivation for the narcissistic person will be for recognition, status and other signs of success, whereas the prototypic antisocial person would be motivated more for material gain or for the subjugation of others. Antisocial persons will also display an impulsivity, recklessness and lax irresponsibility that may not be seen in narcissistic persons.

### Epidemiology and Comorbidity

Approximately 18% of males and 6% of females may be characterized as being excessively immodest (i.e., arrogant or conceited; Costa and McCrae 1992) but only a small percent of these persons would be diagnosed with NPD. In fact, the median prevalence rate obtained across 10 community data collections was zero. The absence of any cases within community studies, however, may reflect inadequacies within the diagnostic criteria or limitations of semi-structured interview assessments of narcissism. NPD is observed within clinical settings (approximately 2 to 20% of patients) although it is also among the least frequently diagnosed personality disorders (American Psychiatric Association, 2000). Persons with NPD are considered to be prone to mood disorders, as well as anorexia and substance-related disorders, especially cocaine. Persons with NPD are likely to have comorbid antisocial (psychopathic), histrionic, paranoid and borderline personality traits.

### Course

Little is known about the premorbid behavior pattern of NPD, other than through retrospective reports of persons diagnosed when adults. As adolescents, persons with NPD are likely to be self-centered, assertive, gregarious, dominant and perhaps arrogant. They may have achieved well in school or within some other activity. As adults, many persons with NPD will have experienced high levels of achievement. However, their relationships with colleagues, peers and staff will eventually become strained as their exploitative use of others and self-centered egotism become evident. Success may also be impaired by their difficulty in acknowledging or resolving criticism, deficits and setbacks. Interpersonal and sexual relationships are usually easy for them to develop but difficult to sustain due to their low empathy, self-centeredness and need for admiration. Persons who are deferential and obsequious, or who share a mutual need for status and recognition, may help sustain a relationship. As parents, persons with NPD may attempt to live through their children, valuing them as long as they are a source of pride. Their personal sense of adjustment may be fine for as long as

they continue to experience or anticipate success. Some may not recognize the maladaptivity of their narcissism until middle-age, when the emphasis given to achievement and status may begin to wane.

### Treatment

Persons with narcissistic personality traits seek treatment for feelings of depression, substance-related disorders and occupational or relational problems that are secondary to their narcissism. Their self-centeredness and lack of empathy are particularly problematic within marital, occupational and other social relationships, and they usually lack an appreciation of the contribution of their conflicts regarding self-esteem, status and recognition. It is difficult for them even to admit that they have a psychological problem or that they need help, as this admission is itself an injury to their self-esteem. In addition, one of the characteristics of NPD is the belief that they can only be understood by persons of a comparably high social status or recognition. They may be unable to accept advice or insight from persons they consider less intelligent, talented, or insightful than themselves, which may eventually effectively eliminate most other persons.

When they are involved in treatment, persons with NPD will often require some indication that their therapist is among the best or at least worth their time. They are prone to idealizing their therapists (to affirm that he or she is indeed of sufficient status or quality) or to devalue them (to affirm that they are of greater intelligence, capacity, or quality than their therapist, to reject the insights that they have failed to identify, and to indicate that they warrant or deserve an even better therapist). How best to respond is often unclear. It may at times be preferable simply to accept the praise or criticism, particularly when exploration will likely be unsuccessful, whereas at other times it is preferable to confront and discuss the motivation for the devaluation (or the idealization).

Psychodynamic approaches to the treatment of NPD vary in the extent to which emphasis is given to an interpretation of underlying anger and bitterness, or to the provision of empathy and a reflection (or mirroring) of a positive regard and self-esteem (Cooper and Ronningstam, 1992; Kernberg, 1991; Kohut, 1977; Gabbard, 2000). It does appear to be important to identify the current extent and historical source of the conflicts and sensitivities regarding self-esteem. Active confrontation may at times be useful, particularly when the therapeutic alliance is strong, but at other times the vulnerability of the patient may require a more unconditional support. Cognitive-behavior approaches to NPD emphasize increasing awareness of the impact of narcissistic behaviors and statements on interpersonal relationships. The idealization and devaluation can be responsive to role playing and rational introspection, an intellectual approach that may itself be valued by some persons with NPD. However, therapists must be careful not to become embroiled within intellectual conflicts (or competitions). This approach may not work well with the narcissistic person who is motivated to defeat or humiliate the therapist.

Group therapy can be useful for increasing awareness of the grandiosity, lack of empathy and devaluation of others. However, these traits not only interfere with the narcissistic person's ability to sustain membership within groups (and within individual therapy), they may also become quite harmful and destructive to the rapport of the entire group. There is no accepted pharmacologic approach to the treatment of narcissism.

### Clinical Vignette 1

RP was a well-regarded clinician with a good publication record and a successful private practice. However, one of his patients filed a complaint with the state board after their sexual relationship ended. He offered in his defense that his behavior was simply the result of marital stress. His license to practice was suspended indefinitely. One of the terms of his probation was to complete successfully 2 years of psychotherapy. RP agreed that treatment would be beneficial but questioned whether any clinician within his local community was sufficiently qualified, as he considered himself to be among the leading clinicians within this community.

Treatment was problematic from the very beginning. RP felt that their discussions should be *quid pro quo*: if he was going to reveal aspects of himself then the therapist should do likewise. When confronted with the understanding that he was the one in treatment, RP argued that the therapist must be having “narcissistic conflicts” if he is unwilling to accept the insight and guidance that he could offer. Some of the difficulty within the treatment was attributable to the situation (i.e., it would probably be difficult for most therapists to be mandated to receive therapy from a colleague) but as treatment progressed it became apparent that he had similar conflicts with other persons in his life.

RP’s wife was threatening divorce in part because of a history of extramarital affairs. RP did not deny the existence of these affairs but argued that his wife was exaggerating their importance: the other women meant little to him, why should they be of concern to her? He said that he did not keep his affairs secret from her prior to marriage (at least those that he was unable to keep secret), and therefore she knew from the beginning that extramarital affairs would occur. In addition, he felt that his affairs were only petty philandering and that his wife should tolerate them because she was “frankly lucky” to have him for a husband. He was good looking, wealthy and professionally successful, and felt that if he had been more patient he might have found someone better than her.

RP was popular with women, at least at the beginning of relationships. He was charming, engaging and verbally facile. However, he acknowledged during the course of therapy that some women eventually became unhappy, dissatisfied and at times even angry with him. It is quite possible that his perception of his past relationships even understated the extent of the dissatisfaction. He attributed their dissatisfaction to “unrealistic and neurotic expectations”. He stated that women would flirt with him because he is an “attractive catch” and that he was only fulfilling their fantasies by letting them become involved with him. He would soon lose interest though in the women with whom he became involved, and he acknowledged that it was not always easy to extricate himself from a relationship without any cost to himself.

He evidenced only a marginal insight into the potential harm he had caused the patient with whom he had the sexual relationship. He argued that the proscription against sexual involvements should not have been enforced in this instance because he had been very careful in determining

that their relationship was not the intended target of the ethical guidelines: she was herself a “competent” professional who had “freely” entered the relationship and, in any case, no complaint would have been filed if he had been willing to continue the relationship. She was a well-known public figure. She testified to the state board that he repeatedly suggested to her that she accompany him on his business trips, and it was her impression that he wanted to show her off as a “trophy” to his colleagues. She stated that she ended the relationship when she discovered from her colleagues that he was bragging to others about their relationship and revealing details of their sexual activities.

Treatment was terminated by RP after 6 months of treatment upon reading the biannual report by his therapist to the state board regarding his progress. RP felt that he had been making substantial progress that was not being adequately appreciated by his therapist. He noted, for example, that his wife was no longer seeking a divorce and that his ex-patient was engaged to be married. He did indicate that he was dissatisfied with treatment, and felt that progress would be improved by “a more experienced and respected” clinician. He attributed the therapist’s negative evaluation of his progress to professional jealousy.

## Avoidant Personality Disorder

### Definition

Avoidant personality disorder (AVPD) is a pervasive pattern of timidity, inhibition, inadequacy and social hypersensitivity (American Psychiatric Association, 2000). Persons with AVPD may have a strong desire to develop close, personal relationships but feel too insecure to approach others or to express their feelings. AVPD is indicated by the presence of four or more of the seven diagnostic criteria presented in the DSM criteria for AVPD.

### Etiology and Pathology

AVPD appears to be an extreme variant of the fundamental personality traits of introversion and neuroticism. Introversion includes such facets as passivity, social withdrawal and inhibition, while neuroticism includes self-consciousness, vulnerability and anxiousness. The personality dimensions of neuroticism and introversion have substantial heritability, as do the more specific traits of social anxiousness and shyness.

In childhood, neuroticism appears as a distress-prone or inhibited temperament. Shyness, timidity and interpersonal insecurity might be exacerbated further in childhood through overprotection and excessive cautiousness. Parental behavior coupled with a distress-prone temperament has been shown to result in social inhibition and timidity. Most children and adolescents will have many experiences of interpersonal embarrassment, rejection, or humiliation, but these will be particularly devastating to the person who is already lacking in self-confidence or is temperamentally passive, inhibited, or introverted.

AVPD may involve elevated peripheral sympathetic activity and adrenocortical responsiveness, resulting in excessive autonomic arousal, fearfulness and inhibition (Siever and Davis, 1991). Just as ASPD may involve deficits in the functioning of

**DSM-IV-TR Criteria 301.82****Avoidant Personality Disorder**

A pervasive pattern of social inhibition, feelings of inadequacy, and hypersensitivity to negative evaluation, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:

- (1) avoids occupational activities that involve significant interpersonal contact, because of fears of criticism, disapproval, or rejection
- (2) is unwilling to get involved with people unless certain of being liked
- (3) shows restraint within intimate relationships because of the fear of being shamed or ridiculed
- (4) is preoccupied with thoughts of being criticized or rejected in social situations
- (5) is inhibited in new interpersonal situations because of feelings of inadequacy
- (6) views self as socially inept, personally unappealing, or inferior to others
- (7) is unusually reluctant to take personal risks or to engage in any new activities because they may prove embarrassing

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

a behavioral inhibition system, AVPD may involve excessive functioning of this same. The pathology of AVPD, however, may also be more psychological than neurochemical, with the timidity, shyness and insecurity being a natural result of a cumulative history of denigrating, embarrassing and devaluing experiences. Underlying AVPD may be excessive self-consciousness, feelings of inadequacy or inferiority, and irrational cognitive schemas that perpetuate introverted, avoidant behavior.

**Differential Diagnosis**

The most difficult differential diagnosis for AVPD is with generalized social phobia. Both involve an avoidance of social situations, social anxiety and timidity, and both may be evident since late childhood or adolescence. Many persons with AVPD in fact seek treatment for a social phobia. To the extent that the behavior pattern pervades the person's everyday functioning and has been evident since childhood, the diagnosis of a personality disorder would be more descriptive. There are arguments to subsume all cases of AVPD into the diagnosis of generalized social phobia (as was done for schizoid disorder of childhood in DSM-IV-TR) but there is considerable empirical support for the existence of the personality dimensions of introversion and neuroticism and for an understanding of AVPD as a maladaptive variant of these personality traits.

Many persons with AVPD may also meet the criteria for dependent personality disorder (DPD). This might at first glance seem unusual, given that AVPD involves social withdrawal whereas DPD involves excessive social attachment. However,

once a person with AVPD is able to obtain a relationship, he or she will often cling to this relationship in a dependent manner. Both disorders include feelings of inadequacy, needs for reassurance and hypersensitivity to criticism and neglect (i.e. abnormally high levels of anxiousness, self-consciousness and vulnerability). A distinction between AVPD and DPD is best made when the person is seeking a relationship. Avoidant persons tend to be very shy, inhibited and timid (and are therefore slow to get involved with someone) whereas dependent persons urgently seek another relationship as soon as one ends (i.e., avoidant persons are high in introversion whereas dependent persons are high in extraversion). Avoidant persons may also be reluctant to express their feelings whereas dependent persons can drive others away by continuous expressions of neediness. The differentiation of AVPD from the schizoid, paranoid and schizotypal personality disorders was discussed in previous sections.

**Epidemiology and Comorbidity**

Timidity, shyness and social insecurity are not uncommon problems and AVPD is one of the more prevalent personality disorders within clinical settings, occurring in 5 to 25% of all patients (American Psychiatric Association, 2000). However, AVPD may be diagnosed in only 1 to 2% of the general population. It appears to occur equally among males and females, with some studies reporting more males and others reporting more females. Persons with AVPD are likely to have symptoms that meet the DSM-IV criteria for a generalized social phobia, and others may have a mood disorder.

**Course**

Persons with AVPD are shy, timid and anxious as children. Many are diagnosed with a social phobia during childhood. Adolescence is a particularly difficult developmental period due to the importance at this time of attractiveness, dating and popularity. Occupational success may not be significantly impaired, as long as there is little demand for public performance. Persons with AVPD may in fact find considerable gratification and esteem through a job or career that they are unable to find within their relationships. The job may serve as a distraction from intense feelings of loneliness. Their avoidance of social situations will impair their ability to develop adequate social skills, and this will then further handicap any eventual efforts to develop relationships. As parents, they may be very responsible, empathic and affectionate, but may unwittingly impart feelings of social anxiousness and awkwardness. Severity of the AVPD symptomatology diminishes as the person becomes older.

**Treatment**

Persons with AVPD seek treatment for their avoidant personality traits, although many initially seek treatment for symptoms of anxiety, particularly social phobia (generalized subtype). It is important in such cases to recognize that the shyness is not due simply to a dysregulation or dyscontrol of anxiousness. There is instead a more pervasive and fundamental psychopathology, involving feelings of interpersonal insecurity, low self-esteem and inadequacy.

Social skills training, systematic desensitization and a graded hierarchy of *in vivo* exposure to feared social situations have been shown to be useful in the treatment of AVPD. However, it is also important to discuss the underlying fears and insecurities regarding attractiveness, desirability, rejection,

or intimacy. Persons with AVPD are at times reluctant to discuss such feelings, as they may feel embarrassed, they may fear being ridiculed, or they may not want to “waste the time” of the therapist with such “foolish” insecurities. They may prefer a less revealing or involved form of treatment. It is important to be understanding, patient and accepting, and to proceed at a pace that is comfortable for the patient. Insecurities and fears can at times be addressed through cognitive techniques as the irrationality is usually readily apparent. It remains useful though to identify the historical source of their development as this understanding will help the patient appreciate the irrationality or irrelevance of their expectations and perceptions for their current relationships.

Persons with AVPD often find group therapies to be helpful. Exploratory and supportive groups can provide them with an understanding environment in which to discuss their social insecurities, to explore and practice more assertive behaviors, and to develop an increased self-confidence to approach others and to develop relationships outside of the group. Focused and specialized social skills training groups would be preferable to unstructured groups that might be predominated by much more assertive and extraverted members.

Many persons with AVPD will respond to anxiolytic medications, and at times to antidepressants, particularly such monoamine oxidase inhibitors as phenelzine. Normal and abnormal feelings of anxiousness can be suppressed or diminished through pharmacologic interventions. This approach may in fact be necessary to overcome initial feelings of intense social anxiety that are markedly disruptive to current functioning (e.g., inability to give required presentations at work or to talk to new acquaintances). However, it is also important to monitor closely a reliance on medications. Persons with AVPD could be prone to rely excessively on substances to control their feelings of anxiousness, whereas their more general feelings of insecurity and inadequacy would require a more comprehensive treatment.

## Dependent Personality Disorder

### Definition

Dependent personality disorder (DPD) involves a pervasive and excessive need to be taken care of that leads to submissiveness, clinging and fears of separation (American Psychiatric Association, 2000). Persons with DPD will also have low self-esteem, and will often be self-critical and self-denigrating. DPD is indicated by the presence of five or more of the eight diagnostic criteria presented in DSM-IV-TR Criteria for DPD.

### Etiology and Pathology

Central to the etiology and pathology of DPD is an insecure interpersonal attachment. Insecure attachment and helplessness may be generated through a parent–child relationship, perhaps by a clinging parent or a continued infantilization during a time in which individuation and separation normally occurs. However, DPD may also represent an interaction of an anxious–inhibited temperament with inconsistent or overprotective. Dependent persons may turn to a parental figure to provide a reassurance, security and confidence that they are unable to generate for themselves. They may eventually believe that their self-worth is contingent upon the worth or importance they have to another person.

## DSM-IV-TR Criteria 301.6

### Dependent Personality Disorder

A pervasive and excessive need to be taken care of that leads to submissive and clinging behavior and fears of separation, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

- (1) has difficulty making everyday decisions without an excessive amount of advice and reassurance from others.
- (2) needs others to assume responsibility for most major areas of his or her life.
- (3) has difficulty expressing disagreement with others because of fear of loss of support or approval (**Note:** Do not include realistic fears of retribution).
- (4) has difficulty initiating projects or doing things on his or her own (because of a lack of self-confidence in judgment or abilities rather than to a lack of motivation or energy).
- (5) goes to excessive lengths to obtain nurturance and support from others, to the point of volunteering to do things that are unpleasant.
- (6) feels uncomfortable or helpless when alone, because of exaggerated fears of being unable to care for himself or herself.
- (7) urgently seeks another relationship as a source of care and support when a close relationship ends.
- (8) is unrealistically preoccupied with fears of being left to take care of himself or herself

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

### Differential Diagnosis

Excessive dependency will often be seen in persons who have developed debilitating mental and general medical disorders such as agoraphobia, schizophrenia, mental retardation, severe injuries and dementia. However, a diagnosis of DPD requires the presence of the dependent traits since late childhood or adolescence (American Psychiatric Association, 2000). One can diagnose the presence of a personality disorder at any age during a person's lifetime, but if, for example, a DPD diagnosis is given to a person at the age of 75 years, this presumes that the dependent behavior was evident since the age of approximately 18 years (i.e., predates the onset of a comorbid mental or physical disorder).

Deference, politeness and passivity will also vary substantially across cultural groups. It is important not to confuse differences in personality that are due to different cultural norms with the presence of a personality disorder. The diagnosis of DPD requires that the dependent behavior be maladaptive, resulting in clinically significant functional impairment or distress.

Many persons with DPD will also meet the criteria for histrionic and borderline personality disorders. Persons with DPD and HPD may both display strong needs for reassurance,

attention and approval. However, persons with DPD tend to be more self-effacing, docile and altruistic, whereas persons with HPD tend to be more flamboyant, assertive and self-centered and persons with BPD will tend to be much more dysfunctional and emotionally dysregulated.

### Epidemiology and Comorbidity

DPD is among the most prevalent of the personality disorders (American Psychiatric Association, 2000), occurring in 5 to 30% of patients and 2 to 4% of the general community (Mattia and Zimmerman, 2001). A controversial issue is its differential sex prevalence. DPD is diagnosed more frequently in females but there is some concern that there might be a failure to recognize adequately the extent of dependent personality traits within males. Many studies have indicated that dependent personality traits provide a vulnerability to the development of depression in response to interpersonal loss.

### Course

Persons with DPD are likely to have been excessively submissive as children and adolescents, and some may have had a chronic physical illness or a separation anxiety disorder during childhood (American Psychiatric Association, 2000). Persons with DPD fear intensely a loss of concern, care and support from others, particularly the person with whom they have an emotional attachment. They are unable to be by themselves, as their sense of self-worth, value, or meaning is obtained by or through the presence of a relationship. They have few other sources of self-esteem. Along with the need for emotional support are perpetual doubts and insecurities regarding the current source of support. Persons with DPD constantly require reassurance and reaffirmation that any particular relationship will continue, because they anticipate or fear that at some point they may again be alone. Because of their intense fear of being alone they may become quickly attached to persons who are unreliable, unempathic and even exploitative or abusive. More desirable or reliable partners are at times driven away by their excessive clinging and continued demands for reassurance. Occupational functioning is impaired to the extent that independent responsibility and initiative are required. Persons with DPD are prone to mood disorders, particularly major depressive disorder and dysthymic disorder, and to anxiety disorders, particularly agoraphobia, social phobia and perhaps panic disorder. However, the severity of the symptomatology tends to decrease with age, particularly if the person has obtained a reliable, dependable and empathic partner.

### Treatment

Persons with DPD are often in treatment for one or more Axis I disorders, particularly a mood (depressive) or an anxiety disorder. They tend to be very agreeable, compliant and grateful patients, at times to excess. An important issue in the treatment of persons with DPD is not letting the relationship with the therapist become an end in itself (Stone, 1993). Many persons with DPD find the therapeutic relationship to satisfy their need for support, concern and involvement. The therapist can be perceived as a nurturing, caring and dependable partner who is always available for as long as the patient desires. Successful treatment can in fact be feared because it suggests the termination of the relationship, an outcome that is at times avoided at all costs. As a result, they may be excessively compliant, submissive, agreeable and cooperative in order to be the patient that the therapist would want to

retain. Therapists need to be careful not unwittingly to encourage or exploit this submissiveness, nor to commit the opposite error of rejecting and abandoning them to be rid of their needy and clinging dependency. Such responses are common in the interpersonal (marital and sexual) history of persons with DPD, and are at times experienced as well within therapeutic relationships. Persons with DPD tend to have unrealistic expectations regarding their therapist. They may attempt to have the therapist take control of their lives, and may make unrealistic requests or demands for their therapist's time, involvement and availability.

Exploration of the breadth and source of the need for care and support is often an important component of treatment. Persons with DPD often have a history of exploitative, rejecting and perhaps even abusive relationships that have contributed to their current feelings of insecurity and inadequacy. Cognitive-behavioral techniques are useful in addressing the feelings of inadequacy, incompetence and helplessness (Beck and Freeman, 1990). Social skills, problem-solving and assertiveness training also makes important contributions.

Persons with DPD may also benefit from group therapy. A supportive group is useful in diffusing the feelings of dependency onto a variety of persons, in providing feedback regarding their manner of relating to others, and in providing practice and role models for more assertive and autonomous interpersonal functioning. There is no known pharmacologic treatment for DPD.

## Obsessive-Compulsive Personality Disorder

### Definition

Obsessive-compulsive PD (OCPD) includes a preoccupation with orderliness, perfectionism, and mental and interpersonal control (American Psychiatric Association, 2000). OCPD is indicated by the presence of four or more of the eight diagnostic criteria presented in DSM criteria for OCPD.

### Etiology and Pathology

A variety of studies have indicated heritability for the trait of obsessiveness. OCPD may also relate to the adult personality trait of conscientiousness-constraint and the childhood temperament of attentional self-regulation, both of which have demonstrated substantial heritability.

Early psychoanalytic theories regarding OCPD concerned issues of unconscious guilt or shame (Gunderson and Gabbard, 2000). A variety of underlying conflicts have since been proposed, including a need to maintain an illusion of infallibility to defend against feelings of insecurity, an identification with authoritarian parents, or an excessive, rigid control of feelings and impulses (Gabbard, 2000; Oldham and Frosch, 1991; Stone, 1993). Any one or more of these conflicts might be relevant for a particular person with OCPD but there is quite limited empirical support for these particular models of etiology and pathology. OCPD includes personality traits that are highly valued within most cultures (e.g., conscientiousness) and some instances of OCPD may reflect exaggerated or excessive responses to the expectations of or pressures by parental figures.

### Differential Diagnosis

Devotion to work and productivity will vary substantially across cultural groups. One should be careful not to confuse normal cultural variation in conscientiousness with the presence of this personality disorder. A diagnosis of OCPD requires that the

**DSM-IV-TR Criteria 301.4****Obsessive–Compulsive Personality Disorder**

A pervasive pattern of preoccupation with orderliness, perfectionism, and mental and interpersonal control at the expense of flexibility, openness, and efficiency, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:

- (1) is preoccupied with details, rules, lists, order, organization, or schedules to the extent that the major point of the activity is lost
- (2) shows perfectionism that interferes with task completion (e.g., is unable to complete a project because his or her own overly strict standards are not met)
- (3) excessive devotion to work and productivity to the exclusion of leisure activities and friendships (not accounted for by obvious economic necessity)
- (4) is overconscientious, scrupulous, and inflexible about matters of morality, ethics, or values (not accounted for by cultural or religious identification)
- (5) is unable to discard worn-out or worthless objects even when they have no sentimental value
- (6) is reluctant to delegate tasks or to work with others unless they submit to exactly his or her way of doing things
- (7) adopts a miserly spending style toward both self and others; money is viewed as something to be hoarded for future catastrophes
- (8) shows rigidity and stubbornness

devotion to work be maladaptive or to the exclusion of leisure activities and friendships (American Psychiatric Association, 2000).

OCPD resembles to some extent the obsessive–compulsive anxiety disorder (OCAD). However, many persons with OCPD fail to develop OCAD, and vice versa. OCAD involves intrusive obsessions or circumscribed and repetitively performed rituals whose purpose is to reduce or control feelings of anxiety (American Psychiatric Association, 2000). OCPD, in contrast, involves rigid, inhibited and authoritarian behavior patterns that are more egosyntonic. If both behavior patterns are present, both diagnoses should be given as these disorders are sufficiently distinct that it is likely that in such cases two different disorders are in fact present.

OCPD may at times resemble narcissistic PD, as both disorders can involve assertiveness, domination, achievement and a professed perfectionism. However, the emphasis in OCPD will be on work for its own sake whereas narcissistic persons will work only to achieve status and recognition. Persons with OCPD will also be troubled by doubts, worries and self-criticism, whereas the narcissistic person will tend to be overly self-assured.

**Epidemiology and Comorbidity**

Conscientiousness is one of the fundamental dimensions of personality characterized by the tendency to emphasize duty, order, deliberation, discipline, competence and achievement (Costa and McCrae, 1992). Persons who are excessively organized, ordered, deliberate, dutiful and disciplined would be characterized as having OCPD (Widiger *et al.*, 2002). Only 1 to 2% of the general community may meet the diagnostic criteria for the disorder but this could be an underestimation (Oldham and Frosch, 1991). Up to 10% of the population has been estimated to be maladaptively stubborn, 4% excessively devoted to work, and 8% excessively perfectionistic. OCPD is one of the less frequently diagnosed personality disorders within inpatient settings, occurring in approximately 3 to 10% of patients (American Psychiatric Association, 2000) but its prevalence may be much higher within private practice settings. This disorder does appear to occur more often in males than in females but exceptions to this finding have been reported.

**Course**

As children, some persons with OCPD may have appeared to be relatively well-behaved, responsible and conscientious. However, they may have also been overly serious, rigid and constrained. As adults, many will obtain good to excellent success within a job or career. They can be excellent workers to the point of excess, sacrificing their social and leisure activities, marriage and family for their job (Oldham and Frosch, 1991; Stone, 1993). Relationships with spouse and children are likely to be strained due to their tendency to be detached and uninvolved, yet authoritarian and domineering with respect to decisions. A spouse may complain of a lack of affection, tenderness and warmth. Relationships with colleagues at work may be equally strained by the excessive perfectionism, domination, indecision, worrying and anger. Jobs that require flexibility, openness, creativity, or diplomacy may be particularly difficult. Persons with OCPD may be prone to various anxiety and physical disorders that are secondary to their worrying, indecision and stress. Those with concomitant traits of angry hostility and competitiveness may be prone to cardiovascular disorders. Mood disorders may not develop until the person recognizes the sacrifices that have been made by their devotion to work and productivity, which may at times not occur until middle-age. However, most will experience early employment or career difficulties or even failures that may result in depression.

**Treatment**

Persons with OCPD may fail to seek treatment for the OCPD symptomatology. They may seek treatment instead for disorders and problems that are secondary to their OCPD traits, including anxiety disorders, health problems (e.g., cardiovascular disorders), and problems within various relationships (e.g., marital, familial and occupational). Treatment will be complicated by their inability to appreciate the contribution of their personality to these problems and disorders. It is not unusual for persons with OCPD to perceive themselves as being simply conscientious, dutiful, moral and responsible, rather than perfectionistic, stubborn, rigid, domineering and unavailable. Their understanding is complicated further by the contribution of their traits to various achievements and successes (e.g., career advancement) and to the control of negative affect (e.g., ability to control feelings of dysphoria during a crisis). The OCPD traits are not invariably or always maladaptive, and persons with this disorder may not

appreciate the disorder's cost to their physical health, psychological well-being and personal relationships.

Cognitive-behavioral techniques that address the irrationality of excessive conscientiousness, moralism, perfectionism, devotion to work and stubbornness can be effective in the treatment of OCPD (Beck and Freeman, 1990). Persons with OCPD may in fact appreciate the rational approach to treatment provided by cognitive-behavioral therapy. A common difficulty though is the tendency to drift into lengthy and unproductive ruminations and intellectualized speculations (Beck and Freeman, 1990). Therapeutic techniques that emphasize the acknowledgment, recognition and acceptance of feelings will therefore be useful. Gestalt techniques that focus upon and confront feeling states will often feel threatening to persons with OCPD but precisely for this reason they can also be quite revealing and useful. Persons with OCPD will attempt to control therapeutic sessions, and techniques that encourage uncontrolled, freely expressed associations to explore historical motivations for control, perfectionism and workaholism are often helpful.

Persons with OCPD can be problematic in groups. They will tend to be domineering, constricted and judgmental. There is no accepted pharmacologic treatment for OCPD. Some persons with OCPD will benefit from anxiolytic or antidepressant medications, but this will typically reflect the presence of associated features or comorbid disorders. The core traits of OCPD might not be affected by pharmacologic interventions.

### Personality Disorder Not Otherwise Specified

As indicated earlier, DSM-IV includes a diagnostic category, personality disorder not otherwise specified (PDNOS), for persons with a personality disorder who do not meet the diagnostic criteria for any one of the 10 officially recognized diagnoses. PDNOS has in fact been the singly most commonly used personality disorder diagnosis in almost every study in which it has been considered. It would not, of course, be possible to discuss the etiology, pathology, course, or treatment of the PDNOS disorder as the diagnosis refers to a wide variety of personality types. However, one usage of PDNOS is for the two personality disorders presented in the appendix to DSM-IV for criterion sets provided for further study, the passive-aggressive and the depressive (American Psychiatric Association, 2000).

### Passive-Aggressive (Negativistic) Personality Disorder

#### Definition

Passive-aggressive personality disorder (PAPD) is a pervasive pattern of negativistic attitudes and passive resistance to authority, demands, responsibilities, or obligations (American Psychiatric Association, 2000). PAPD would be diagnosed by the presence of four or more of the seven criteria presented in DSM-IV-TR criteria for PAPD.

PAPD is in the appendix of DSM-IV because there has been little research to support its validity. There was concern that the DSM-III-R diagnosis described a situational reaction rather than a pervasive and chronic personality disorder, and the criteria were revised substantially for DSM-IV-TR to describe a more general and pervasive negativism. Compelling objections were

raised in response to the decision to downgrade the recognition of this longstanding diagnosis and the new criteria may eventually prove to have more validity and clinical utility than the DSM-III-R version but this additional research needs to be conducted in order for the diagnosis to be given an official recognition.

### DSM-IV-TR Criteria

#### Passive-Aggressive Personality Disorder

- A. A pervasive pattern of negativistic attitudes and passive resistance to demands for adequate performance, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:
- (1) passively resists fulfilling routine social and occupational tasks
  - (2) complains of being misunderstood and unappreciated by others
  - (3) is sullen and argumentative
  - (4) unreasonably criticizes and scorns authority
  - (5) expresses envy and resentment toward those apparently more fortunate
  - (6) voices exaggerated and persistent complaints of personal misfortune
  - (7) alternates between hostile defiance and contrition
- B. Does not occur exclusively during major depressive episodes and is not better accounted for by dysthymic disorder.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

#### Etiology and Pathology

Central to the psychopathology of PAPD appears to be bitter resentment. Passive-aggressive persons have a hostile, angry and bitter attitude towards the world. There are no data on its heritability or psychosocial etiology. It has been suggested that passive-aggressive behavior is due in part to conflicts concerning dependency and resentment, or a history of mistreatment and neglect. One might find a history of being exploited, neglected, mistreated, or abused by persons upon whom the person with PAPD relied. Negativistic traits may also be modeled by parental figures.

#### Assessment and Differential Diagnosis

Most of the DSM-IV semi-structured interviews include items for the assessment of PAPD. It is particularly important when assessing for PAPD to recognize that passive-aggressive behavior might be confined to settings in which persons have lost freedom, responsibility, or decision-making authority that was previously available to them and overt expressions of assertiveness or opposition are being discouraged. For example, it would not be surprising to observe passive-aggressive behavior within the military, prison, or some inpatient hospitals. It is important in such settings to verify that the negativistic behavior was evident earlier and is currently evident within other situations.

## Epidemiology and Comorbidity

Approximately 1 to 2% of the community will meet the DSM-III-R criteria for PAPD. Up to 5% of patients were diagnosed with PAPD earlier. The rate was higher when semi-structured interviews were used but still low compared with most other personality disorders. The prevalence rate with the DSM-IV criteria are likely to be higher, given the expansion of the disorder from simply a passive resistance to demands for adequate performance to a more general negativism. The broader formulation of negativism resembles closely the general trait of oppositionalism (characterized by the tendency to be complaining, discontented, grumbling, whining and argumentative) which does appear to occur more often in males than in females (Costa and McCrae, 1992).

## Course

Many persons with PAPD may have met the criteria for an oppositional defiant disorder during childhood, which is also characterized by the tendency to be irritable, complaining, oppositional, argumentative and negativistic (American Psychiatric Association, 1980). As adults, impairment is likely to be most evident with respect to employment. Persons with PAPD are irresponsible, lax and negligent employees, as well as resistant, oppositional and even hostile. Resolution of interpersonal conflicts is difficult due to the tendency of the passive-aggressive person to blame others. They are argumentative, sullen and critical of their peers and friends, who may not tolerate their antagonism.

## Treatment

Persons with PAPD rarely enter treatment to make effective changes to their personality or behavior. They are more likely to seek treatment for Axis I disorders (e.g., depression, anxiety, or somatoform disorder), or for marital, family, or occupational problems. The initiation of treatment is often at the insistence of a spouse, relative, or employer. They can be very difficult patients to treat due to their tendency to be blaming, argumentative, pessimistic and passively resistant. It is important for the therapist to remain supportive and empathic; carefully and benignly offering observations, suggestions, and reflections on the patient's tendency to be their own worst enemy. Cognitive treatment can be useful directly to address the false perceptions, assumptions and attributions (Beck and Freeman, 1990) as long as the therapist is not drawn into unproductive disagreements and arguments. It is common for therapists to become frustrated, impatient and defensive in response to the negativism, criticism and complaints. Periodic consultation with colleagues are advisable. Group therapy is often helpful once the patient has developed a commitment to the group, as the various members can provide consistent and confirmatory feedback regarding the negativistic and passive-aggressive behavior. There is no known pharmacologic treatment for PAPD.

## Depressive Personality Disorder

### Definition

Depressive personality disorder (DPPD) is a pervasive pattern of depressive cognitions and behaviors that have been evident since adolescence and characteristic of everyday functioning (American Psychiatric Association, 2000). These are persons

who characteristically display a gloominess, cheerlessness, pessimism, brooding, rumination and dejection. DPPD would be diagnosed by the presence of five or more of the seven criteria presented in the DSM criteria for DPPD.

A field trial by the DSM-IV Mood Disorders Work Group indicated that many persons do meet diagnostic criteria for DPPD rather than early-onset dysthymia (Phillips *et al.*, 1995; Widiger, 1999). In addition, many persons diagnosed with early-onset dysthymia may not be adequately described as having a disorder that is confined to the regulation or control of their mood. However, the DSM-IV diagnostic criteria for DPPD lack sufficient empirical support to warrant full recognition.

## DSM-IV-TR Criteria

### Depressive Personality Disorder

- A. A pervasive pattern of depressive cognitions and behaviors beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:
- (1) usual mood is dominated by dejection, gloominess, cheerlessness, joylessness, unhappiness
  - (2) self-concept centers around beliefs of inadequacy, worthlessness, and low self-esteem
  - (3) is critical, blaming, and derogatory toward self
  - (4) is brooding and given to worry
  - (5) is negativistic, critical, and judgmental toward others
  - (6) is pessimistic
  - (7) is prone to feeling guilty or remorseful
- B. Does not occur exclusively during major depressive episodes and is not better accounted for by dysthymic disorder.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

## Etiology and Pathology

DPPD may represent a characterologic variant of mood disorder, in the same manner that STPD is perhaps a characterologic variant of schizophrenia. Support for this hypothesis is provided by recent family history and biogenetic studies. Trait depression is also a facet of the personality trait of neuroticism or negative affectivity, which has demonstrated substantial heritability within the general population. A characteristically low self-esteem, self-criticism, pessimism, brooding and guilt may also result from continued, sustained criticism, derogation and discouragement by a significant parental figure that is accepted and incorporated by the child.

## Assessment and Differential Diagnosis

Most of the DSM-IV-TR semi-structured interviews include items for the assessment of DPPD (First *et al.*, 1997; Pfohl *et al.*, 1997; Widiger *et al.*, 1995; Zanarini *et al.*, 1995) and there is

also available a semi-structured interview that is devoted to its assessment, the Diagnostic Interview for Depressive Personality (Gunderson *et al.*, 1994).

DPPD overlaps substantially with early-onset dysthymia. Early-onset dysthymia was in fact conceptualized previously as depressive personality or a characterologic depression prior to DSM-III-R and the alternative criteria for dysthymia that were placed in the appendix to DSM-IV-TR were developed in part on research on DPPD. It is in fact noted in DSM-IV that there may not be a meaningful distinction between these diagnoses (American Psychiatric Association, 2000). Some may prefer to use the diagnosis of early-onset dysthymia, but a dysregulation in mood may not adequately explain why some persons are characterized by chronic attitudes of pessimism, negativism, hopelessness and dejection.

### Epidemiology and Comorbidity

There are not yet published data on the prevalence of DPPD within the general population. DPPD is likely to be comorbid with early onset dysthymia, although not all cases of DPPD will meet the DSM-IV-TR criteria for dysthymia. Many of the persons who meet the DSM-IV-TR criteria for DPPD will also likely meet the DSM-IV-TR criteria for PAPD and BPD.

### Course

As children, persons with DPPD are pessimistic, gloomy, passive and withdrawn. Performance in school is often inadequate to poor. This behavior pattern continues essentially unchanged into and through adulthood. Some, however, may eventually become good workers, exhibiting tremendous discipline and devotion to their work. Relationships with peers and sexual partners, however, are invariably problematic. They are gloomy and irritable company, and have difficulty finding pleasure, joy, or satisfaction in leisure activities. They may also be quite withdrawn and lonely, but lack an apparent motivation or energy to seek or maintain relationships.

### Treatment

Many persons with DPD are referred or seek treatment for a depressive mood disorder. It is important in such cases to recognize the extent to which the depressed mood reflects their fundamental view of themselves and the world. Their pessimism involves more than simply a dysregulation of mood. Cognitive-behavioral techniques have demonstrated efficacy in the treatment of depressive personality traits (Beck and Freeman, 1990). The depressive individual's pessimistic view of themselves and their future should be systematically challenged. Explorations of the faulty reasoning, arbitrary inferences, selective perceptions and misattributions can be influential in overcoming the pessimistic, gloomy, critical and negativistic attitudes. Audio- or videotaped role playing is useful in helping the person recognize the occurrence and pervasiveness of the depressive cognitions, and in generating, developing and rehearsing more realistic and accurate reasoning. However, exploration of the source for and historical development of self-defeating behaviors may also be helpful, not only to undermine their credibility and validity within current relationships and situations but also to address any motivation for their perpetuation. Persons with DPPD will also be responsive to antidepressant pharmacotherapy, particularly tricyclic antidepressants.

### Comparison of DSM-IV/ICD-10 Diagnostic Criteria

The items sets for paranoid, schizoid, schizotypal, antisocial, histrionic, avoidant, dependent and obsessive-compulsive personality disorders in the ICD-10 Diagnostic Criteria for Research and the DSM-IV-TR criteria differ but define essentially the same condition. Furthermore, ICD-10 does not consider schizotypal to be a personality disorder and instead includes this condition in the section containing schizophrenia and other psychotic disorders. ICD-10 also refers to several of the DSM-IV disorders by different names: antisocial is called "dissocial", borderline is called "emotionally unstable personality disorder, borderline type", and obsessive-compulsive is called "anankastic".

ICD-10 includes an "emotionally unstable personality disorder" with two subtypes: impulsive type and borderline type; criteria are provided for each subtype but not for emotionally unstable personality disorder. Neither of these subtypes by themselves correspond to the DSM-IV-TR borderline personality disorder, which includes some items from each of these subtypes. Narcissistic personality disorder in DSM-IV-TR is not included in ICD-10 as a specific personality disorder, although the DSM-IV-TR criteria set is included in Annex I of ICD-10 (i.e., "provisional criteria for selected disorders").

# Psychological Factors Affecting Medical Condition

## Definition

This diagnostic category recognizes the variety of ways in which specific psychological or behavioral factors can adversely affect medical illnesses. Such factors may contribute to the initiation or the exacerbation of the illness, interfere with treatment and rehabilitation, or contribute to morbidity and mortality. Psychological factors may themselves constitute risks for medical diseases, or they may magnify the effects of nonpsychological risk factors. The effects may be mediated directly at a pathophysiological level (e.g., psychological stress inducing myocardial ischemia) or through the patient's behavior (e.g., noncompliance).

The criteria in the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (DSM-IV) includes situations in which psychological factors interfere with medical treatment, pose health risks, or cause stress-related pathophysiological changes. This diagnosis is structured in DSM-IV so that both the psychological factor and the general medical condition are to be specified. The psychological factor can be an Axis I or Axis II mental disorder (e.g., major depressive disorder aggravating coronary artery disease), a psychological symptom (e.g., anxiety exacerbating asthma), a personality trait or coping style (e.g., type A behavior contributing to the development of coronary artery disease), maladaptive health behaviors (e.g., unsafe sex in a person with human immunodeficiency virus [HIV] infection), a stress-related physiological response (e.g., tension headache), or other unspecified psychological factors. The medical condition is noted on Axis III.

The subject of psychological factors affecting medical condition (PFAMC) has become the focus of intense research because of the illumination it may provide of basic disease mechanisms (e.g., psychoneuroimmunology) and because of the deep interest in improving both the outcomes and the efficiency of health care delivery. In epidemiological studies, several psychiatric disorders increase the likelihood of mortality especially depression, bipolar disorder, schizophrenia, and alcohol abuse or dependence. Psychiatric disorders or symptoms in patients with medical illness may increase their use of health care services, particularly the length of costly hospital stays. Interest has been further increased by intervention trials aimed at psychological factors or disorders that have demonstrated improvements in medical outcomes and in quality of life in patients with serious medical disorders.

It should be evident that this diagnosis is not really a discrete diagnostic category but rather a label for the interactive effects of psyche on soma. Mind-body interactions have long been a focus of interest, both in health and in disease. Psychiatric

## DSM-IV-TR Criteria 361

### Psychological Factors Affecting Medical Condition

- A. A general medical condition (coded on Axis III) is present.
- B. Psychological factors adversely affect the general medical condition in one of the following ways:
  - (1) the factors have influenced the course of the general medical condition as shown by a close temporal association between the psychological factors and the development or exacerbation of, or delayed recovery from, the general medical condition
  - (2) the factors interfere with the treatment of the general medical condition
  - (3) the factors constitute additional health risks for the individual
  - (4) stress-related physiological responses precipitate or exacerbate symptoms of the general medical condition

*Choose name based on the nature of the psychological factors (if more than one factor is present, indicate the most prominent):*

**Mental disorder affecting... [indicate the general medical condition]** (e.g., an Axis I disorder such as major depressive disorder delaying recovery from a myocardial infarction)

**Psychological symptoms affecting... [indicate the general medical condition]** (e.g., depressive symptoms delaying recovery from surgery; anxiety exacerbating asthma)

**Personality traits or coping style affecting... [indicate the general medical condition]** (e.g., pathological denial of the need for surgery in a patient with cancer; hostile, pressured behavior contributing to cardiovascular disease)

**Maladaptive health behaviors affecting... [indicate the general medical condition]** (e.g., overeating; lack of exercise; unsafe sex)

**Stress-related physiological response affecting... [indicate the general medical condition]** (e.g., stress-related exacerbations of ulcer, hypertension, arrhythmia, or tension headache)

**Other or unspecified psychological factors affecting...**  
**[indicate the general medical condition]** (e.g.,  
 interpersonal, cultural, or religious factors)

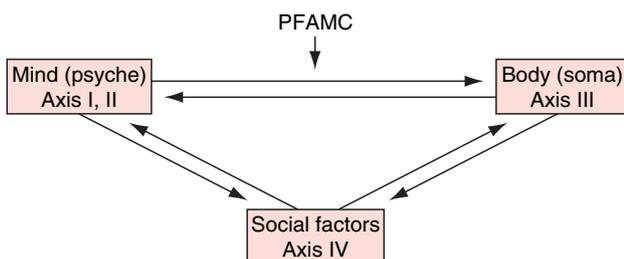

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

illness and medical disease frequently coexist. Psychiatrists and investigators of past eras were misled by this frequent comorbidity into premature conclusions that the psychological factors were preeminent in the causation of the medical disorders, and these were designated psychosomatic. A more modern approach has been to recognize that all medical illnesses are potentially affected by many different factors in the biological, psychological and social realms. The earlier designation of certain disorders as psychosomatic (e.g., peptic ulcer disease) overvalued the contribution of psychological factors to those disorders and undervalued their contribution to other medical disorders (e.g., cancer). Furthermore, whereas labeling medical illnesses as psychosomatic drew attention to the importance of mind–body interactions, it unfortunately and falsely implied to many patients and physicians that the illness was basically psychogenic, that the symptoms were not “real”, and that the illness was somehow the patient’s fault.

The diagnosis of PFAMC focuses attention on one causal direction in the interactions between psyche and soma, that is, the effects of psychological factors on the medical condition (Figure 63.1). This represents a heuristic simplification, highlighting a particular process for further exploration, understanding, and intervention. In most patients, there are effects in the other direction as well (i.e., the effects of general medical illness on psychological function). Furthermore, both mind and body interact with social and environmental factors both dramatic (e.g., poverty, racism, war) and more subtle (e.g., employment status, neighborhood), that affect the incidence and outcome of medical illness. Diagnosing PFAMC may help psychiatrist and patient address an important dimension of care, but the other “arrows” of Figure 63.1 often warrant attention too.

## Etiology and Pathophysiology

How do psychological factors affect medical illnesses? Physicians have long recognized that psychological factors seem to affect medical illnesses, and research elucidating the intervening causal mechanisms is now rapidly growing. From their clinical experience, physicians recognize many ways in which psy-

**Figure 63.1** Psychological factors affecting medical condition (PFAMC): Interaction between psyche and soma. Social factors warrant attention as well.

chological factors affect the onset, progression and outcome of their patients’ illnesses. First, psychological factors may promote other known risks for medical illness. Smoking is a risk factor for heart disease, cancer and pulmonary and many other diseases, and individuals with schizophrenia or depression are much more likely to smoke than the general population. A wide variety of psychiatric illnesses are associated with an increased likelihood of abuse of other substances. Depression and schizophrenia are also associated with a sedentary lifestyle. Patients with affective disorders often have chronic pain and chronically tend to overuse analgesics. Individuals with schizophrenia, bipolar disorder and some personality disorders are more likely to engage in unsafe sex, which in turn increases the risk of sexually transmitted diseases, including HIV infection and hepatitis B. Depression, eating disorders and other emotional and behavioral factors affect the pattern and content of diet.

In addition to promoting known risk factors for medical illness, psychological factors also have an impact on the course of illness by influencing how patients respond to their symptoms, including whether and how they seek care. For example, the defense mechanism of denial may lead an individual to ignore anginal chest pain, attribute it to indigestion, delay seeking medical attention, or minimize the pain when describing it to a physician. This tends to result in treatment delay after the acute onset of coronary symptoms, with consequently greater morbidity and mortality. Anxiety is also a common cause of avoidance or delay of health care; phobic fears of needles, sight of blood, surgery and other health care phobias are common. Patients may also neglect their symptoms and fail promptly to seek medical care because of depression, psychosis, or personality traits (e.g., procrastination).

Psychological factors also affect the course of illness through their effects on the physician–patient relationship, since they influence both patients’ health behaviors and physicians’ diagnostic and treatment decisions. A substantial proportion of the excess mortality experienced by individuals with mental disorders is explained by their receiving poorer quality medical care (Druss *et al.*, 2001a). One explanation for the poorer quality and outcomes of medical care in patients with both serious medical and mental illnesses is the lack of integration between their medical and mental health care (Druss *et al.*, 2001b). Psychological factors can also reduce a patient’s compliance with diagnostic recommendations, treatment and lifestyle change, and can interfere with rehabilitation through impairment of motivation, understanding, optimism, or tolerance. A recent meta-analysis found that patients with depression are three times as likely to be noncompliant with medical treatment than patients without (DiMatteo *et al.*, 2000). In addition, many of the effects of psychological factors on medical illness appear to be mediated through a wide array of social factors, including social support, job strain, disadvantaged socioeconomic and educational status, and marital stress.

There is an increasing body of scientific evidence that psychological factors, in addition to their impact on classic (nonpsychological) risk factors, patient behaviors and the physician–patient interaction, have direct effects on pathophysiological processes. For example, stress has been experimentally shown to cause myocardial ischemia in patients with coronary disease. Stress and depression are associated with a wide range of immunological effects. Many psychiatric disorders (especially mood disorders) are associated with disruptions in homeostasis including sleep architecture, other circadian rhythms, and

endocrine secretion and feedback. For example, depression causes increased bone remodeling and decreased bone density (Herran *et al.*, 2000). That such effects occur is well established, but the magnitude of their clinical significance in medical disease is often unclear, and full explanatory causal linkages have for the most part not been demonstrated yet. Nevertheless, investigators have learned a great deal about changes in autonomic, hematologic, endocrine, immunologic and sensory function, as well as gene expression that bring us closer to understanding how psychological factors may affect medical illness. These issues of pathophysiology are discussed later in this chapter for each organ system or specialty category.

### Assessment and Diagnosis

The diagnosis of PFAMC differs from most other psychiatric diagnoses in its focus on the interaction between the mental and medical realms. As noted, the criteria require more than that the patient have both a medical illness and contemporaneous psychological factors, because their coexistence does not always include significant interactions between them. To make the diagnosis of PFAMC, either the factors must have influenced the course of the medical condition, interfered with its treatment, contributed to health risks, or physiologically aggravated the medical condition.

Let us consider each of these four ways of making the diagnosis of PFAMC in more detail. The psychological factor's influence on the course of a general medical condition can be inferred from a close temporal relationship between the factor and the development or exacerbation of the medical condition (or delayed recovery). For example, a 45-year-old male executive reports symptoms sounding like typical angina, but occurring only on weekends. Further questioning reveals that he is depressed over deterioration in his marriage. During the week he works late and has limited contact with his family but he spends the weekend at home. The symptoms began after he and his wife started arguing every weekend. The temporal link between onset and recurrence of angina and marital arguments supports a diagnosis of PFAMC.

PFAMC can be diagnosed when the psychological factor interferes with treatment including not seeking medical care, not following up, nonadherence to prescribed drugs or other treatment, or maladaptive modifications in treatment made by the patient or family. The executive with angina rejected his physician's recommendations for further assessment and treatment. He said, "I do get upset at home but I feel just fine at the office, so there couldn't be anything really wrong with me". The patient is able to acknowledge marital discord, but the defense of denial clouds his perception of his physical health and blocks appropriate medical care. This is another form of PFAMC.

PFAMC can also be diagnosed when the psychological factor contributes to health risks, exemplified by the executive increasing his smoking and drinking despite his physician's warnings. ("It's the only way I can cope with my wife.") Finally, PFAMC is an appropriate diagnosis when there are stress-related physiological responses precipitating or exacerbating symptoms of the medical condition. The same man observes that angina is most likely to occur after marital arguments during which he becomes irate, yells, slams doors and throws things.

When a patient's medical illness is faring worse than expected and not responding well to standard treatment, physicians should and often do consider whether a psychological factor may

be responsible for the poorer than expected outcome. This is a far from trivial task. To ignore the possibility of PFAMC may miss the crucial barrier to the patient's recovery. On the other hand, premature or facile attribution to psychological factors may lead the physician to overlook medical or social explanations for "treatment-resistant disease" and unfairly blame the patient, with resultant further deterioration in health outcomes and the physician-patient relationship.

To illustrate, a common clinical problem is the brittle diabetic adolescent with labile blood glucose levels and frequent episodes of ketoacidosis and hypoglycemia, despite vigorous attempts by the physician to improve diabetic management and glucose control. The considerable difficulty in controlling such patients' diabetes is often attributed to adolescents' dislike of lifestyle restrictions, their tendency to act out and rebel against authority figures, their denial of vulnerability, their ambivalence about their need for nurturance and their wish to be "normal". There are many adolescent (and some adult) diabetic patients for whom these psychological issues do play an important role in undermining diabetes management through noncompliance regarding medication, diet, visits to the physician, substance use and activity limitations. However, psychological factors do not always account for brittleness and are sometimes incorrectly suspected. It has been demonstrated that much of the difficulty in achieving stable glucose control in adolescent diabetics is the result of the dramatically labile patterns of hormone secretion (cortisol, growth hormone) typical of adolescence, independent of psychological status.

PFAMC has descriptive names for subcategories described as follows.

### Mental Disorder Affecting a General Medical Condition

If the patient has a mental disorder meeting criteria for an Axis I or Axis II diagnosis, the diagnostic name is mental disorder affecting medical condition, with the particular medical condition specified. In addition to coding PFAMC, the specific mental disorder is also coded on Axis I or Axis II. Examples include major depressive disorder that reduces energy and compliance in a hemodialysis patient; panic disorder that makes an asthmatic patient hypersensitive to dyspnea; and schizophrenia in a patient with recurrent ventricular tachycardia who refuses placement of an automatic implantable defibrillator because he fears it will control his mind.

### Psychological Symptoms Affecting a General Medical Condition

Patients who have psychological symptoms that do not meet the threshold for an Axis I diagnosis may still experience important effects on their medical illness, and the diagnosis would be psychological symptoms affecting a medical condition. Examples include anxiety that aggravates irritable bowel syndrome; depressed mood that hinders recovery from hip replacement surgery; and anger that interferes with rehabilitation after spinal cord injury.

### Personality Traits or Coping Style Affecting a General Medical Condition

This may include personality traits or coping styles that do not meet criteria for an Axis II disorder and other patterns of response considered to be maladaptive because they may pose a

risk for particular medical illnesses. An example is the competitive hostility component of the type A behavior pattern, and its impact on coronary artery disease. Maladaptive personality traits or coping styles are particularly likely to interfere with the physician–patient relationship as well as the patient’s relationships with other caregivers.

### Maladaptive Health Behaviors Affecting a General Medical Condition

Many maladaptive health behaviors have significant effects on the course and treatment of many medical conditions. Examples include sedentary lifestyle, smoking, abuse of alcohol or other substances, and unsafe sexual practices. If the maladaptive behaviors can be better accounted for by an Axis I or Axis II disorder, the first subcategory (mental disorder affecting a medical condition) should be used instead.

### Stress-related Physiological Response Affecting a General Medical Condition

Examples of stress-related physiological responses affecting a medical condition include the precipitation by psychological stress of angina, cardiac arrhythmia, migraine, or attack of colitis in medically vulnerable individuals. In such cases, stress is not the cause of the illness or symptoms; the patient has a medical condition that etiologically accounts for the symptoms (e.g., coronary artery disease, migraine, or ulcerative colitis), and the stressor instead represents a precipitating or aggravating factor.

### Other or Unspecified Psychological Factors Affecting a General Medical Condition

There are other psychological phenomena that may not fit within one of these subcategories. An interpersonal example is marital dysfunction. A cultural example is the extreme discomfort women from some cultures may experience being alone with a male physician, even while they are fully dressed. A religious example is a Jehovah’s Witness who ambivalently refuses blood transfusion. These fall under the residual category of other or unspecified psychological factors affecting a medical condition.

### Differential Diagnosis

As noted before, the close temporal association between psychiatric symptoms and a medical condition does not always reflect PFAMC. If the two are considered merely coincidental, then separate psychiatric and medical diagnoses should be made. In some cases of coincident psychiatric and medical illness, the mental symptoms are actually the result of the medical condition (i.e., the causality is in a direction opposite from that of PFAMC). When a medical condition is judged to be pathophysiologically causing the mental disorder (e.g., hypothyroidism causing depression), the correct diagnosis is the appropriate mental disorder due to a general medical condition (e.g., mood disorder due to hypothyroidism, with depressive features). In PFAMC, the psychological or behavioral factors are judged to precipitate or aggravate the medical condition.

Substance use disorders may adversely affect many medical conditions, and this can be described through PFAMC. However, in some patients, all of the psychiatric and medical symptoms are direct consequences of substance abuse, and it is usually parsimonious to use just the substance use disorder diagnosis. For example, a patient with delirium tremens after alcohol

withdrawal would receive a diagnosis of alcohol withdrawal delirium, not PFAMC, but a patient with alcohol dependence who repeatedly missed hemodialysis treatments because of intoxication would receive diagnoses of alcohol dependence and PFAMC (mental disorder affecting end stage renal disease).

Patients with somatoform disorders (e.g., somatization disorder, hypochondriasis) present with physical complaints which may mimic a medical illness, but the somatic symptoms are actually accounted for by the psychiatric disorder. In principle, it might seem that somatoform disorders are easily distinguished from PFAMC, because PFAMC requires the presence of a diagnosable medical condition. The distinction in practice is sometimes difficult because the patient may have both a somatoform disorder and one or more medical disorders. For example, a patient with seizures regularly precipitated by emotional stress might have true epilepsy aggravated by stress (PFAMC), pseudo-seizures (conversion disorder), or both.

### Epidemiology and Comorbidity

Because this diagnosis describes a variety of possible interactions between the full range of psychiatric disorders (as well as symptoms and behaviors) on the one hand and the complete range of medical diseases on the other, it is impossible to estimate overall rates of prevalence or incidence. We can start, however, by noting how frequently medical and psychiatric disorders coexist. Psychiatric problems are common in medical patients, although the measured frequency varies, depending on the criteria and method of measurement used. A reasonable estimate is that 25 to 30% of medical outpatients and 40 to 50% of general medical inpatients have diagnosable psychiatric disorders (Table 63.1). Most common in medical outpatients are depression, anxiety and substance abuse; medical inpatients most often have cogni-

**Table 63.1** Prevalence of Selected Psychiatric Disorders

Disorder	Community	Primary Care Patients	Medical Inpatients
All psychiatric disorders	15–20%	25–30%	40–50%
Depression			
Depressive symptoms	10–15%	10–30%	20–35%
Major depressive disorder	2–4%	5–10%	5–25%
Anxiety			
Anxiety symptoms	10–20%	12–20%	20–30%
Panic disorder	1–2%	2–15%	—
Cognitive disorders			
	1%	—	15–20%
	5–10%	—	30–50%
	(>65 yr)	—	(>65 yr)

tive impairment (delirium, dementia), depression and substance abuse. Depression, both as a diagnosis and as a symptom, has been better studied in the medically ill than any other psychiatric syndrome. Major depressive disorder occurs in 18 to 25% of patients with serious coronary disease, in 25% of those with cancer, and at three times the normal rate in diabetic patients. Individuals presenting with symptoms of chronic fatigue have a 50 to 75% lifetime prevalence of major depression.

Nonpsychiatric physicians under diagnose and under treat psychiatric disorders in the medically ill. Medical disorders are also common in patients seen for mental health treatment, and mental health specialists often under recognize the presence and significance of coexisting medical disorders. Regardless of whether the patient has come seeking medical care or mental health care, medical and psychiatric problems are often both present. Such coincidence by itself is not sufficient for the diagnosis of PFAMC. In some cases, the illnesses may coexist with little effect on each other; in other cases, the effects of the medical illness on the psychiatric condition may be more important. The diagnosis of PFAMC in DSM-IV is reserved for patients in whom psychological factors adversely affect a medical condition in a specifiable way.

### Course

Given the wide range of psychiatric disorders and psychological factors that may affect medical illness and the large number of different medical disorders that may be influenced, there are no general rules about the course of the PFAMC interaction. Psychological factors may have minor or major effects at a particular point or throughout the course of a medical illness. We do know in general that patients with medical disorders who also have significant psychological symptoms have poorer outcomes and higher medical care costs than those patients with the same medical disorders but without psychological distress. A number of studies now document that psychological or psychiatric problems (particularly cognitive disorder, depression and anxiety) in general medical inpatients are associated with significant increases in length of hospital stay. Psychosocial interventions have been able to improve outcomes in medical illness, sometimes with an attendant savings in health care costs.

The impact of psychological factors on the course and natural history of medical disorders is discussed further in this chapter in the context of specific diseases.

### Treatment

Management of psychological factors affecting the patient's medical condition should be tailored both to the particular psychological factor of relevance and to the medical outcome of concern. Some general guidelines, however, can be helpful. The physician, whether in primary care or a specialty, should not ignore apparent psychiatric illness. Unfortunately, this occurs all too often because of discomfort, stigma, lack of training, or disinterest. Referring the patient to a mental health specialist for evaluation is certainly better than ignoring the psychological problem but should not be regarded as "disposing" of it, because the physician must still attend to its potential impact on the patient's medical illness. Similarly, psychiatrists and other mental health practitioners should not ignore coincident medical disease and should not assume that referral to a nonpsychiatric physician absolves them of all responsibility for the patient's medical problem.

### Mental Disorder Affecting a Medical Condition

If the patient has a treatable Axis I disorder, treatment for it should be provided. Whereas this is obviously justified on the basis of providing relief from the Axis I disorder, psychiatric treatment is further supported by the myriad ways in which the psychiatric disorder may currently or in future adversely affect the medical illness. The same psychopharmacological and psychotherapeutic treatments used for Axis I mental disorders are normally appropriate when an affected medical condition is also present. However, even well-established psychiatric treatments supported by randomized controlled trials have seldom been validated in the medically ill, who are typically excluded from the controlled trials. Thus, psychiatric treatments may not always be directly generalizable to, and often must be modified for, the medically ill.

When prescribing psychiatric medications for patients with significant medical comorbidity, the psychiatrist should keep in mind potential adverse effects on impaired organ systems (e.g., anticholinergic exacerbation of postoperative ileus; tricyclic antidepressant causing completion of heart block), changes in pharmacokinetics (absorption, protein binding, metabolism and excretion) and drug–drug interactions. Psychotherapy may also require modification in patients with comorbid medical illness, including greater flexibility regarding the length and frequency of appointments, and deviations from standard therapeutic abstinence and neutrality. Psychotherapists treating patients with PFAMC should usually be much more active in communicating with other health care professionals caring for the patient (with the patient's consent) than is usually the case in psychotherapy.

If the patient has an Axis II personality disorder or other prominent personality or coping style, the psychiatrist should modify the patient's treatment accordingly, which is usually more easily accomplished than trying to change the patient's personality. For example, patients who tend to be paranoid or mistrustful should receive more careful explanations, particularly before invasive or anxiety-provoking procedures. With narcissistic patients, the psychiatrist should avoid relating in ways that may seem excessively paternalistic or authoritarian to the patient. With some dependent patients, it may be advisable to be more directive, without overdoing it and fostering excessive dependency.

### Psychological Symptoms Affecting a General Medical Condition

In some instances, psychiatric symptoms not meeting the threshold for an Axis I diagnosis will respond positively to the same treatments used for the analogous Axis I psychiatric disorder, with appropriate modifications as noted before. There is not a great amount of treatment research on subsyndromal psychiatric symptoms, and even less in patients with comorbid medical illness, so this area of practice remains less evidence-based. Some psychiatric symptoms affecting a medical condition may be amenable to stress management and other behavioral techniques as well as appropriate reassurance.

Any intervention directed by the psychiatrist at a particular patient's psychological symptoms or behavior should be grounded in exploratory discussion with the patient. Interventions without such grounding tend to seem at best superficial and artificial and at worst are entirely off the mark. For example, if the psychiatrist wrongly presumes to know why a particular

patient seems anxious without asking, the patient is likely to feel misunderstood. Facile, nonspecific reassurance can undermine the physician–patient relationship because the patient is likely to feel that the psychiatrist is out of touch with and not really interested in the patient’s experience. It is especially important with depressed patients that psychiatrists avoid premature or unrealistic reassurance or an overly cheerful attitude; this tends to alienate depressed patients, who feel that their psychiatrist is insensitive and either does not understand or does not want to hear about their sadness. Physicians **should** provide specific and realistic reassurance, emphasize on a constructive treatment plan and mobilize the patient’s support system.

### Personality Traits or Coping Style Affecting a General Medical Condition

As with Axis II disorders affecting a medical condition, psychiatrists should be aware of the personality style’s effects on the physician–patient relationship and modify management better to fit the patient. For example, with type A “time urgent” patients, psychiatrists may need to be more sensitive to issues of appointment scheduling and waiting times. Group therapy interventions can enhance active coping with serious medical illnesses like cancer, heart disease and renal failure but to date have usually been designed to be broadly generalizable rather than targeted to one particular trait or style (with the exception of type A behavior).

Another general guideline is not to attack or interfere with a patient’s defensive style unless the defense is having an adverse impact on the medical illness or its management. Psychiatrists are particularly tempted to intervene when the defense is dramatic, breaks with reality, or makes the psychiatrist uncomfortable.

For example, denial is a defense mechanism that reduces anxiety and conflict by blocking conscious awareness of thoughts, feelings, or facts that an individual cannot face. Denial is common in the medically ill but varies in its timing, strength and adaptive value. Some patients are aware of what is wrong with them but consciously suppress this knowledge by avoiding thinking about or discussing it. Others cope with the threat of being overwhelmed by their illness by unconsciously repressing it and thereby remain unaware of their illness. Marked denial, in which the patient emphatically refuses to accept the existence or significance of obvious symptoms and signs of the disease, may be seen by the psychiatrist as an indication that the patient is “crazy” because the patient seems impervious to rational persuasion. In the absence of signs of another major psychiatric disorder (e.g., paranoid delusions), such denial is not often a sign of psychosis but rather represents a defense against overwhelming fear.

The adaptive value of denial may vary, depending on the nature or stage of illness. When a patient’s denial does not preclude cooperation with treatment, the psychiatrist should leave it alone. The psychiatrist does have an ethical and professional obligation to ensure that the patient has been informed about the illness and treatment. After that, if the patient accepts treatment but persists with an irrationally optimistic outlook, the psychiatrist should respect the patient’s need to use denial to cope. For some, the denial is fragile, and the psychiatrist must decide whether the defense should be supported and strengthened, or if the patient had better give up the denial to discuss fears directly and receive reassurance from the psychiatrist. The psychiatrist should not support denial by giving the patient false information, but rather encourage hope and optimism. When denial is extreme, patients may refuse vital treatment or threaten to leave against medical advice. Here, the psychiatrist must try to help reduce denial but not by

directly assaulting the patient’s defenses. Because such desperate denial of reality usually reflects intense underlying anxiety, trying to scare the patient into cooperation will intensify denial and the impulse to flight. A better strategy for the psychiatrist is to avoid directly challenging the patient’s claims while simultaneously reinforcing concern for the patient and maximizing the patient’s sense of control.

---

#### Clinical Vignette 1

Mr B is a 60-year-old married judge with coronary artery disease. He was referred for psychiatric evaluation by his cardiologist because he declined coronary artery bypass surgery despite strong and repeated recommendations for surgery by the cardiologist. The cardiologist perceived that the patient’s resistance to surgery was not due to lack of information or understanding.

Mr B had no acute psychiatric symptoms, although he had several lifelong phobias including fear of cats, fear of being buried alive and claustrophobia (recent episodes in the hospital elevator and during magnetic resonance imaging). His only previous psychiatric contact was some marital therapy 20 years earlier. His coronary artery disease was severe, with two myocardial infarctions and recurrent malignant arrhythmias. He continued to have recurrent angina despite maximal medical management; his pain occurred mainly at night as “a predictable consequence of pushing too hard at work” (he typically worked 12-hour days). He had also had a stroke 3 months ago, from which he had made a complete recovery with no sequelae. Twenty years earlier, he had surgery for a renal stone that was complicated postoperatively with five pulmonary emboli. He said that he has had “eight near-death experiences” amidst his various illnesses.

Mr B was eager to discuss his reluctance to have coronary bypass surgery. He had not decided against the surgery but had been unable to reach a decision. He brought to the appointment with the psychiatrist a two-page list of arguments for and against surgery and other variables that could influence the decision and outcome. He was aware that he was approaching the question of surgery with the same style of carefully balanced consideration of all sides of an issue that he prided himself on in his occupation as a judge. He worked longer days than his colleagues because he believed it took more time to make fair, proper and legally correct decisions. His analysis of the pros and cons of surgery, as well as intervening factors affecting and affected by the decision, appeared to the psychiatrist to be well informed, accurate, flexible and appropriate. There was no evidence of rigidity in his thinking, premature closure, or distorted perceptions. Whereas the thought processes were logical, they had not enabled him to reach a decision, despite extensive discussions with the cardiologist over a period of months. He was aware that this was another decision in his life that was taking much longer than average, but he thought it could not be resolved any other way.

This case represents an example of personality trait or coping style affecting a general medical condition. His obsessional style was largely adaptive in his chosen occupation, although it reduced his efficiency. Now

confronted with a major health care decision, and mindful of major complications he had suffered after surgery in the past, the need to weigh all sides of an issue had paralyzed his decision-making. The presence of phobias in his history raised the possibility of these too affecting his decision-making, but he denied feeling fearful of the surgery, anesthesia, intubation and the like. The anxiety he was experiencing was entirely focused around making the right decision.

### Maladaptive Health Behavior Affecting a General Medical Condition

This is an area of research with many promising approaches. To achieve smoking cessation, bupropion, nicotine replacement, behavioral therapies and other pharmacological strategies all warrant consideration. Behavioral strategies are also useful in promoting better dietary practices, sleep hygiene, safe sex and exercise. For some patients, change can be achieved efficiently through support groups, whereas others change more effectively through a one-to-one relationship with a health care professional.

### Stress-related Physiological Response Affecting a Medical Condition

Biofeedback, relaxation techniques, hypnosis and other stress management interventions have been helpful in reducing stress-induced exacerbations of medical illness including cardiac, gastrointestinal, headache and other symptoms. Pharmacological interventions have also been useful (e.g., the widespread practice of prescribing benzodiazepines during acute myocardial infarction to prevent stress-induced increase in myocardial work).

### Psychological Factors in Specific Medical Disorders

In the remainder of this chapter, the effects of psychological factors on selected medical disorders are reviewed. The primary focus is on those effects for which there is reasonable evidence from controlled studies. Space considerations preclude inclusion of all valuable studies and all medical disorders.

Most of the early research suffers from serious methodological flaws, including use of small biased samples, limited or no statistical analysis, poor (if any) controls and retrospective designs subject to recall and other biases. This early work generated excitement and interest in psychosomatic medicine but also produced ideas that in retrospect were intellectually appealing but erroneous and simplistic regarding the special designation of certain diseases as psychosomatic.

Later research has shown improvements in methodology, but problems in design and interpretation continue. Several studies that seem to show significant effects of psychological factors on medical disease are inconclusive because of nonequivalence in groups at baseline either in medical disease severity or in treatments received (many studies do not even monitor this possibility). Some studies fail to attend to important potential confounding factors such as smoking or diet. A number of studies measure too many psychological variables and then overly emphasize the few “discovered” positive associations in the published results. Failure to standardize measures of initial psychological factors and measures of medical outcome has also been frequent. Despite

these and other critiques, a large and growing body of disease-specific research is illuminating the full range of PFAMC.

### Psychological Factors in Oncology

Many health professionals and lay people believe that psychological factors play a major role in cancer onset and progression. The media have promoted popular ideas of overcoming cancer through “mind over body”. Enthusiasm for these optimistic theories and practices should be tempered by the recognition that scientific evidence clarifying the relationship between psychological factors and cancer lags far behind. Nevertheless, there is an exciting frontier of exploration of immune and endocrine mechanisms that may provide a pathophysiological basis for some PFAMC in cancer. In this section, aspects of PFAMC in oncology that have received support in the research literature are reviewed.

### Mental Disorders and Psychological Symptoms Affecting Cancer

The most active area of study has been the linking of affective states, particularly depression (as a symptom or as a disorder), with the onset and course of cancer. A meta-analysis of studies relating depression to later cancer development found a small statistically significant but clinically insignificant association (McGee *et al.*, 1994). The interpretation of epidemiologic studies is complex with many methodological problems.

Besides epidemiologic studies, other research has focused on the impact of affective states on outcome in cancer patients. Emotional distress may predict lower survival with lung cancer as may anger in metastatic melanoma patients. Other studies have found positive, negative, or mixed associations between depression and mortality in cancer patients. Besides survival, depression in cancer patients may result in poorer pain control, poorer compliance and less desire for life-sustaining therapy. Neither cancer onset nor progression have been clearly shown to be influenced by bereavement.

### Personality Traits or Coping Style Affecting Cancer

A large body of literature has described cancer patients’ degree of emotional expressiveness and its purported effect on prognosis. Epidemiological studies, however, have not supported a relationship between emotional suppression and cancer occurrence or mortality.

### Other Psychological Factors in Cancer

An enormous literature documents the adverse effects of maladaptive health behaviors as risk factors for the development of various cancers, especially smoking but also excessive alcohol use, unsafe sex and dietary practices. Relatively less research has examined the effects of interpersonal variables on cancer, but there is some evidence that the quality of relationships may affect cancer onset and its course. Social relations and social support and their effects on cancer patients (as with other diseases) are complex phenomena and may vary with cancer site and extent of disease.

A number of human studies have shown an increased frequency of stressful life events preceding the onset of cervical,

pancreatic, gastric, lung, colorectal and breast cancer. Many other studies have failed to find any association between preceding stressful life events and cancer onset, relapse, or progression.

## Psychosocial Intervention and Cancer Outcome

A number of studies have shown improvement in the quality of life in cancer patients receiving group therapy including improved mood and vigor, decreased pain and better. The possibility that cancer patients receiving psychotherapy might have increased survival time as well as improved quality of life has generated intense study with more evidence showing improvement in pain control and mood than for increased survival.

## Psychological Factors in Cardiology

### Coronary Disease

One of the most studied examples of PFAMC is the type A behavior pattern and its relationship to coronary artery disease. Type A is a complex set of traits including impatience, hostility, intense achievement drive and time urgency, among others. However, the relationship between type A behavior pattern and coronary disease has come under serious question. Later epidemiological studies have not strongly supported type A behavior pattern as a coronary risk factor, and most angiographic studies have failed to find an association between type A behavior and the extent of coronary artery disease. The possibility that type A behavior pattern is nevertheless an important risk factor should be kept in mind, considering that the evidence for other risk factors (e.g., exercise or cholesterol) has often been ambiguous. Whereas global type A behavior ratings are probably not reliable predictors of coronary artery disease outcome, the component behavior of hostility may be although here too there are conflicted studies. Only one large randomized study has been reported, in which men were assigned after myocardial infarction to receive cardiac group counseling with or without type A counseling. The coronary artery disease recurrence rate was 7.2% in the group that received type A behavior counseling and 13% in the control subjects, with no difference in mortality (Friedman *et al.*, 1986).

Although it has received less media attention than type A, the evidence that depression is a risk factor affecting both the onset and course of coronary artery disease is stronger than that for type A. The weighting of depression as an independent risk factor in coronary artery disease has had to adjust for its interrelationships with other risk factors, especially smoking. Depression in coronary artery disease is associated with increased morbidity and mortality, which cannot be accounted for by other variables including severity of cardiac disease. Frasure-Smith and coworkers (1993) reported a fourfold increase in mortality 6 months after myocardial infarction in patients with major depression compared with those without depression. In a large epidemiologic study, major depression tripled the relative risk of cardiac mortality in those without heart disease, and quadrupled it in those who did have heart disease (Penninx *et al.*, 2001). Depression is also associated with an increased risk for serious arrhythmia. The severity of depressive symptoms has more impact on disability than does the number of stenosed coronary arteries. Depression also reduces the return to work in patients with coronary artery disease. A recent randomized trial of 1834 post-MI subjects who were categorized as depressed and/or socially isolated

were treated with antidepressant medication (Taylor *et al.*, 2005). Subjects taking SSRIs were at lower risk of death and recurrent MI compared with untreated subjects.

Although the mechanisms by which depression increases morbidity and mortality in coronary artery disease has not been firmly established, evidence is mounting regarding depression's adverse effects on heart rate variability, autonomic imbalance and arrhythmia, and platelet activation. In coronary artery disease, depression also reduces functional capacity, amplifies somatic symptoms (especially pain), and reduces motivation and compliance with medication, lifestyle change and cardiac rehabilitation.

One specific mechanism by which psychological factors can affect coronary artery disease (CAD) has been demonstrated experimentally. Silent myocardial ischemia (ischemic changes on the electrocardiogram without symptoms of angina) can be precipitated by acute mental stress. Those who experience it are twice as likely to have major cardiac events compared with those who do not. Silent ischemia may be partly a consequence of cognitive or defensive traits such as denial, hyposensitivity to somatic sensation, or systematic misperception of angina. Psychological stress also changes the balance between procoagulation and fibrinolysis. Psychological factors may also affect outcome in CAD via differences in health care received. After myocardial infarction, patients with mental disorders are less likely to undergo cardiac catheterization and coronary revascularization than those without mental disorder.

Although the diagnosis and treatment of anxiety in patients with cardiac symptoms have received much attention, there has been less examination of anxiety as a risk factor affecting CAD. Increases in myocardial infarction and/or sudden death have been documented in epidemiologic studies of populations undergoing missile attacks, earthquakes and other disasters. A cohort study of 34000 initially healthy men showed that phobic anxiety predicted deaths from CAD, although not nonfatal myocardial infarctions (MI) (Kawachi *et al.*, 1994). Anxiety following MI may lead to more frequent readmission for unstable angina and more MI recurrences as well as higher mortality. Anxiety's adverse effects on CAD outcome may occur via effects on heart rate variability, QT prolongation, or other autonomically-mediated phenomena, like the stress-induced silent ischemia described above.

Denial is another common and significant psychological factor in patients with coronary disease. Denial may prevent individuals from acknowledging acute cardiac symptoms and promptly seeking medical care. The length of delay between the onset of symptoms of a myocardial infarction and hospitalization is a powerful predictor of morbidity and mortality, so denial at the onset of symptoms has an adverse impact on acute coronary disease. In contrast, denial **during** hospitalization may have adaptive value, perhaps even reducing morbidity and mortality.

There are other psychological factors deserving of study. Women with severe marital stress have triple the risk of recurrent coronary events than those without marital stress. Many studies have also examined maladaptive health behaviors as risk factors in coronary disease, with the effects of smoking better established than those of sedentary lifestyle, obesity, or specific diet. The effects of psychopathology and of smoking on heart disease are easily confounded, as persons with psychiatric disorders are overall twice as likely to smoke as others, with the increased risk found with all the major anxiety, mood and psychotic disorders.

## Arrhythmias

There is evidence that psychological stressors can also play an important role in precipitating serious ventricular arrhythmias. Sudden cardiac death after psychological distress has been reported anecdotally for a long time but is difficult to study scientifically. A systematic review of published cases of ventricular fibrillation in patients without known cardiac disease could identify preceding psychological distress in 22% (Viskin and Belhassen, 1990). A recent review of 96 published studies investigating psychosocial risk factors for arrhythmia found that 92% were positive (Hemingway *et al.*, 2001). Whether type A personality traits predict sudden cardiac death after myocardial infarction remains controversial.

## Congestive Heart Failure

Depression is especially common in patients with congestive heart failure. In patients hospitalized for congestive heart failure, major depression is independently associated with increased mortality and readmission 3 and 12 months later.

## Hypertension

The stress-related physiological response subcategory of PFAMC is particularly relevant to hypertension. There are some data suggesting that blood pressure reactivity to stress is a risk factor for the development of hypertension and may influence progression of disease as well. Many studies have examined relationships between personality, coping style, blood pressure reactivity and hypertension, but conflicting results and methodological limitations have precluded any consensus conclusions. Findings regarding the effects of stress, anger, hostility, or anxiety on blood pressure in normotensive individuals are not necessarily relevant to clinical hypertension. A high level of anxiety at baseline evaluation independently predicted twice the risk for development of hypertension in middle-aged men but not in women in one study, but in another study by the same investigators, anxiety did predict hypertension in women (Markovitz *et al.*, 1991). Some epidemiologic studies have found depression and/or anxiety symptoms predictive of later development of hypertension even after controlling for confounding factors. Several measures of occupational stress appear to be independent risk factors for hypertension in the general population. Some of the apparent association between psychological distress and hypertension is chiefly attributable to health risk behaviors (obesity, smoking, alcohol and sedentary lifestyle).

Studies of psychological treatments for hypertension (mainly biofeedback and relaxation techniques) have demonstrated the possibility of modest but clinically significant sustained reduction in blood pressure but less effectively than with drug therapy. The major limiting factor in using behavioral treatments for hypertension is compliance, because the treatments must be self-administered indefinitely. Behavioral therapies may be helpful as an adjunctive treatment in patients receiving antihypertensive drugs; psychological treatment should seldom be given as the sole treatment for hypertension.

## Psychological Factors in Endocrinology

### Diabetes Mellitus

Despite some of the early psychosomatic literature, there is no unique diabetic personality, but physicians who take care of

diabetic patients attest to a close interrelationship between psychological factors and glucose control. There is conflicting evidence whether psychological factors directly affect the onset of diabetes. That psychological stress can adversely affect glucose control in diabetics seems expectable because the hormones of the stress response are part of the counterregulatory response to insulin. A number of studies have shown that glycemic control is poorer in those diabetic patients who have more perceived stress. As assessed by hemoglobin A1c, metabolic control was poorer in depressed children and in adult depressed type 1 but not type 2 diabetics. A recent meta-analysis of 24 studies concluded that depression consistently is associated with a small-to-moderate increase in hyperglycemia in both type 1 and type 2 diabetes (Lustman *et al.*, 2000). Depression is associated with more diabetic complications. Most such research has been retrospective or cross-sectional, leaving it unclear which came first – poor metabolic control and complications or the psychological factor – and what is the relationship between them.

When psychiatric illness antedates and adversely affects the course of diabetes, it may be mediated by noncompliance (diet, medication, activity, visits to the physician, self-care) (Ciechanowski *et al.*, 2000) or by neurohumoral mechanisms. The adverse effects in diabetic control cannot all be attributed to noncompliance. Psychological stress administered under laboratory conditions can impair glucose control in both insulin-dependent and noninsulin-dependent diabetes. In insulin-dependent diabetes, this effect appears to be mediated by mental stress-induced insulin resistance.

Randomized controlled trials have demonstrated improvements in glucose control in diabetics receiving psychological interventions. Antidepressants are effective in the treatment of depression in diabetics, but can cause increases or decreases in blood glucose by themselves. Deterioration in glucose control in schizophrenic diabetics may be due to some of the newer antipsychotic drugs, but diabetes was a major problem for schizophrenics before their advent, presumably because of obesity (a side effect of almost every antipsychotic), unhealthy diet and poorer health care. Optimal management of diabetes requires a degree of organization very difficult for most patients with schizophrenia.

### Thyroid Disease

It is well established that too little or too much thyroid hormone can result in disturbances in mood and activity. In the other direction, the effects of emotion and stress on thyroid function, although long a focus of interest, are less well established. Recent studies have supported stressful life events as a risk factor for Graves' disease. Psychological stress may also be a result of less optimal control of hyperthyroidism.

Whereas there has been little well-substantiated evidence of the impact of psychological factors on thyroid disease, alterations in thyroid function or its hypothalamic–pituitary control have been demonstrated in relation to affective disorders, schizophrenia and post traumatic stress disorder. Depression has been most studied, revealing a variety of thyroid abnormalities, most frequently a relative increase in thyroxine without changes in the activated (triiodothyronine) and inactive (reverse triiodothyronine) forms and a blunting of the thyroid-stimulating hormone response to thyrotropin-releasing hormone. There is no agreement regarding the relationship between these endocrine changes and depressive pathophysiological processes, and it remains unknown whether depression modifies endocrine measures in clinical thyroid disease.

### Psychological Factors in Pulmonary Disease

Although asthma was once regarded as a classic psychosomatic disorder, it is currently viewed as a primary respiratory disease with varying immunological and autonomic pathophysiological changes. Many physicians still believe that psychological factors play an important role in the precipitation and aggravation of asthma, particularly anxiety. One must remember, however, that respiratory distress itself causes a wide array of anxiety symptoms (panic attacks, generalized and anticipatory anxiety, phobic avoidance), and most of the drugs used to treat asthma have anxiety as a potential side effect. Brittle asthmatic patients, like brittle diabetic patients, are more likely to have current or past psychiatric disorder (particularly anxiety disorders) than are other asthmatic individuals, but which came first is not established. There is no typical personality type susceptible to development of asthma. Studies have shown that anxiety and depression are associated in asthmatic patients with more respiratory symptom complaints but no differences in objective measures of respiratory function. However, psychological factors and psychosocial problems in hospitalized asthmatics were a more powerful predictor of which ones required intubation than any other examined variable (e.g., smoking, infection, prior hospitalization, etc.) (Le Son and Gershwin, 1996). Psychological morbidity is associated with high levels of denial and delays in seeking medical care, which may be life-threatening in severe asthma as well as less medication adherence and consequently poorer control of the condition. Not surprisingly then psychopathology in severe asthmatics is associated with increased health care utilization including hospitalizations, and outpatient and emergency room visits, independent of asthma severity.

Similar problems exist in interpreting relationships between anxiety or depression and other chronic obstructive pulmonary diseases (COPD) (chronic bronchitis, emphysema). Depression and anxiety are common in COPD though this partly reflects their increased prevalence in past or current smokers. As in asthma, psychological distress in COPD amplifies dyspnea without usually causing changes in objective pulmonary functions. Depression and anxiety do lead to lower exercise tolerance, noncompliance with treatment, and increased disability in COPD. Anxious COPD patients can improve their exercise tolerance through cognitive-behavioral therapy and pulmonary rehabilitation. Smoking is a well-established maladaptive health behavior causing and exacerbating chronic obstructive pulmonary disease, and its elimination is the most beneficial intervention available.

### Psychological Factors in Rheumatoid Arthritis

There is no particular personality type susceptible to development of RA and earlier research suggesting that stressful events play a role in the development or onset of RA has not been supported by more recent studies. Psychological factors and disease manifestations account for comparable proportions of disability. Psychological morbidity in RA results in more pain, poorer quality of life, more joint surgery, lower compliance and increased use of health care resources.

Depression has been the most frequently studied psychological disturbance in RA; depression is very common, as in other chronic medical conditions. Depression appears to adversely affect outcome in rheumatoid arthritis, aggravating chronic pain, increasing health care use and increasing social isolation.

Randomized controlled trials of antidepressants in depressed RA patients demonstrate improvements in pain, morning stiffness and disability in addition to depression.

There is a consensus among investigators that passive, avoidant, emotion-laden coping strategies (e.g., wish-fulfilling fantasy, self-blame) are associated with poorer adjustment to illness in RA compared with active, problem-focused coping (e.g., information seeking, cognitive restructuring). Rheumatoid arthritis patients with high helplessness are more likely to receive psychotropic, analgesic and anti-inflammatory drugs and to be less adherent with treatment than those with low helplessness. Patients with RA may be more vulnerable to stress-induced increases in immune and endocrine function. A randomized controlled trial of cognitive-behavioral therapy as an adjunct to standard treatment in recently diagnosed patients with rheumatoid arthritis showed it efficacious in reducing both psychological and physical morbidity (Sharpe *et al.*, 2001).

### Psychological Factors in Neurology

Depression is frequent after stroke, particularly in the acute phase during hospitalization and the first few weeks after stroke. The presence of depression is associated with poorer outcome, including higher later mortality and functional status is improved with treatment of depression after stroke. A negative attitude after stroke (i.e., feeling there is nothing one can do to help oneself) is associated with decreased survival. Research has focused on depression as a complication of stroke but there is also evidence that depression and other psychological factors constitute risks for stroke, consistent with widespread lay and folk beliefs regarding stress and stroke. There is preliminary evidence that anger and hostility may pose a risk for carotid atherosclerosis just as it may for coronary disease. Recent studies have found depressive symptoms increase the risk of stroke in older adults. As with many other major medical illnesses, stroke patients with extensive social support have better functional outcomes than those who do not.

Depression is common in Parkinson's disease, may antedate the development of motor symptoms and is associated with cognitive dysfunction. Physicians observe that depression and other psychological factors interact to affect the course and outcome of Parkinson's disease, but there has been little formal study of such relationships. Depression is also common and erodes quality of life in multiple sclerosis (MS) and in epilepsy. The study of depression as an independent risk factor affecting the onset or course of neurological diseases is challenging because depression may also be consequence of the disease, a psychological reaction to the illness, or a complication of pharmacotherapy. In MS depression may increase and its treatment decrease production of proinflammatory cytokines. Depression is especially difficult to study in MS because of its uncertain relationship to the MS-fatigue syndrome.

Patients with chronic migraine headaches have often been described as having a "typical" personality characterized as conscientious, perfectionistic, ambitious, rigid, tense and resentful, but controlled studies have not supported any consistent conclusion. Specific personality traits in migraine appear more likely to be a consequence rather than a cause of suffering from recurrent headaches. Migraine and depression are highly comorbid. But there is no relationship between headache frequency and the severity of psychological distress or personality abnormality. Thus, the relationship between psychological factors and migraine remains to be worked out.

## Psychological Factors in End-stage Renal Disease

Studies of the influence of psychological factors upon the course of end-stage renal disease (ESRD) have nearly all focused on depression or noncompliance. There has been essentially no investigation of psychological factors in chronic renal failure before end stage. Depression is associated with smoking, alcoholism and other forms of substance abuse that are highly prevalent in ESRD patients. It is clear that depression predicts higher mortality.

Compliance is a complex, multidimensional array of behaviors, and its relationship with health outcomes in dialysis patients is difficult to study. Thus, whereas effects of noncompliance on dialysis patients' outcomes are well recognized by physicians, they have not been adequately characterized empirically. Nevertheless, the widespread belief among physicians and nurses that noncompliance results in worse outcomes including higher mortality in ESRD is supported by a large multicenter study (Leggat *et al.*, 1998). The chronic overuse of nonsteroidal anti-inflammatory agents and analgesics is a maladaptive health behavior recognized as a fairly common contributing cause of chronic renal insufficiency.

## Psychological Factors in Gastroenterology

### Inflammatory Bowel Disease

Ulcerative colitis is another disorder that was described in the early literature as a psychosomatic disease, but no specific psychogenic factor contributing to the development of ulcerative colitis or Crohn's disease has ever been substantiated. As with other chronic medical diseases, patients with more psychological distress tend to be those with more severe physical disease and poorer functional capacity, but the causal relationships are not clear. Psychological stress does appear to aggravate both symptom complaints and mucosal disease activity in ulcerative colitis. Disability and distress in patients with inflammatory bowel disease are increased by the presence of a concurrent psychiatric disorder. In fact, depression is a better predictor of subjective impairment in inflammatory bowel disease than is inflammatory activity. Psychotherapy has the potential to improve outcomes in inflammatory bowel disease, as suggested by controlled trials.

### Peptic Ulcer Disease

The central role of the bacterium *Helicobacter pylori* in the etiology of peptic ulcer disease (PUD) has been clearly established. Many physicians have consequently discarded the longstanding belief that stress causes PUD, and concluded that PUD is an infectious disease, except when attributable to nonsteroidal anti-inflammatory drugs (NSAIDs). Nevertheless, psychological factors appear to be a significant part of the explanation for why only a fraction of those colonized by *H. pylori* or taking NSAIDs develop ulcers. Psychological stress is an independent risk factor for the development and recurrence of duodenal ulcer. The frequency of peptic ulcer increases following catastrophic stressful events, including bombardment, earthquake, economic crisis, or being a prisoner of war or "boat people" refugee. Overall, psychosocial factors contribute between 30 and 65% of peptic ulcers (Levenstein, 2000), and are most likely to be present in patients with duodenal ulcers who do not have conventional medical risk factors (*H. pylori*, NSAIDs). Occupational stress, family conflicts, depression, maladjustment and hostility also are prospectively associated with PUD.

Psychological factors appear to influence PUD through both health risk behaviors (smoking, alcohol abuse, overuse of NSAIDs, poor diet, poor sleep) and psychophysiological mechanisms (pepsinogen and acid secretion, altered blood flow, impairment of mucosal defenses, and slowing of healing related to the action of cortisol) (Levenstein, 2000).

### Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) is a heterogeneous condition with a high frequency of comorbid anxiety especially panic attacks, depression and somatization. Whereas patients with IBS are psychologically more distressed than normal subjects, they do not have a common profile of psychological symptoms or personality traits. Patients with IBS are more likely to have a history of childhood sexual abuse than are those with other gastrointestinal disorders in studies of patients seeking care at tertiary referral centers. In fact, almost all psychological characteristics and psychopathology thought to be more common in IBS are differentially increased only in those who seek medical care for their symptoms.

Both IBS patients and their physicians observe that their gastrointestinal symptoms seem aggravated by stress, but there is no clear evidence that stress causes a different gastrointestinal smooth muscle response than in control subjects. Instead, psychological factors' effects on IBS appear predominantly on perception of pain and other somatic symptoms, and on health care seeking behaviors. After an acute episode of infectious gastroenteritis, individuals with more life stress, and who were more hypochondriacal, were the ones most likely to go on to develop IBS, without any differences in intestinal physiology (Gwee *et al.*, 1999).

### Psychological Factors in Dermatology

Dermatologists routinely observe the effect of psychological factors, especially anxiety, in the aggravation of a wide variety of dermatological conditions. There are few systematic studies, and perhaps the most important relationships are not uniquely related to particular dermatological disorders. Both anxiety and depression appear to worsen pruritus (itching). So-called neurotic excoriation complicates many dermatological disorders and is aggravated by anxiety, depression and other behavioral factors. That so many skin diseases appear to be precipitated or exacerbated by psychological stress also suggests a nonspecific impairment of cutaneous function. There is now evidence in both animals and humans that stress negatively affects skin's function as a permeability barrier.

Dermatologists clinically observe important relationships between psychological factors and urticaria, angioedema, atopic dermatitis, hyperhidrosis, acne and psoriasis, but controlled studies are lacking. Excessive sun exposure is a maladaptive health behavior contributing to skin cancer and various other dermatological conditions.

## Psychological Factors Affecting Infectious Diseases

HIV infection is the most destructive example of unsafe sexual practices, as a maladaptive health behavior, contributing to development and transmission of an infectious medical condition. Once contracted, HIV infection appeared to be a likely candidate for important effects of psychological factors, because of the work demonstrating changes in normal immune function

after stress, bereavement and depression. The effects of stress and depression on disease progression, immune function and mortality in HIV infection have been an active field of investigation, with varying conclusions. There is less doubt that anxiety worsens symptoms and functioning in HIV patients. No research has demonstrated that depression predicts the onset of somatic symptoms in HIV infection, acquired immunodeficiency syndrome, or death.

Psychological factors influence other infectious diseases as well, including the common cold, pneumonia, genital herpes and recurrent urinary tract infections. A number of studies have convincingly shown that psychological stress suppresses the secondary (but not primary) antibody response to immunization.

### Psychological Factors in Obstetrics

While much more attention has been paid to postpartum depression, antepartum depression also adversely affects pregnancy outcome. Both antepartum anxiety and depression have been associated with growth retardation and premature birth, resulting in lower birth weights, but potential confounding factors have often not been adequately controlled for. Whether depression and other psychological dysfunction cause poorer obstetric outcomes through poor nutrition, substance abuse (including tobacco), poor adherence or no prenatal care, and/or physiological (hormonal, vascular) effects require further investigation.

### Psychological Factors in Infertility

Psychological factors are likely to affect fertility because frequency and timing of sexual intercourse are important determinants of fertility. Nonconsummation, avoidance of intercourse, vaginismus and psychogenic amenorrhea are attributable to psychological origins. Psychogenic causes do not account for most male impotence but may play a secondary role in many cases.

Whereas some prospective data support psychological factors influencing fertility in the general population, psychological factors appear less potent in predicting pregnancy outcome in couples receiving treatment for infertility. In general, measures of stress, but not of psychopathology, have been associated with infertility. This is a particularly complex subject for study because it involves potential psychological factors in both members of the couple and interactions between them as well as their effects on sexual behavior and fertility. Most psychological distress seen in infertile couples is a result of, rather than a cause of, infertility.

### Comparison of DSM-IV/ICD-10 Diagnostic Criteria

Although the corresponding ICD-10 category (“Psychological and behavioural factors associated with disorders or diseases classified elsewhere”) does not have specified diagnostic criteria, it is defined in essentially the same way as DSM-IV-TR.

# Medication-induced Movement Disorders

## Introduction

Perhaps the most uncomfortable side effects from psychotropic medications (especially antipsychotics or neuroleptics) are the acute and chronic movement disorders. Any psychiatrist in clinical practice has witnessed the intense distress that medication-induced movement disorders may bring to patients. Perhaps most disturbing is that unlike other medications, antipsychotics can produce “tardive” or late-occurring movement disorders that may be persistent or even irreversible. Patients in whom movement disorders develop may have more than subjective distress; they may suffer psychosocial embarrassment that makes them avoid being seen in public, and they may even suffer occupational impairment in severe cases. The responsibility this places on the prescribing psychiatrist is significant. Careful and reasoned thought must go into the analysis of whether the benefit of treatment with a medication exceeds the risk to the patient. This includes adequately explaining and obtaining informed consent from patients.

When a psychiatrist prescribes a medication that has the potential to induce a movement disorder, the physician–patient relationship is of paramount importance. Patients who require these medications are sometimes not amenable to trusting relationships (i.e., the paranoid patient). Working with a patient who has a psychotic illness requires that the psychiatrist establish a strong therapeutic bond with the patient.

## Historical Background

Approximately 5 years after chlorpromazine was observed to be effective for psychotic disorders, orobuccal dyskinesias after prolonged exposure to chlorpromazine were noted. This condition lasted nearly 3 months after the medication was stopped. This was in marked contrast to the parkinsonism-like EPS that had been previously described to reverse on discontinuation of antipsychotics. The term **tardive dyskinesia** (TD) was first used in the 1960s to describe this condition. The number of reports grew rapidly in a period of years, and many of the cases were reported to be irreversible.

## Classification

There are different types of movement disorders that may result from treatment with psychotropic (especially neuroleptic) medications. They can generally be divided into those that occur acutely or subacutely and those that occur late in treatment (tardive). For the purpose of this discussion, we group the movement disorders into the relatively acute neuroleptic-induced disorders (acute dystonia,

parkinsonism, and akathisia) neuroleptic-induced TD and neuroleptic malignant syndrome (NMS). We also devote a section to the discussion of medication-induced postural tremor that predominantly focuses on lithium-induced tremor. This covers the major diagnostic groupings contained within the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR) under the general title medication-induced movement disorders.

A time line for the emergence of the neuroleptic-induced movement disorders is provided in Table 64.1.

## Informed Consent and Medicolegal Issues

In general, the more a patient is able to understand the nature of his or her illness and the reason that a particular medication is being prescribed, the more likely he or she is to be adherent. When the psychiatrist does not devote adequate time to informing and instructing the patient, the result may be poor trust, poor communication and possible legal difficulties for everyone involved. Unless declared incompetent by a court of law, a patient is considered to be legally competent to consent to or refuse psychotropic medications. The only exception to this rule is when an emergency situation exists and a patient must be medicated to prevent harm to self or others. The psychiatrist must provide information to the patient or the patient’s decision-maker about the nature and purpose of the medication, its risks and benefits, alternatives to the proposed treatment, and prognosis without treatment. Obtaining a written informed consent is one way of documenting the consent process. Another way is noting in the chart a summary of the discussion with a patient (or caregiver) about the consent to neuroleptic treatment.

Although the antipsychotics can produce unpleasant side effects, a patient who has been prepared openly and honestly for their possibility is more likely to view the side effects as evidence of the psychiatrist’s excellent fund of knowledge rather than as a terrible surprise thrust on him or her by a dishonest or ignorant physician. On a final note, it may not be assumed that a patient already receiving antipsychotics prescribed by another physician has received an adequate informed consent. The process must begin anew with the new treating physician. A new twist in the legal issues surrounding antipsychotic agents is the lower incidence of EPS and TD with atypical agents. The question of what is standard of care and how this relates to patients’ prescribed conventional antipsychotics who are at a higher risk of developing a movement disorder such as TD presents interesting legal issues.

**Table 64.1** Time of Emergence of Neuroleptic-induced Movement Disorders

Condition	Highest Risk of Emergence
Acute dystonia	Days 0–7
Neuroleptic malignant syndrome	Days 0–7 (continues at lesser degree until end of first mo)
Akathisia	Days 7–14 (continues at lesser degree until 2.5 mo)
Parkinsonism	Days 14–30 (continues at lesser degree until 2.5 mo)
Tardive dyskinesia	Month 3* → onward (risk increases with increasing time on neuroleptic)

\*In patients older than 60yr, month 1 → onward.

In general, the literature continues to expand with trials demonstrating reduced incidence of new onset neuroleptic-induced movement disorders with atypical antipsychotics and at least partial improvement of existing movement disorders caused by conventional antipsychotics. While atypical antipsychotics are not without a risk of movement disorders, the improved motor side-effect profile of the atypical agents provides a compelling argument for the use of atypical antipsychotics when initiating therapy, especially in susceptible populations such as the elderly. Switching to an atypical agent should be considered for those patients maintained on a conventional agent who develop or have a high risk of movement disorders.

## Acute Neuroleptic-induced Movement Disorders

A summary of the treatment of these disorders is provided in Table 64.2.

### Neuroleptic-induced Acute Dystonia

#### Etiology and Pathophysiology

This long-lasting contraction or spasm of musculature develops in conjunction with the use of antipsychotic medication. The pathophysiological mechanism of neuroleptic-induced acute dystonia is presently unknown. The finding that anticholinergic medication reverses the dystonia consistently may suggest that a hypercholinergic state is a correlate of dystonia. There is some suggestion of a correlation with changing blood–brain levels of antipsychotic medication. It is also possible that dystonia is related to the changing ratio of dopamine  $D_2$  to  $D_1$  receptors that accompany the normal aging process.

Abnormalities in dopamine–acetylcholine balance have been suggested as a possible mechanism because cholinergic antagonists and dopaminergic agonists seem to improve the dystonia in many patients, in contrast to dopaminergic antagonists, which seem to exacerbate or even cause dystonia. In contrast, some investigators have proposed that dopaminergic excess may be the responsible factor.

#### Epidemiology and Comorbidity

Acute dystonia is generally less common than most other extrapyramidal side effects of antipsychotics. Its frequency has been reported to range from 2 to 12% of patients taking conventional antipsychotic medication. For patients who receive high doses of high-potency conventional agents, however, the frequency may be as high as 50%. Incidence of acute dystonia can probably be reduced

**Table 64.2** Treatment of Acute Neuroleptic-induced Movement Disorders

Condition	First Choice	Second Choice	Third Choice
Acute dystonia	Anticholinergic medication, e.g., 2 mg benztropine PO, IM, IV 50 mg diphenhydramine PO, IM, IV	Benzodiazepine, e.g., lorazepam 1 mg IM, IV	—
Parkinsonism	Decrease neuroleptic to lowest effective dose  Consider change to lower potency neuroleptic	Anticholinergic, e.g., benztropine at 2 mg/d	Consider high-dose anticholinergic  Consider discontinuation of neuroleptic  Consider experimental treatment
Akathisia			
with high-potency neuroleptic	$\beta$ -blocker, e.g., propranolol 10–30 mg t.i.d.	Anticholinergic, e.g., 2 mg/d benztropine	Benzodiazepine, e.g., lorazepam, e.g., 1 mg t.i.d.
with low-potency neuroleptic	$\beta$ -blocker	Benzodiazepine	Anticholinergic
with other extrapyramidal signs	Anticholinergic	Anticholinergic plus $\beta$ -blocker	Anticholinergic plus benzodiazepine

Reprinted with permission from Arana GW and Rosenbaum JF (2000) *Handbook of Psychiatric Drug Therapy*, 4th edn. Lippincott, Williams & Wilkins, Philadelphia, pp. 6–52.

to approximately 2% if low-dose treatment strategies are employed. Furthermore, acute dystonia is considerably less likely to occur with atypical antipsychotic medications (i.e., less than 5% of individuals) (American Psychiatric Association, 2000). For example, dystonic reactions occurred in less than 5% of patients in a study of ziprasidone and 1% in a dose comparison study with quetiapine.

Large doses of high-potency conventional antipsychotics appear to be the most consistent risk factor reported for acute dystonia. Other factors that also seem to predispose to dystonia are young age and male sex. A prior dystonic reaction is a good predictor of a repeated episode when the same antipsychotic at the same dose is reapplied.

### DSM-IV-TR Criteria 333.7

#### Neuroleptic-induced Acute Dystonia

- A. One (or more) of the following signs or symptoms has developed in association with the use of neuroleptic medication:
- (1) abnormal positioning of the head and neck in relation to the body (e.g., retrocollis, torticollis)
  - (2) spasms of the jaw muscles (trismus, gaping, grimacing)
  - (3) impaired swallowing (dysphagia), speaking, or breathing (laryngeal-pharyngeal spasm, dysphonia)
  - (4) thickened or slurred speech due to hypertonic or enlarged tongue (dysarthria, macroglossia) tongue protrusion or tongue dysfunction
  - (5) eyes deviated up, down, or sideward (oculogyric crisis)
  - (6) abnormal positioning of the distal limbs or trunk
- The signs or symptoms in B. criterion A developed within 7 days of starting or rapidly raising the dose of neuroleptic medication, or of reducing a medication used to treat (or prevent) acute extrapyramidal symptoms (e.g., anticholinergic agents).
- C. The symptoms in criterion A are not better accounted for by a mental disorder (e.g., catatonic symptoms in schizophrenia). Evidence that the symptoms are better accounted for by a mental disorder might include the following: the symptoms precede the exposure to neuroleptic medication or are not compatible with the pattern of pharmacological intervention (e.g., no improvement after neuroleptic lowering or anticholinergic administration).
- D. The symptoms in criterion A are not due to a nonneuroleptic substance or to a neurological or other general medical condition. Evidence that the symptoms are due to a general medical condition might include the following: the symptoms precede the exposure to the neuroleptic medication, unexplained focal neurological signs are present, or the symptoms progress in the absence of change in medication.

## Assessment and Differential Diagnosis

Neuroleptic-induced dystonia (sometimes referred to as a dystonic reaction) usually begins 12 to 36 hours after a new antipsychotic is started or the dosage of a preexisting one is increased. It is unusual to see a dystonia after 2 weeks of antipsychotic treatment, and probably 90% of all neuroleptic-induced dystonias occur within the first 5 days of antipsychotic treatment. Patients may report a sense of tongue “thickness” or difficulty in swallowing in the 3 to 6 hours preceding the acute dystonia.

Acute dystonia presents as a sustained, painful muscle spasm that produces twisting, squeezing and pulling movements of the muscle groups involved. The most common muscle groups affected are the eyes, jaw, tongue and neck, but any muscle group in the body can be involved. On occasion, the larynx or pharynx may be involved, and this can result in rapid respiratory compromise (American Psychiatric Association, 2000).

Neuroleptic-induced acute dystonias are dramatic and usually easy to diagnose. There are, however, a number of other conditions that can present similarly and need to be ruled out. Spontaneously occurring focal or segmental dystonias may persist for days to weeks independent of medication. Neurological conditions such as temporal lobe seizures, infections, trauma, or tumors can produce symptoms similar to the neuroleptic-induced acute dystonia. A number of medications, while generally less common than antipsychotics, can cause dystonias (e.g., anticonvulsant medications and selective serotonin reuptake inhibitors) (American Psychiatric Association, 2000).

Neuroleptic malignant syndrome (NMS) can produce muscle contractions that look similar to acute dystonia but can be distinguished by generalized “lead pipe” type of rigidity, fever, fluctuating consciousness and unstable vital signs. Catatonia associated with an affective or psychotic disorder can be difficult to distinguish from dystonia clinically but does not respond to the administration of anticholinergic or antihistaminic medication. Furthermore, patients with catatonia are typically not concerned about their stiffness, whereas the patient with dystonia are likely to be extremely distressed (American Psychiatric Association, 2000).

On occasion, an acute dystonic reaction may resemble tardive dyskinesia (TD). This is easily clarified by administering anticholinergic medications, which rapidly clear dystonia and do not affect (or may worsen) TD. Making a differential diagnosis between an acute dystonia and tardive dystonia can be difficult. Tardive dystonia (similar to TD) is a diagnosis made late in the course of antipsychotic treatment and is generally a chronic condition compared with acute dystonia, which occurs early in the course of medication treatment and typically responds rapidly to pharmacological intervention.

### Course

A neuroleptic-induced acute dystonia typically subsides spontaneously within hours after onset. However, treatment should be started as soon as the dystonia is diagnosed because the experience is “intensely” distressing to the patient.

### Treatment

The standard approach to treatment is the immediate administration of an anticholinergic or antihistaminic agent. In most cases, this medication may be administered orally, intramuscularly, or intravenously. The first dose of medication should be the equivalent of 2 mg of benztropine or 50 mg of diphenhydramine. This should be repeated if the first dose does not produce a robust

response within 30 minutes. This standard approach is usually successful in resolving the dystonia.

In the unusual refractory case, intramuscular or intravenous anticholinergic or antihistaminic drugs should be used at more frequent dosing intervals, and consideration should be given to adding an intramuscular injection of lorazepam for additional sedation. Since even the milder dystonias respond much more quickly to intramuscular or intravenous medication, it may therefore be worth avoiding the use of oral medication in treating dystonia. Oral medication takes much longer to work and is likely to result in unnecessarily prolonged distress of the patient.

In cases of laryngeal or pharyngeal dystonias with airway compromise, repeated dosing of medication should occur at shorter intervals until resolution is achieved. Arana and Rosenbaum (2000) recommended that the patient receive 4 mg of intravenous bupropion within 10 minutes followed by 1 to 2 mg of intravenous lorazepam. If airway compromise continues for any appreciable amount of time, emergent support from an anesthesiologist should be obtained and the patient should receive general anesthesia with airway protection. Fortunately, the need for such measures is rare.

After a dystonia, a patient should be maintained with oral anticholinergic or antihistaminic medication for at least 48 hours. If there is a history of previous dystonias, the medication should be continued for 2 weeks. Consideration should be given to decreasing the previous dose of the antipsychotic or possibly switching to a low-potency neuroleptic or atypical agent if the patient has been prescribed a conventional antipsychotic. The use of prophylactic anticholinergic medication will be discussed later.

## Neuroleptic-induced Parkinsonism

### Etiology and Pathophysiology

Neuroleptic-induced parkinsonism (NIP) is defined as parkinsonian signs or symptoms (tremor, muscle rigidity, or akinesia) that develop in association with the use of an antipsychotic medication. NIP is presumed to result from blockade of postsynaptic dopamine ( $D_2$ ) receptors in the corpus striatum causing a pathological state functionally resembling the loss of dopaminergic cells in the striatum in idiopathic Parkinson's disease (PD). However, it is not clear whether nigrostriatal dopamine loss is adequate to explain the clinical symptoms seen in NIP or PD. It is possible that other neurochemical abnormalities may coexist with dopaminergic depletion to produce the syndrome. Abnormalities in norepinephrine and serotonin have also been reported to be involved in the mechanism.

Positron emission tomography (PET) and other technologies have been utilized to examine the relationship between  $D_2$  receptor blockade in the basal ganglia with antipsychotic efficacy and NIP. Clinically effective doses of conventional antipsychotics have been shown to block 70 to 90% of  $D_2$  receptors in the basal ganglia. Of note are findings that with conventional agents at least 60% occupancy is needed for satisfactory antipsychotic response but that NIP tends to occur with 80% or greater occupancy of the  $D_2$  receptors. With regard to atypical agents, the lower  $D_2$  receptor blockade at recommended dosages with some agents and the serotonergic blockade seen with these medications are believed to lead to the reduced risk of NIP. Similar to conventional antipsychotics, higher doses of some atypical agents also appear to be related to an increase in NIP, as greater  $D_2$  receptor blockade has been reported.

## DSM-IV-TR Criteria 332.1

### Neuroleptic-induced Parkinsonism

- A. One (or more) of the following signs or symptoms has developed in association with the use of neuroleptic medication:
  - (1) parkinsonian tremor (i.e., a coarse, rhythmic, resting tremor with a frequency between 3 and 6 cycles per second, affecting the limbs, head, mouth, or tongue)
  - (2) parkinsonian muscular rigidity (i.e., cogwheel rigidity or continuous "lead-pipe" rigidity)
  - (3) akinesia (i.e., a decrease in spontaneous facial expressions, gestures, speech, or body movements)
- B. The symptoms in criterion A developed within a few weeks of starting or raising the dose of a neuroleptic medication, or of reducing a medication used to treat (or prevent) acute extrapyramidal symptoms (e.g., anticholinergic agents).
- C. The symptoms in criterion A are not better accounted for by a mental disorder (e.g., catatonic or negative symptoms in schizophrenia, psychomotor retardation in a major depressive episode). Evidence that the symptoms are better accounted for by a mental disorder might include the following: the symptoms precede the exposure to neuroleptic medication or are not compatible with the pattern of pharmacological intervention (e.g., no improvement after lowering the neuroleptic dose or administering anticholinergic medication).
- D. The symptoms in criterion A are not due to a nonneuroleptic substance or to a neurological or other general medical condition (e.g., Parkinson's disease, Wilson's disease). Evidence that the symptoms are due to a general medical condition might include the following: the symptoms precede the exposure to neuroleptic medication, unexplained focal neurological signs are present, or the symptoms progress despite a stable medication regimen.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

### Epidemiology and Comorbidity

The reported frequency of NIP varies from 5 to 90%, depending on the study reviewed. This wide variation is due to different definitions of parkinsonism in different studies as well as the inclusion of mild bradykinesia as a sign of NIP in some investigations. The usual incidence of "clinically significant" NIP with conventional antipsychotics is 10 to 15. When, however, high-potency conventional agents are used without anticholinergic drugs and signs of rigidity are carefully assessed, one is likely to find that the majority of patients have some NIP. Rates of parkinsonism induced by atypical antipsychotics are considerably lower (American Psychiatric Association, 2000). The incidence of NIP in older psychiatric patients is considerably greater. A study of newly medicated older patients on low doses

of conventional antipsychotics found 32% of patients met criteria for NIP (Caligiuri *et al.*, 1999). In an investigation of extrapyramidal side effects in patients with Alzheimer disease treated with very low dose conventional antipsychotics, 67% of patients met criteria for NIP at some time during the 9-month follow-up period (Caligiuri *et al.*, 1998).

A number of patient-related and medication-related risk factors have been proposed. A history of prior episodes of NIP, older age, and concomitant dementia or delirium are thought to predispose to NIP (American Psychiatric Association, 2000). Neuroleptic potency and preexisting extrapyramidal symptoms may also increase the risk of NIP.

Rapid increases in antipsychotic dosage, administration of higher absolute doses of antipsychotics and absence of concurrent anticholinergic medication represent other risk factors for NIP initiation (American Psychiatric Association, 2000). Highly anticholinergic antipsychotics (i.e., chlorpromazine and thioridazine) are less likely to cause NIP than less anticholinergic agents (i.e., haloperidol and fluphenazine).

### Assessment and Differential Diagnosis

NIP symptoms may develop quickly after the initiation of an antipsychotic or insidiously during the course of treatment. It most typically develops 2 to 4 weeks after antipsychotic initiation. The three cardinal symptoms of NIP are tremor, muscle rigidity and akinesia.

Parkinsonian tremor is a steady, rhythmical, oscillatory motion generally at an alternating rhythm of 3 to 6 Hz. The most affected body area tends to be the upper extremities, but the tremor may spread to the head, neck, jaw, face, tongue, legs and trunk. The tremor is typically suppressed during action and increases during times of anxiety, stress, or fatigue (American Psychiatric Association, 2000).

Parkinsonian muscle rigidity appears clinically as a firmness and spasm of muscles at rest that may affect all skeletal muscles or be confined to just a few specific muscle groups. It can appear as a continuous lead pipe-type rigidity that resists movement or a cogwheel-type rigidity that presents a “ratchet-like” resistance when a muscle is moved around a joint. Cogwheeling may represent an extremely high frequency (8–12 Hz) “action” tremor that is physiologically imposed on the rigidity. The psychiatrist may diagnose cogwheel rigidity by placing his or her hand over the joint that is being passively moved. Generalized muscle pain, body aches and discoordination are features associated with NIP rigidity (American Psychiatric Association, 2000).

Parkinsonian akinesia is seen clinically as decreased spontaneous motor activity and a global slowness in the initiation and execution of movements. It can be associated with drooling, bent over neck, stooped shoulders and masked facial expression (the so-called masked facies) (American Psychiatric Association, 2000). Parkinsonism occurs in numerous medical and neurological conditions and can be caused by many medications or substances. Idiopathic PD can be difficult to distinguish from NIP.

The tremor of NIP must be distinguished from tremor caused by other conditions. In general, nonparkinsonian tremors are finer, faster and worse on intention. Tremor associated with substance withdrawal typically presents with associated hyperreflexia and increased autonomic signs. Cerebellar disease-induced tremor may present with associated nystagmus, ataxia, or scanning speech. Strokes and other central nervous system lesions usually have associated focal neurological symptoms. NMS can often present with akinesia and lead pipe-type rigidity but

also has other associated findings, such as fever, elevated creatine kinase and fluctuating consciousness (American Psychiatric Association, 2000). It appears that TD and NIP frequently coexist in the same patient.

A number of primary psychiatric illnesses may mimic symptoms of NIP and may be difficult to separate. These include major depressive disorder, catatonic-type schizophrenia, mood disorder with catatonic features, schizophrenia with a predominance of negative features, delirium, dementia, anxiety disorders and certain conversion disorders (American Psychiatric Association, 2000). It may be particularly easy to confuse negative symptoms of schizophrenia and depression with the akinesia and rigidity of NIP. Catatonia and NIP may also be difficult to differentiate, and there is evidence that the two conditions are related to each other. Often, the diagnosis of NIP should be made provisionally and clarified by a dosage reduction of antipsychotic or trial of anticholinergic medication (American Psychiatric Association, 2000).

### Course

NIP symptoms usually continue unchanged or diminish slowly in 2 to 3 months after onset. The signs and symptoms typically improve with a dose reduction, discontinuation of antipsychotic medication, or switch to an atypical antipsychotic in patients previously receiving a conventional antipsychotic. Improvement is also seen with the addition of antiparkinsonian agents.

### Treatment

Many milder cases of NIP do not require treatment because they are not bothersome to the patient. A switch to an atypical agent should be strongly considered if troublesome NIP develops while on a conventional antipsychotic. Large randomized controlled trials have demonstrated reductions in parkinsonian symptoms in patients treated with atypical antipsychotics. If symptoms become troublesome, the initial step should be to decrease the dose of antipsychotic to the lowest effective dose for the patient. The next step is to add a low dosage of an anticholinergic medication. The equivalent of 2 mg/day of benztropine generally represents a reasonable starting point. Periodic attempts should be made to wean the patient from the anticholinergic agent. As many as 90% of patients do not require anticholinergic medication at the end of 3 months. Anticholinergic medication should always be tapered slowly to avoid the rapid redevelopment of parkinsonian symptoms as well as the possibility of uncomfortable cholinergic rebound symptoms.

Refractory cases of NIP do occur and may require more aggressive management. Increasing the dose of the anticholinergic medication is a good starting point because some patients may require up to the equivalent of 20 mg/day of benztropine to achieve relief from NIP. If such high doses are to be employed, they should be used for the shortest possible time, and rigorous attention should be paid to the possibility of untoward anticholinergic effects (i.e., delirium, urinary retention, fecal impaction). Consideration may be given to starting a dopamine-releasing agent, such as amantadine or perhaps even levodopa. A major concern with this treatment approach is the possibility of exacerbating the psychosis for which the antipsychotic medication was prescribed in the first place. Trials of dopaminergic agents are therefore best attempted in an inpatient setting or with careful outpatient observation and assessment. A number of experimental treatment strategies have been proposed for the treatment of the refractory cases including vitamin E, calcium supplementation, electroconvulsive therapy and L-deprenyl.

Another treatment approach for the refractory case is to lower the dose of the antipsychotic medication or even discontinue it until the NIP resolves, then resume the antipsychotic (preferably a different one) at a lower dose. This treatment strategy may also need to be carried out in an inpatient setting to monitor early emergence of psychotic symptoms.

## Neuroleptic-induced Acute Akathisia

### Etiology and Pathophysiology

Neuroleptic-induced acute akathisia is defined as a subjective feeling of restlessness and an intensely unpleasant need to move occurring secondary to antipsychotic treatment. The pathophysiological mechanism of akathisia remains unknown. Marsden and Jenner (1980) suggested that dopamine blockade in the mesocortical system may account for the hyperactive symptoms of akathisia. Mesocortical dopaminergic neurons that innervate the prefrontal cortex seem to be resistant to depolarization induced by long-term antipsychotic treatment, suggesting a possible explanation for why akathisia often does not improve with time.

The possibility that excessive noradrenergic activity plays a role in the pathogenesis of akathisia is supported by the efficacy of beta-adrenergic blockers in improving some cases of akathisia. Additionally, opioid mechanisms have been proposed to contribute to akathisia on the basis of reported therapeutic effects of opioid drugs. The lower likelihood of akathisia with atypical antipsychotics and reports of selective serotonin reuptake inhibitors causing akathisia have implicated serotonin as having a possible role in akathisia, however this is still under investigation.

### Epidemiology and Comorbidity

Akathisia is a common side effect of antipsychotic treatment. It is estimated to occur in 20 to 75% of all patients treated with conventional agents. The wide discrepancy in reported prevalence may result from a lack of consistency in the definition of akathisia, different prescribing practices, different study designs and differences in population demographics (American Psychiatric Association, 2000). While atypical antipsychotics are less likely to cause akathisia compared with typical agents, prevalence rates have varied. Clozapine-induced akathisia has ranged from 0 to 39% and a point prevalence of 13% has been reported for risperidone. Akathisia is thought by many psychiatrists to be a leading cause of nonadherence.

Higher doses of high-potency conventional antipsychotics appear to be most frequently associated with the appearance of akathisia (American Psychiatric Association, 2000). Previous episodes of neuroleptic-induced akathisia increase the risk for future episodes if antipsychotics are restarted.

### Assessment and Differential Diagnosis

Akathisia tends to occur within the first 4 weeks of initiating or increasing the dose of antipsychotic medication. It can develop rapidly after the initiation or the dose increase of an antipsychotic. Patients with akathisia tend to have subjective complaints of “inner restlessness”, most often in the legs. It may be difficult for the patients to describe their feelings. They feel that they must move, and this manifests as fidgeting, frequent changes in posture, crossing and uncrossing of the legs, rocking while sitting and shuffling when walking (American Psychiatric Association, 2000).

Akathisia is often associated with severe dysphoria, anxiety and irritability. When the akathisia is particularly severe,

## DSM-IV-TR Criteria 333.99

### Neuroleptic-induced Acute Akathisia

- A. The development of subjective complaints of restlessness after exposure to a neuroleptic medication.
- B. At least one of the following is observed:
  - (1) fidgety movements or swinging of the legs
  - (2) rocking from foot to foot while standing
  - (3) pacing to relieve restlessness
  - (4) inability to sit or stand for at least several minutes

The onset of the symptoms in C. criteria A and B occurs within 4 weeks of initiating or increasing the dose of the neuroleptic, or of reducing medication used to treat (or prevent) acute extrapyramidal symptoms (e.g., anticholinergic agents).

- D. The symptoms in criterion A are not better accounted for by a mental disorder (e.g., schizophrenia, substance withdrawal, agitation from a major depressive or manic episode, hyperactivity in attention-deficit/hyperactivity disorder). Evidence that symptoms may be better accounted for by a mental disorder might include the following: the onset of symptoms preceding the exposure to the neuroleptics, the absence of increasing restlessness with increasing neuroleptic doses, and the absence of relief with pharmacological interventions (e.g., no improvement after decreasing the neuroleptic dose or treatment with medication intended to treat the akathisia).
- E. The symptoms in criterion A are not due to a nonneuroleptic substance or to a neurological or other general medical condition. Evidence that symptoms are due to a general medical condition might include the onset of the symptoms preceding the exposure to neuroleptics or the progression of symptoms in the absence of a change in medication.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

aggression or suicide attempts may be a possible result, although this is controversial. Akathisia in a psychotic patient can easily be mistaken for worsening of psychotic features, resulting in an increase in antipsychotic dose and an exacerbation of the akathisia.

The strange subjective discomfort associated with akathisia is the feature that seems to be most useful in making a differential diagnosis between neuroleptic-induced akathisia and other neuroleptic-induced movement disorders. TD is often associated with a lack of sensory perception of having a movement disorder. This contrasts with akathisia in which patients tend to be acutely aware of their distress. When patients with TD are uncomfortable, it is usually a result of social factors such as embarrassment and functional factors such as frustration over not being able to perform certain tasks. Another differentiating factor is that TD

usually involves the face, mouth and upper extremities, whereas akathisia more commonly involves the lower extremities.

The rhythmical appearance of akathisia may sometimes suggest a tremorous condition. Thus, the tremor of NIP and idiopathic PD may be mistaken for akathisia, especially if the feet and legs are involved. Iron deficiency anemia can also present with symptoms phenomenologically similar to neuroleptic-induced akathisia. A number of other medications but particularly selective serotonin reuptake inhibitor antidepressant medications may produce akathisia clinically identical to that produced by antipsychotics (American Psychiatric Association, 2000).

It is critical to differentiate akathisia from other psychiatric disorders presenting with agitation, such as depressive episodes, manic episodes, anxiety disorders, schizophrenia, dementia, delirium, substance intoxication or withdrawal and attention-deficit/hyperactivity disorder. The reason for the importance of this differentiation is that mistaking akathisia for a primary psychiatric disorder can result in an intervention that would be the exact opposite of what is appropriate (i.e., increasing the dose of an antipsychotic instead of decreasing it because akathisia is mistaken for worsening psychosis) (American Psychiatric Association, 2000).

### Course

Neuroleptic-induced akathisia typically lasts as long as antipsychotic treatment is continued but may have variable intensity in time (American Psychiatric Association, 2000). Treatment of akathisia may or may not alter the course of the akathisia.

### Treatment

Akathisia may be difficult to treat effectively. The best initial approach is to try and reduce the chance of developing akathisia by minimizing the dosage of antipsychotic medication. The use of atypical antipsychotics should be considered as a result of their lower risk of akathisia. If using conventional antipsychotics, a switch to a low-potency agent such as thioridazine or chlorpromazine may prove helpful because these antipsychotics seem to have somewhat lower propensity to cause akathisia than high-potency conventional antipsychotics. After these initial steps, consideration should be given to initiation of an antiakathitic drug regimen. A number of agents have been reported to be effective, including beta-adrenergic blockers, anticholinergic drugs, benzodiazepines and clonidine (American Psychiatric Association, 2000).

When choosing an agent to treat akathisia, a beta-blocker such as propranolol should generally be considered first-line as its efficacy has been proven and it has been shown to be superior to other possible treatments such as benztropine and lorazepam. In terms of antiakathitic effects, the beta-blocker chosen should be lipophilic so as to cross the blood–brain barrier and should also have activity at the beta-2 receptor. Benzodiazepines such as clonazepam and lorazepam have been shown to be efficacious in the treatment of akathisia and are also a reasonable therapeutic option, especially when considering the interplay between anxiety and akathisia, however, their side effects and abuse potential should be considered. Anticholinergic agents such as benztropine may also be tried, but less evidence exists to support their use. A limited number of studies have also shown possible roles for clonidine and amantadine in the treatment of akathisia. Agents with serotonin receptor blocking activity (i.e., ritanserin, mianserin) have also been reported to be of benefit in akathisia.

### Clinical Vignette 1

#### Confusion Between Neuroleptic-Induced Akathisia and Psychotic Agitation

Ms B, a 77-year-old widow, lived in a nursing home. As a result of severe degenerative arthritis and neuropathic pain due to type 2 diabetes, she was confined mainly to her bed and a wheelchair. She had a past psychiatric history significant for Alzheimer-type dementia diagnosed at age 74. Ms B was started on haloperidol 1 mg b.i.d. 6 weeks ago due to frequent, bothersome delusions regarding her roommate and health care personnel.

Two weeks ago, Ms B's roommate complained that Ms B was increasingly agitated, restless and boisterous throughout the day while in bed. Believing that her behavioral disturbance was inadequately controlled, Ms B's physician increased her haloperidol to 2 mg b.i.d. A few days later, Ms B was noted to be increasingly agitated and restless. Subjective discomfort was noted upon further interviews with the patient. Since the haloperidol-induced akathisia worsened by increased dosages of haloperidol, Ms B was started on low-dose risperidone and haloperidol was stopped over the course of 1 week. Ms B is currently receiving risperidone 0.5 mg b.i.d. without any symptoms of akathisia and noted reductions in her delusions.

### Prophylactic Anticholinergic Medication?

One issue that remains controversial among researchers and psychiatrists is whether preventive anticholinergic medication should be given to patients who are starting antipsychotics. Arguments against this practice include the risk of anticholinergic side effects such as dry mouth, blurry vision, constipation and urinary retention. Further, anticholinergic medication is associated with cognitive side effects, such as memory impairment, confusion and delirium. The relationship between anticholinergic medications and TD is not definitive.

Arguments in favor of initiating prophylactic anticholinergic therapy point to the decrease in the frequency of EPS (including dystonias, akathisia and akinesia) when anticholinergic drugs are prescribed prophylactically. Furthermore, medication nonadherence and decompensation may relate to inadequately treated NIP, especially akathisia and akinesia. With the introduction and increased use of atypical antipsychotics, the risk of EPS and TD has decreased, thus reducing the need for prophylactic anticholinergic medication for many patients prescribed atypical agents.

Although this complicated issue remains unresolved, some basic guidelines can be proposed. When psychosis is severe and unmanageable and adherence with medications needs to be rigorously enforced, antipsychotic and anticholinergic medication may be administered concurrently, with the anticholinergic medication tapered slowly within the next few weeks. When the psychosis is milder and antipsychotic medication may be gradually increased, it may be best to avoid anticholinergic medications until such time as they become clinically necessary. In patients with any degree of cognitive impairment (especially the elderly or demented patient with agitation or psychosis), it is best to aim for the administration of less anticholinergic medication. In younger patients, especially young men (who have a high frequency of dystonia), it may be preferable to use anticholinergic medication

prophylactically because it may prevent an uncomfortable dystonic reaction and can generally be used with relative impunity of serious side effects. In general, long-term prophylactic use of anticholinergic medication is not recommended nor its use in the elderly.

## Neuroleptic-induced tardive dyskinesia

### Etiology and Pathophysiology

Neuroleptic-induced tardive dyskinesia (TD) is a syndrome consisting of abnormal, involuntary movements caused by long-term treatment with antipsychotic medication. The movements are typically choreoathetoid in nature and principally involve the mouth, face, limbs and trunk. TD, by definition, occurs late in the course of drug treatment. It is likely that a number of separate neurotransmitter systems are involved in the pathogenesis of TD. There may be different subtypes of TD, each perhaps involving a unique profile of neurochemical imbalance. Neuroleptic-induced striatal pathological change represents another possibility for explaining mechanisms of TD and some have suggested that long-term antipsychotic use may produce “toxic free radicals” that damage neurons and result in persistent TD.

### Epidemiology and Comorbidity

The reported prevalence of TD has been somewhat variable as a result of differences in populations of patients and in the methods used. Yassa and Jeste (1992) reviewed 76 studies of the prevalence of TD published from 1960 to 1990. In a total population of approximately 40 000 patients, the overall prevalence of TD was 24.2%, although it was much higher (about 50%) in studies of elderly patients treated with antipsychotics.

There have been relatively few studies of the incidence of TD. Kane and coworkers (1988) prospectively studied more than 850 patients (mean age 29 years) and found the incidence of TD after cumulative exposure to conventional antipsychotics to be 5% after 1 year, 18.5% after 4 years and 40% after 8 years. Incidence in older populations has been found to be much higher. Saltz and colleagues (1991) reported an incidence of 31% after 43 weeks of conventional antipsychotic treatment in a population of elderly patients. Jeste and colleagues (1999) evaluated 439 psychiatric patients with a mean age of 65 years and found that 28.8% of the sample met criteria for TD during the first 12 months of study treatment; 50.1% had TD by the end of 24 months; and 63.1% by the end of 36 months. The risk of severe TD has also been reported to be higher in older patients.

Evidence supporting a reduced risk of TD with atypical antipsychotics is beginning to emerge. The lower risk of EPS with atypical agents has led to the widespread conclusion that these agents will also have reduced TD risk. The low risk of tardive dyskinesia in clozapine-treated individuals has been well established. In addition, a lower incidence of TD has been reported in patients treated with risperidone and olanzapine. More long-term prospective studies are needed with the atypical agents.

Aging consistently appears to be the most important risk factor for the development of TD. Prevalence and severity of TD seem to increase with age. The reasons for this increased risk of TD with aging are not known but may be related to the propensity of the nigrostriatal system to degenerate with age as well as pharmacokinetic and pharmacodynamic factors.

Gender (female) was thought to be a risk factor for TD. A meta-analysis of the published reports demonstrated a greater

## DSM-IV-TR Criteria 333.82

### Neuroleptic-induced Tardive Dyskinesia

- A. Involuntary movements of the tongue, jaw, trunk, or extremities have developed in association with the use of neuroleptic medication.
- B. The involuntary movements are present over a period of at least 4 weeks and occur in any of the following patterns:
  - (1) choreiform movements (i.e., rapid, jerky, nonrepetitive)
  - (2) athetoid movements (i.e., slow, sinuous, continual)
  - (3) rhythmic movements (i.e., stereotypies)
- C. The signs or symptoms in criteria A and B develop during exposure to a neuroleptic medication or within 4 weeks of withdrawal from an oral (or within 8 weeks of withdrawal from a depot) neuroleptic medication.
- D. There has been exposure to neuroleptic medication for at least 3 months (1 month if age 60 years or older).
- E. The symptoms are not due to a neurological or general medical condition (e.g., Huntington's disease, Sydenham's chorea, spontaneous dyskinesia, hyperthyroidism, Wilson's disease), ill-fitting dentures, or exposure to other medications that cause acute reversible dyskinesia (e.g., L-dopa, bromocriptine). Evidence that the symptoms are due to one of these etiologies might include the following: the symptoms precede the exposure to the neuroleptic medication or unexplained focal neurological signs are present.
- F. The symptoms are not better accounted for by a neuroleptic-induced acute movement disorder (e.g., neuroleptic-induced acute dystonia, neuroleptic-induced acute akathisia).

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

prevalence of TD in women (26.6%) compared with that in men (21.6%) (Yassa and Jeste, 1992). Interestingly, studies of incidence of TD in older patients failed to confirm the reported propensity of women to have TD at a higher rate than men. A possible relationship between gender and age of onset of schizophrenia to severity of dyskinesia has been reported as women with late-onset schizophrenia (LOS) and men with early-onset schizophrenia (EOS) had more severe dyskinesia than men with LOS and women with EOS.

There are conflicting reports regarding ethnicity as a risk factor for TD and people with diabetes mellitus may be at a higher risk for development of TD. Some have proposed that diabetes mellitus might be a risk factor for TD in patients treated with metoclopramide.

Patients who experience an acute neuroleptic-induced movement disorder (especially parkinsonism or akathisia) are likely to be at a greater risk for development of TD if antipsychotic treatment is continued. Total exposure to typical antipsychotic

agents has been correlated with TD risk and within elderly populations, cumulative amount of typical antipsychotics has also been associated with TD risk, especially with high-potency conventional agents. The observation that anticholinergic drugs exacerbate some symptoms of TD does not appear to indicate that the drugs promote the onset of the disorder.

### Assessment and Differential Diagnosis

TD may develop at any age and typically has an insidious onset. It may develop during exposure to antipsychotic medication or within 4 weeks of withdrawal from an oral antipsychotic (or within 8 weeks of withdrawal from a depot neuroleptic). There must be a history of at least 3 months of antipsychotic use (or 1 month in the elderly) before TD may be diagnosed (American Psychiatric Association, 2000).

The most common features of TD are involuntary movements of the tongue, face and neck muscles. Less common are movements in the upper and lower extremities as well as in the trunk. Most rare of all are involuntary movements of the muscle groups involved with breathing and swallowing. The earliest symptoms typically involve buccolingual–masticatory movements. The movements of TD are choreiform (rapid, jerky), athetoid (slow, sinuous), or rhythmical (stereotypical) (American Psychiatric Association, 2000).

Severe choreoathetoid dyskinesia differs from the milder forms, mainly in the frequency and amplitude of the abnormal movements. Some cases of severe dyskinesia consist of generalized choreoathetosis of the face, trunk and all four limbs. TD may be accompanied by dystonias, parkinsonism and akathisia. TD is worsened by stimulants, short-term withdrawal of antipsychotic medication, anticholinergic medication, emotional arousal, stress and voluntary movements of other parts of the body. It is improved by relaxation, voluntary movements of the involved parts of the body, sleep and increased dose of antipsychotics.

The differential diagnosis of TD is extensive. The major task for the psychiatrist is to rule out other causes of dyskinesia. It may be useful for the psychiatrist to keep in mind three questions for the facilitation of the differential diagnosis: 1) Does the patient have dyskinesia? 2) Does another disorder fully explain the cause of the dyskinesia? 3) If the dyskinesia is related to antipsychotic use, is it TD?

A number of nondyskinetic movement disorders are part of the differential diagnosis of TD. Tremor can be confused with TD, including the tremor of neuroleptic-induced parkinsonism, rabbit syndrome, Wilson's disease and cerebellar disease. Further, fine tremors of the fingers and hands are produced by anxiety states, alcoholism, hyperthyroidism and drugs. Acute dystonias, myoclonus, tics, mannerisms, compulsions and akathisia must be differentiated from TD. The differentiation is made on the basis of the clinical assessment.

Once it has been established that the patient suffers from a dyskinesia, the main cause must be determined. In children and young adults, a number of conditions may cause dyskinesia besides antipsychotic treatment. The use of drugs, especially amphetamines and antihistamines, are associated with dyskinesia. Sydenham's chorea can produce choreiform movements. Conversion disorder and malingering are conditions that can present with apparently involuntary movements. Hyperthyroidism and hypoparathyroidism are two endocrinological conditions that can produce dyskinesias similar to TD. Huntington's disease is a condition that can be difficult to distinguish clinically from TD, but certain characteristics may aid in the diagnosis, including 1) a

family history of Huntington's disease, 2) the presence of dementia, 3) a slowly progressive downhill course, and 4) atrophy of the caudate nucleus on computed tomography scan.

In the middle-aged or elderly patient, denture or dental problems may commonly mimic TD. Lesions of the basal ganglia may result in dyskinesias. The use of antiparkinsonian medications such as levodopa, amantadine and bromocriptine can cause dyskinetic movements. The presence of spontaneous dyskinesias must also be ruled out.

When it has been established that antipsychotics are responsible for the dyskinesia, it does not follow that the dyskinesia is necessarily TD. Acute dyskinesia occurring early in antipsychotic treatment is common and responds well to antihistaminic or anticholinergic medications. Withdrawal–emergent dyskinesia also occurs in a variable proportion of patients. This phenomenon refers to the appearance or worsening of dyskinetic movements on reduction or discontinuation of antipsychotic medication. Withdrawal–emergent dyskinesia is phenomenologically similar to TD and often has the full range of involuntary choreiform and athetoid movements. A typical case may begin within a few days after a sudden decrease in dosage and worsen as the antipsychotic is withdrawn. This phase is followed by rapid improvement in a period of weeks to months. A history of antipsychotic exposure and remission of dyskinetic symptoms within 3 months of antipsychotic withdrawal are suggestive of the diagnosis of withdrawal–emergent dyskinesia.

Finally, tardive Tourette's disorder must be differentiated from TD. A number of cases of tardive Tourette's disorder have been reported as a result of treatment with antipsychotics, emerging during treatment or after cessation of treatment. Tardive Tourette's disorder presents with symptoms similar to those of idiopathic Tourette's disorder. Motor tics are usually compulsive organized stereotypies that may, in certain cases, be difficult to distinguish from the choreoathetoid movements of TD. Typically, vocal tics (including barks, grunts, coughs and yelps) represent part of tardive Tourette's disorder but not TD. Tardive Tourette's disorder seems to show a pharmacological response similar to that of TD, leading to the assumption that the syndrome may be a type of the more commonly seen TD. Thus, tardive Tourette's disorder may be masked by an increase in antipsychotics and exacerbated by withdrawal.

### Course

One-third of the TD patients experience remission within 3 months of discontinuation of antipsychotic medication, and approximately half have remission within 12 to 18 months of antipsychotic discontinuation (American Psychiatric Association, 2000). Elderly patients are reported to have lower rates of remission, especially if antipsychotics are continued. When TD patients must be maintained with antipsychotics, TD seems to be stable in 50%, worsen in 25% and improve in the rest. Time may be the most important factor in outcome of TD. In studies that have followed up patients for longer than 5 years, TD seems to improve in half of patients with or without antipsychotic treatment. Furthermore, TD may improve as slowly as it develops and may exist on a spectrum between resolution and persistence.

Severe TD may lead to numerous physical complications and psychosocial problems. Dental and denture problems are common sequelae of severe oral dyskinesia as are ulcerations of the tongue, cheeks and lips. Hyperkinetic dysarthria has been described. Swallowing disorders represent another complication. Respiratory disturbances, although fairly rare, have been

reported by a number of investigators. These disturbances are usually manifested by shortness of breath at rest, irregularities in respiration, and various grunts, snorts and gasps. Respiratory alkalosis may be seen on laboratory tests. Gastrointestinal complications of severe TD may involve vomiting and dysphagia secondary to disruption of the normal activity of the esophagus; weight loss may result from such a disturbance.

Subjective distress is a common accompaniment of severe dyskinesia. Suicidal ideation may result from distress over the dyskinesia, and there have been reports of some successful suicides. General impairment of functioning may be related to the severity of the dyskinetic disorder. Social embarrassment as a result of TD may represent a reason that some patients with TD tend to be reluctant to leave their homes. Even mild dyskinesia may lead to anxiety, guilt, shame and anger. These symptoms can lead to severe depressive episodes.

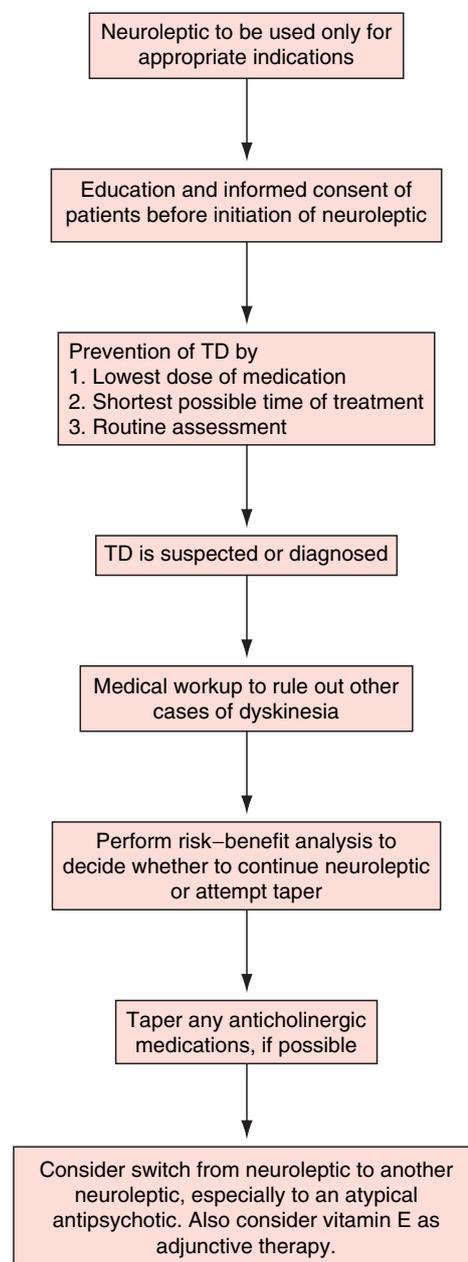

## Treatment

Despite intense effort, there is as yet no consistently reliable therapy for TD. As a result, the psychiatrist must focus primary efforts toward prevention of the disorder. The use of atypical antipsychotics are recommended due to their probable lower risk of TD. Antipsychotic use should be minimized in all patients. Patients with nonpsychotic mood or other disorders who need antipsychotics should receive the minimal necessary amounts of antipsychotic treatment and should have the medication tapered and then stopped once the clinical need is no longer present. In general, there must be enough clinical evidence to show that the benefits outweigh the potential risks of TD development. Antipsychotics should be used with particular caution in elderly patients because of their high risk for development of TD (Figure 64.1).

Gradual taper of the antipsychotic medication may be attempted as long as the risk/benefit ratio of antipsychotic maintenance versus withdrawal does not preclude such a strategy. A slow taper of medication to the lowest effective dose is probably the preferred strategy for the treatment of chronic schizophrenia in a large number of stable patients.

Paradoxically, antipsychotics themselves represent the most effective short-term treatment for TD. An increase in dosage of a conventional agent usually (approximately 66% of patients) results in a clinically significant but temporary reduction in TD symptoms. The most exciting development in the treatment of TD has been the use of the atypical antipsychotics. Clozapine has been shown to be effective in reducing TD in patients with existing TD, however, side effects such as agranulocytosis and clozapine's affinity for anticholinergic side effects limits its use. Additional studies have noted a beneficial effect of other atypical agents (i.e., risperidone and olanzapine) on preexisting TD. The reduced risk of TD with all atypical agents (when used at appropriate doses) supports their use as preventive measures and as therapeutic options for those who develop TD on a conventional antipsychotic.

A number of experimental studies have attempted to treat TD with alternative strategies. One treatment that has demonstrated some efficacy has been the use of vitamin E alpha-tocopherol. If antipsychotic treatment results in the production of free radicals that damage the neuronal components, an antioxidant such as vitamin E would therefore, theoretically, result in improvement in the symptoms of TD. Vitamin E is a possible agent for the treatment and prophylaxis of TD. A number of studies of varying design have shown benefit of vitamin E in TD

**Figure 64.1** Management of tardive dyskinesia (TD).

however, a recent double-blind, placebo-controlled multicenter trial failed to show a difference between vitamin E and placebo after 1 year of treatment (Adler *et al.*, 1999). Although the results are far from conclusive, vitamin E remains a reasonably safe treatment modality for a patient with recently diagnosed TD. Doses are usually in the range of 1200 to 1600 mg/day. Other agents have been investigated, such as calcium channel blockers (i.e., diltiazem, verapamil, nifedipine) and clonazepam, but more studies are warranted.

Psychiatrists must regularly assess for the presence and progression of TD and present the patient (or the patient's guardian, when appropriate) with information about the risks of treatment; they may also give written information sheets, assess understanding by the patient or guardian, and accurately record evidence of the informed consent in the patient's record.

## Neuroleptic Malignant Syndrome

### Etiology and Pathophysiology

Neuroleptic Malignant Syndrome (NMS) is a potentially fatal reaction to antipsychotic medications that is characterized clinically by muscle rigidity, fever, autonomic instability and changes in level of consciousness. The pathophysiological mechanism of NMS remains unclear. The hypothesis of most interest is that of reduced dopaminergic activity secondary to neuroleptic-induced dopamine blockade. This reduced dopamine activity in different parts of the brain (hypothalamus, nigrostriatal system and corticolimbic tracts) may serve to explain the various clinical features of NMS. Dopamine reduction in the hypothalamus may cause fever and autonomic instability; in the nigrostriatal system, dopamine reduction may lead to the rigidity; and the reduction in corticolimbic dopamine activity may explain the altered consciousness. This hypothesis is based on the fact that antipsychotics are dopamine-blocking agents, whereas certain dopamine agonists are reported to help resolve NMS.

The dopaminergic blocking theory does not, however, explain why NMS may develop at a given time and in a given patient. There are probably other genetic (possibly a predisposition similar to that seen in malignant hyperthermia), constitutional, environmental, and pharmacological factors that interact to produce the syndrome. A number of investigators have proposed that other neurotransmitter abnormalities may be responsible for the syndrome, including serotonergic hyperfunction in the hypothalamus, excessive catecholamine secretion, and gamma-aminobutyric acid deficiency.

### Epidemiology and Comorbidity

The exact frequency of NMS is unknown. A number of retrospective and prospective studies have found 0.02 to 3.2% of patients treated with antipsychotics to be affected with NMS. Several factors probably account for this large variability in frequency, including differences in study methods and diagnostic criteria for NMS. A prior episode of NMS appears to predispose to future episodes of NMS. Any preexisting medical problems, especially those associated with agitation or dehydration, may increase the likelihood of NMS development when antipsychotics are used. Patients with a neurological condition as well as patients with presumed psychosis due to human immunodeficiency virus infection may be at higher risk for development of NMS. A number of potential risk factors related to antipsychotic treatment have been identified. Higher doses of antipsychotic, rapid increases in dosage (especially “rapid neuroleptization”) and intramuscular injections of high-potency conventional agents (e.g., haloperidol and fluphenazine) have been reported to be risk factors for NMS. NMS can occur (but rarely) in patients prescribed atypical antipsychotics and a review of atypical-induced NMS concluded that symptoms appear similar to NMS induced by conventional antipsychotics.

NMS is more frequently reported in men than in women and is more frequently seen in a younger population. A previous diagnosis of a mood disorder may place patients at a higher risk for NMS. Warm, humid climates may also predispose to the disorder (American Psychiatric Association, 2000).

### Assessment and Differential Diagnosis

NMS usually presents in the first month of antipsychotic treatment but may develop at any time. Two-thirds of the cases manifest within the first week of treatment (American Psychiatric

### DSM-IV-TR Criteria 303.92

#### Neuroleptic Malignant Syndrome

- A. The development of severe muscle rigidity and elevated temperature associated with the use of neuroleptic medication.
- B. Two (or more) of the following:
  - (1) diaphoresis
  - (2) dysphagia
  - (3) tremor
  - (4) incontinence
  - (5) changes in level of consciousness ranging from confusion to coma
  - (6) mutism
  - (7) tachycardia
  - (8) elevated or labile blood pressure
  - (9) leukocytosis
  - (10) laboratory evidence of muscle injury (e.g., elevated CPK [creatin kinase])
- C. The symptoms in criteria A and B are not due to another substance (e.g., phencyclidine) or a neurological or other general medical condition (e.g., viral encephalitis).
- D. The symptoms in criteria A and B are not better accounted for by a mental disorder (e.g., mood disorder with catatonic features).

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

Association, 2000). The two key diagnostic features for the disorder are severe muscle rigidity (classically referred to as lead pipe rigidity) and elevated temperature. A number of other features are also seen (see DSM-IV-TR criteria). For the psychiatrist, the most suggestive features are fluctuating consciousness (from confusion to coma), labile vital signs (tachycardia, unstable or elevated blood pressure), laboratory evidence of muscle injury (elevation of creatine kinase) and leukocytosis. Other features include diaphoresis, dysphagia, tremor, incontinence and mutism (American Psychiatric Association, 2000).

The differential diagnosis of NMS can be difficult (Table 64.3). The most important point is that the psychiatrist must start by suspecting NMS and then carefully rule out other possible organic problems. Because medical illness is a likely predisposing factor, it is important to consider that NMS may be present even if a definitive organic disease is found to explain the NMS-like symptoms.

Numerous general medical and neurological conditions can present with symptoms that may resemble NMS. Examples include central nervous system infection, status epilepticus, subcortical brain lesions, porphyria and tetanus (American Psychiatric Association, 2000). The presence of significantly elevated temperature and severe muscle rigidity makes the diagnosis of NMS more likely.

**Table 64.3** Differential Diagnosis of Neuroleptic Malignant Syndrome

Feature	Diagnosis				
	Lethal Catatonia	Heat Stroke	Malignant Hyperthermia	Serotonin Syndrome	Neuroleptic Malignant Syndrome
Previous psychiatric illness	Yes	No	No	Yes	Yes
Onset of symptoms	+ Prodromal psychotic symptoms	– Prodromal symptoms; development in several hours	– Prodromal symptoms; development after anesthesia	– Prodromal symptoms; development days to months after serotonergic medication	– Prodromal symptoms; development hours to months after neuroleptic
Preceding anesthesia with muscle cell-depolarizing agents	No	No	Yes	No	No
Preceding neuroleptics	Maybe	Maybe	Maybe	Maybe	Yes
Preceding serotonergic agents	Maybe	Maybe	Maybe	Yes	Maybe
Autonomic dysfunction	Maybe	No	No	No	Yes
Episodes: stupor mixed with episodes of excitement	Yes	No	No	No	Maybe
Diaphoresis	Maybe	No	Maybe	Maybe	Yes
Rigidity	Fluctuating	No	Yes	Yes	Yes

The syndrome of lethal catatonia (seen in patients with uncontrolled manic excitement or catatonic schizophrenia) can mimic NMS (with increased temperature, autonomic irregularities and elevated creatine kinase), and the differential diagnosis can be difficult. It is obviously important to determine whether the patient is indeed being treated with an antipsychotic. Although NMS may clinically look like catatonia, NMS does not typically have alternating periods of catatonic excitement and catatonic mutism. A past history of catatonic episodes is also important in making the differential diagnosis. Lorazepam may be useful in alleviating the symptoms of catatonia but it has not been shown to be useful in treatment of NMS. Therefore, it is possible that a brief lorazepam trial could provide a useful and relatively easy method of distinguishing between these two conditions. The problem, of course, is that not all cases of catatonia respond to lorazepam.

Heat stroke may also look like NMS but typically differs in that it presents with hypotension, dry skin and limb flaccidity (American Psychiatric Association, 2000). Malignant hyperthermia can also have a similar presentation but generally occurs within the context of a patient's receiving halogenated anesthetic agents or succinylcholine. This condition typically begins immediately after administration of the anesthetic agent and only in genetically susceptible individuals (American Psychiatric Association, 2000).

Medications can cause a number of conditions that may present as syndromes similar to NMS. Allergic drug reactions

may produce fever and autonomic instability but not rigidity. Serotonin syndrome, with common clinical characteristics including fever, resting tremor, rigidity, myoclonus and generalized seizures should also be considered. A medication history can usually help distinguish between the two syndromes, but patients receiving antipsychotics may also be treated with selective serotonin reuptake inhibitors, thus making the clinical picture more confusing. Lithium intoxication and anticholinergic delirium can both resemble NMS, as can intoxication with amphetamines, cocaine and phencyclidine as well as rapid termination of antiparkinsonian medication.

### Course

The course of NMS is variable. Some cases may progress to fatality, whereas others may follow a mild self-limited course. Once the syndrome is recognized and the antipsychotic medication is discontinued, the syndrome usually resolves between 2 weeks and 1 month (American Psychiatric Association, 2000).

Mortality rate is reported to be 4 to 25%. The most common medical complications leading to morbidity and mortality are respiratory failure and renal failure. Shalev and coworkers (1989) reported that myoglobinemia and renal failure are the best predictors of mortality in NMS; the presence of either condition imparted a 50% mortality risk. In general, complications are a result of physiologic consequences of severe rigidity and immobilization such as deep vein thrombosis, pulmonary embolism, dehydration and an increased risk for rhabdomyolysis.

## Treatment

The most critical step in treatment (Table 64.4) is to recognize the clinical features of the syndrome and rapidly discontinue the antipsychotic. The importance of this initial step mandates that psychiatrists who use antipsychotics in their practice be cognizant of the early clinical features and recognize that the syndrome can occur at any time during the course of treatment. Once the antipsychotic has been stopped, supportive care remains the core of treatment and often must be carried out in the context of a medical intensive care unit. Each supportive intervention should be targeted to a specific symptom. Examples of interventions include cooling blankets for fever, cardiac monitoring for arrhythmias, parenteral hydration for dehydration and monitoring for urine output and renal function. Dialysis may also be considered for acute renal failure.

It should be noted that despite their widespread use, the efficacy of the muscle relaxant dantrolene and the dopamine agonist bromocriptine has not been thoroughly established. Electroconvulsive therapy is another treatment option in NMS presumably because it increases dopamine turnover in the brain. Electroconvulsive therapy is particularly indicated when there is difficulty in distinguishing between NMS and lethal catatonia and when there seems to be a significant risk of recurrence of NMS on restarting neuroleptics. Some psychiatrists report rapid

and dramatic success in the use of electroconvulsive therapy for NMS.

At present, the appropriate course is to begin with antipsychotic discontinuation and supportive care and to consider antidote therapy only if improvement in symptoms is not seen within the first few days. The treatment of NMS should be individualized for each patient based on clinical signs and symptoms. For example, supportive care may be sufficient in mild and early cases of NMS. Trials of bromocriptine, dantrolene, or amantadine are suggested for patients with moderate symptoms. Anticholinergics can be used in managing afebrile patients with neuroleptic-induced parkinsonian symptoms and benzodiazepines may be useful for agitation in NMS. ECT is recommended in situations where lethal catatonia is suspected, when NMS symptoms are treatment refractory, and in patients who remain psychotic in the immediate post-NMS period.

A particular difficulty for the psychotic patient who has NMS is that rechallenge with antipsychotics may cause NMS to recur. Successful rechallenge seems to be positively related to the length of time elapsed after resolution of NMS. There is some evidence to suggest that clozapine may have relatively little propensity to induce NMS. Clozapine, therefore, may represent one option for the patient who has experienced NMS with a conventional agent. It is likely but not yet known definitively that atypical antipsychotics will prove to have a lower frequency of NMS. In general, it is recommended to switch to an agent in a different chemical class and with a lower  $D_2$  affinity compared with the causal agent.

**Table 64.4 Treatment of Neuroleptic Malignant Syndrome**

Step 1	Assess medication regimen <ul style="list-style-type: none"> <li>• Stop dopamine antagonists</li> <li>• Restart any recently stopped dopamine agonists</li> </ul>
Step 2	Supportive care <ul style="list-style-type: none"> <li>• Monitor vital signs</li> <li>• Administer intravenous fluids</li> <li>• Provide cooling blankets</li> <li>• Administer antipyretics</li> <li>• Consider dialysis for acute renal failure</li> </ul>
Step 3	No improvement within 24–28 h <ul style="list-style-type: none"> <li>• Administer oral bromocriptine 5 mg PO t.i.d. to be increased daily by 5 mg increments until positive response</li> <li>• Continue bromocriptine for 10 d, then withdraw in period of 1 wk</li> <li>• Monitor for relapse</li> </ul>
Step 4	If patient cannot tolerate bromocriptine or cannot take oral medications <ul style="list-style-type: none"> <li>• Administer intravenous dantrolene 1–3 mg/kg/body weight q.i.d.</li> <li>• Gradually increase dose until positive response</li> </ul>
Step 5	Consider adding bromocriptine to dantrolene
Step 6	Consider discontinuing all medications and giving supportive care only
Step 7	Consider electroconvulsive therapy after 3–4 d, if no improvement

## Medication-induced Postural Tremor

### Etiology and Pathophysiology

This category refers to fine postural action tremor that develops as a result of a medication. Medications that have been reported to cause such an effect are lithium, beta-adrenergic agonist medications, stimulants, dopaminergic medications, anticonvulsant medications, antipsychotics, antidepressant medications and methylxanthines (e.g., caffeine) (American Psychiatric Association, 2000). The psychotropic medication most typically associated with such tremor is lithium, and most of the available information on medication-induced tremor relates to that caused by lithium.

Normal muscle contractions are accompanied by tremor as a result of contractions of muscle fiber recruitment. This tremor is typically low in amplitude and is referred to as a physiological tremor. When these contractions are maintained, the amplitude of the tremor increases and it becomes visible. This is referred to as an enhanced physiological tremor. A number of medications, including lithium and bronchodilators, produce an enhanced physiological tremor. The pathophysiological mechanism of these tremors is not well understood but seems to relate to adrenergic changes (probably mediated in the locus coeruleus) in the mechanical properties of the skeletal muscle. The response of these tremors to beta-adrenergic blocking agents and their exacerbation as a result of beta-adrenergic agonists seem to lend support to the notion of adrenergic mediation.

### Epidemiology and Comorbidity

Estimates of the frequency of lithium-induced tremor vary widely across the literature and range between 4 and 65%. Lifetime

**DSM-IV-TR Criteria 333.1****Medication-induced Postural Tremor**

- A. A fine postural tremor that has developed in association with the use of a medication (e.g., lithium, antidepressant medication, valproic acid).
- B. The tremor (i.e., a regular, rhythmic oscillation of the limbs, head, mouth, or tongue) has a frequency between 8 and 12 cycles per second.
- C. The symptoms are not due to a preexisting nonpharmacologically induced tremor. Evidence that the symptoms are due to a preexisting tremor might include the following: the tremor was present prior to the introduction of the medication, the tremor does not correlate with serum levels of the medication, and the tremor persists after discontinuation of the medication.
- D. The symptoms are not better accounted for by neuroleptic-induced parkinsonism.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

incidence of tremor is estimated to be 25 to 50% of patients starting lithium therapy. A number of possible risk factors have been proposed to predispose a person to development of a lithium-induced tremor. These include older age, greater serum lithium levels, concomitant use of antidepressant or antipsychotic medication, greater caffeine intake, history of tremor, alcohol dependence and anxiety (American Psychiatric Association, 2000).

**Assessment and Differential Diagnosis**

Lithium-induced tremor may appear as soon as treatment is initiated. As the lithium level increases, the tremor becomes more severe and coarse and may have associated muscle twitching or fasciculations (American Psychiatric Association, 2000). Complaints about the tremor are typically greatest at the beginning of therapy. There is disagreement as to whether the tremor typically remains stable or improves with time on lithium.

The lithium-induced tremor is reasonably easy to diagnose. It is a rhythmical action tremor. It is most commonly seen in the hands or fingers but can occasionally be seen in the head, mouth, or tongue (American Psychiatric Association, 2000). The frequency of the tremor is typically 8 to 12 Hz and is similar in appearance to an essential tremor. It may usually be seen by asking the patient to hold the affected body part in a stable position. The tremor is made worse by anxiety, stress, fatigue, hypoglycemia, thyrotoxicosis, pheochromocytoma, hypothermia, alcohol withdrawal, performance of voluntary movements and concomitant administration of cyclic antidepressant medications.

The most difficult differential diagnosis involves distinguishing a lithium-induced tremor from a tremor that was preexisting. To be classified as a medication-induced tremor, it must have a temporal relationship to the medication, it must relate to the serum level of the medication, and it must not persist after the medication is discontinued. A similar postural tremor is essential tremor, and differentiation between the two is nearly

impossible clinically without the medication history. Any of the factors listed that may exacerbate a medication-induced tremor can also cause a similar tremor in the absence of the medication. Medication-induced tremor may resemble NIP. NIP, however, is generally worse at rest, is lower in frequency, and has other associated features of parkinsonism (American Psychiatric Association, 2000).

**Course**

The literature suggests that there is some risk that tremor may be embarrassing for certain patients and could impair activities that require delicate movements. The actual percentage of patients who are bothered by their tremor is unknown. There do not appear to be any long-term sequelae as a result of having a medication-induced postural tremor. A sudden worsening of tremor may be indicative of the beginning of lithium intoxication.

**Treatment**

Most treatment options have been described for treatment of lithium-induced tremor. Typically the tremor is benign, is not bothersome to the patient, and requires no specific intervention. Some cases, however, require treatment because of the patient's concern about the side effect. Preliminary measures include possibly reducing the lithium dose (if clinically feasible), changing the lithium dose to one-time evening administration, or changing the lithium preparation. Caffeine intake should be reduced or eliminated, and anxiety should be pharmacologically or behaviorally treated.

Beta-blockers represent the best-studied method for gaining pharmacological control of the tremor if the preliminary measures are ineffective. Arana and Rosenbaum (2000) recommended starting propranolol on an as-needed basis. They suggested 10 to 20 mg a half-hour before the activity in which the tremor must not be present. If a patient requires chronic relief from the tremor, propranolol should be initiated at 10 to 20 mg b.i.d and increased until adequate dose for suppression of the tremor is attained. Propranolol may decrease glomerular filtration rate and may result in a reduction in renal lithium clearance. This suggests that patients who require long-term beta-blocker suppression for tremor need to have lithium levels checked more regularly even when they are taking a stable dose of lithium.

There is little information in the literature as to the possible treatment of tremor induced by medications other than lithium and further investigations are needed to elucidate this syndrome.

**Comparison of DSM-IV/ICD-10 Diagnostic Criteria**

Some of these categories are included in Chapter VI of ICD-10 (Diseases of the Nervous System) but no diagnostic criteria or definitions are provided.

## Introduction

A relational problem is a situation in which two or more emotionally attached individuals (i.e., family members, romantic partners) engage in communication or behavior patterns that are destructive or unsatisfying, or both, to one or more of the individuals. Relational problems deserve clinical attention because, once initiated, they tend to be perpetuating and chronic, and are frequently contemporaneous with or are followed by other serious problems, such as individual symptoms in the most vulnerable members of the family (e.g., depression) or social unit dissolution (e.g., divorce). They may be diagnosed either in the presence or absence of individual disorders given in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM).

The strength and direction of causality between the individual and the relational problem are empirically undetermined. Few empirical investigations of the relational problems that are “precursors” to individual pathology have been conducted. Most of the existing research selects disturbed family units in which one member has an existing disorder (e.g., schizophrenia, depression) and examines the communication difficulties that accompany the disorder. Thus, cause-and-effect relations between individual disorders and relational difficulties have not been experimentally specified.

There is also the issue of generalization: Do those who manifest relational problems with a spouse or other family member manifest these same problems with others and in other contexts? Only a beginning literature exists on this issue. However, preliminary data suggest that some individuals manifest severe communication difficulties with their spouses or other family members but not with persons outside the family.

## Definition

Relational problems are placed in the fourth edition of the DSM (DSM-IV-TR) section on “other conditions that may be a focus of clinical attention”. Five specific relational problems are described chiefly in terms of patterns of impaired family interaction related to:

- a mental or general medical condition
- parent–child problem
- partner
- sibling
- not otherwise specified (e.g. difficulties with others outside of the family).

## Constructs and Manifestations of Relational Problems

The empirical data substantiate the existence of relational difficulties that can be reliably assessed and have clinical significance. The data are sparse in reference to each DSM disorder and coexisting family relational difficulties, with the exceptions of depression and schizophrenia.

In our examination of the construct of relational problems, we emphasize those constructs that have shown reliable assessment in research and that have been found to 1) distinguish distressed from nondistressed couples or families, or 2) to identify couples or families in which one or more members manifest significant individual pathologic conditions.

Four major constructs (Table 65.1) have been investigated that describe nodal areas of relational difficulty in the family and marital environment: structure, communication, expression of affect and problem solving. Relational difficulties in other environments (e.g., work) have not been described in the clinical literature.

It is interesting to compare the constructs investigated in the couples and family contexts. The areas of affective communication and conflict resolution are almost identical in conceptualization, behavioral criteria and importance in the spouse–spouse and parent–child communication domains. However, three other rather sharply defined constructs in the parent–child literature are not fully represented in the spouse–spouse literature: communication deviance (CD), emotional overinvolvement and coercive process. In the cognitive realm, the CD construct (unclear, amorphous, or fragmented communication) has been investigated primarily among schizophrenic patients and their parents; comparable work has not been done with couples. The more general construct of communication has been explored with marital couples, with no theoretical link to thought disorder and schizophrenia.

Coercive processes – the shaping of the behavior of parents by negative behavior on the part of the child – is similar to negative escalation in couples. Although not yet investigated in couples, it is quite conceivable that one spouse could effectively utilize a coercive process with the other spouse. Overinvolvement, which has been explored in the parent–child literature, may have a related domain in the marital literature, specifically, structure. Indeed, the over involvement construct has been seen as most relevant with children and parents and has little predictive utility in adult couple samples. However, it seems that the concept of structure, with the issues of leadership, dominance and submission, and distribution of functions, is an area that needs further exploration in reference to both couples and the entire family.

**Table 65.1** Empirically Derived Family Relational Constructs

Structure	Leadership and distribution of functions
Overinvolvement	Unclear boundaries; overdependence
Communication deviance	Amount and clarity of information exchange Unclear, amorphous, fragmented, and/or unintelligible communication
Communication Coercion	Behavior control by use of aversive communication
Expression of affect	Implicit or explicit verbalization of affective tone
Problem solving	Definition of problems, consideration of alternative lines of action, agreement to use optimal line of action
Conflict resolution and its	Process of resolving differences of opinion

## Structure

For a marriage or family to function as a unit requires leadership and distribution of functions. Leadership, dominance and power distribution can all have a profound effect on the quality of interaction satisfaction and on adequate functioning of both couples and families, both in ordinary and in stressful circumstances.

## Couples

Dominance as measured by verbal frequency has not distinguished functional and dysfunctional families. When one spouse is depressed, the power distribution is not always as theoretically hypothesized (i.e., depressed spouse submissive to dominance of the nondepressed partner). Contrary to expectation, depressed patients produce substantial control-oriented communication with their spouses during an acute depressed episode. Introversion and interpersonal dependency may reflect enduring abnormalities in the functioning of individuals with remitted depression.

## Families

Some parent–offspring relationships are marked by unclear boundaries and overdependence, often inhibiting the offspring’s ability to separate, individuate, or recover from illness. With respect to psychiatric and sometimes medical disorders, it is not unusual to see a pairing of an overprotective, overinvolved parent with a highly disabled, passive, withdrawn offspring. Because ill offspring in these families often elicit such responses, an overinvolved relationship is best thought of as a dyadic attribute rather than a problem generated by a parent. Overinvolvement is often difficult to define or assess in parents of school-age or adolescent children. However, among studies of youth, those focusing

on separation anxiety, and school refusal in particular, describe parental overinvolvement and protectiveness as complicating features.

The term **expressed emotion** (EE) is used to refer to critical comments, hostility, and/or overinvolvement as expressed by a family member toward another family member with a mental disorder. Studies suggest that overinvolvement is a risk factor for later episodes of psychosis among patients diagnosed with schizophrenia, independent of the level of criticism demonstrated by the family.

## Communication of Information

Verbal communication between two or more individuals involves the various aspects of information exchange, including the amount and clarity of the information and the reception of the information by another. This broad concept of communication implies the willingness to convey information, the accuracy and clarity of the information, and the accurate decoding of the information by the other.

## Couples

The amount and quality of verbal communication have differentiated distressed and nondistressed couples, and treatment leads to an improvement in communication.

Five areas of cognitive phenomena are hypothesized to play important roles in marital communication and maladjustment: selective attention, attributions, expectancies, assumptions and standards. Not all of these areas have been equally investigated.

Distressed spouses focus on negative behavior; positive interactions often are ignored. Distressed spouses tend to attribute their partner’s undesired communication behavior as global and the partner is blamed for her or his negative behavior, which is seen as intentional, global, stable and originating from internal factors. In contrast, nondistressed individuals give each other credit for positive behavior and overlook or exonerate their spouses for negative behavior. While the evolution or developmental history of these cognitive sets has not been clearly delineated, current evidence suggests that negative attributions for partner behavior may predict marital satisfaction over time.

## Families

Many of the same disordered processes (e.g., expression of hostility or excessive criticism, poor information exchange, lack of conflict resolution) in the spousal communication literature are presumed to disrupt healthy family functioning. Unlike in the marital literature, however, the independent variable in family studies is often the presence or absence of a psychopathologic condition in an offspring or parent rather than high or low levels of marital distress.

## Diagnosis of Relational Disorders

Although research on structure, expression of affect, communication and problem solving in couples and families has led to a greater understanding of the difficulties that can afflict these relational units, specific relational problems have only been recently included as a diagnostic entity in the DSM and clear diagnostic criteria have yet to be developed. Current textual descriptions of these conditions refer to impairment in the “pattern of interaction” in these relational units (American Psychiatric Association,

2000, p. 736), reflecting the broad range of specific difficulties subsumed under these diagnostic entities.

## Phenomenology

Five specific relational problems are noted in DSM-IV (see the definition section above). Family relational problems and partner relational problems are delineated below. These difficulties may also afflict relational units in the presence of a mental disorder or medical condition. The phenomenology of sibling relational problems and relational problems with other individuals have not been well explored.

### Partner Relational Problems

Clinical experience and the research descriptions suggest that marital (and couples) relational problems manifest in the following ways:

1. Couple does not clarify mutual requests, provide information, or accurately describe problems.
2. Spouse or spouses verbalize underlying attributions, assumptions and expectations that are negative (e.g., spouse is globally negatively intentioned) or exaggerated (e.g., couples should never fight).
3. Affective communication is characterized by negative affect (e.g., anger, hostility, jealousy), critical remarks, disagreement with spouse and nonacceptance of what the mate has communicated.
4. There is a low frequency of self-disclosure of thoughts, feelings and wishes.
5. Couple demonstrates inadequate problem solving characterized by poor problem definition, lack of task focus, mutual criticism and complaint, and negative escalation.
6. Couple displays sequences of negative communication characterized by criticism, disagreement, negative listening and refusal to agree.
7. Couple avoids conflict by withdrawal, lack of discussion and subsequent nonresolution.

Associated features of marital communication difficulties or disorders include poor marital satisfaction, psychiatric disorder in one or both spouses, threatened and contemplated separation and divorce, or concentration and job performance difficulties.

### Family Relational Problems

Family relational problems manifest as the following:

1. Family is unable to communicate clearly, cannot communicate closure, or cannot share a focus of attention (CD).
2. Family communication is characterized by unidirectional hostility or frequent criticism or by bidirectional, negatively escalating cycles of pejorative or critical comments.
3. Parent–offspring relationships are characterized by overprotectiveness, overconcern, unnecessarily self-sacrificing behaviors, intrusiveness, or overdependence (emotional overinvolvement).
4. Parent–offspring interchanges are marked by negatively reinforcing coercive cycles that tend to perpetuate antisocial or aggressive behavior in one or more family members.

5. A broad array of family problems cannot be solved because of the family's inability to agree to try to solve, define, generate, or evaluate solutions to, or implement solutions to, existing problems.

The associated features of parent–child communication difficulties or disorders include adolescent acting out and disruptive behavior, major psychiatric disorders in one or more family members (i.e., schizophrenia, affective disorder), poor parental morale and parenting dissatisfaction.

## Assessment of Relational Disorders

### Overall Relationship Functioning

The Global Assessment of Relational Functioning Scale (GARF) (Group for Advancement of Psychiatry, 1996) included in DSM-IV-TR is a 1 to 100 scale of overall relationship functioning, akin to the Global Assessment Scale for individuals. Recent studies have indicated that the GARF is reliable in clinical settings and that changes in GARF scores are positively associated with both patient and therapist-reported change in treatment and with treatment satisfaction.

### Epidemiology of Relational Disorders

The raw frequency of relational disorders (broadly defined) in the general population is unknown. No epidemiological studies have been done, in part because of the absence of accepted diagnostic criteria for these disorders. There are rather vague “proxies” of relational disorders that are useful in making estimations of their prevalence, such as the approximate frequencies of divorce in the general population (40–50% of all couples) or of marital violence (12–33% of couples). Factors such as divorce or violence, however, are best thought of as relational events rather than relational disorders. A single incident of marital violence does not necessarily signal the presence of a family relational disorder (in the absence of confirmatory information), nor is a diagnosable relational disorder in a spousal couple necessarily associated with divorce. Thus, the prevalence of specific types of relational disorders, as described in this chapter, is difficult to estimate.

A further difficulty in making these estimations in the normal population is that certain of the constructs conveyed, such as expressed emotion (EE) assume the presence of a psychiatric disorder in an index family member. Also, the goal of EE and other family psychopathological studies has been to examine family attribute–outcome relationships on a within-group basis in psychiatric disorders rather than to making comparisons between families of psychiatric patients and nonpsychiatric control subjects. Thus, data are lacking on the frequencies of high-EE attitudes or other family attributes in normal control groups.

The paucity of studies on the frequency of family relational disorders points to the need to develop strict operational criteria for these disorders and to conduct epidemiological studies using random sampling techniques, much as is done for individual disorders. The availability of epidemiological data would allow us to determine not only the need for treatment of specific relational disorders, but also their comorbidity with individual or other relational disorders, their associated features, and the social conditions under which they are most likely to arise.

## Treatment

### Specific Goals of Treatment

The primary goal of treatment is to bring the relational unit to a more satisfying, organized and less conflictual level of functioning. The mediating goals of treatment are focused on improvement in the specific areas of functioning of the relational unit (i.e., structure, communication, affect expression, problem solving). In relational units where one member is suffering from a mental disorder or medical condition (e.g., schizophrenia, depression, childhood disruptive behavior disorder), additional goals include the reduction of individual symptoms and improvements in psychosocial functioning.

### Treatment Format

Relational problems are best observed and treated directly in a family format in which the conflicted family members are present with the therapist. However, there may be certain situations in which relational problems are more conducive to change within an individual treatment format. For example, relational problems related to an individual with a mental disorder (e.g., a 25-year-old son with schizophrenia, in conflict with his mother and father) may in some cases best be approached by individual sessions with the affected person. Further, when one adult in a family unit is depressed, individual interpersonal or cognitive psychotherapies may be used and focused on conflict resolution.

### Treatment Strategies and Techniques

The specific techniques available to family therapists can be divided into five categories: psychoeducational, cognitive-behavioral, structural, strategic-systemic and insight-oriented. Psychoeducational approaches are most helpful when there is a family member with a specific medical or psychiatric disorder, and the family can utilize information on how to manage the disorder with the least tension and stress on the patient. Cognitive-behavioral techniques are useful in improving communication and problem-solving skills and the positive interactive behaviors in marital-family units. Structural and strategic-systemic approaches are most useful in rearranging the repetitive interactions in a family that constitute the boundaries and alliances in the social system.

In practice, there are many common elements and much eclectic usage of strategies and techniques across the various schools of family intervention. Family therapy shares many of the common treatment elements with other forms of psychotherapy. All psychosocial treatments require the development and maintenance of a good patient-therapist relationship, or therapeutic alliance. There is an assumption that most patients experience some degree of corrective emotional experience, or reliving of significant life experiences in the presence of an empathic therapist who demonstrates new ways of relating. In this context, the patient (or patients) is able to identify with the therapist and utilize the behaviors discussed and modeled. In all forms of psychotherapy, there is a certain degree of transmission of new information. The learning can be about methods of behavior, ways of thinking, or increased awareness of complex emotions. Most therapies involve some shaping of people's behavior through implicit and explicit rewards for behavior considered appropriate, and discouragement of behaviors considered harmful. This shaping can occur through advice, suggestion, persuasion, role-playing and practice.

### Standard Approach to Treatment

There is increasing evidence for the efficacy of family and marital interventions in the treatment of a broad range of relational problems and psychopathology. However, several specific questions about treatment efficacy can be asked here in reference to the previous review of relational difficulties:

1. Do the specific relational difficulties (i.e., structure, communication, affect and problem solving) respond to intervention?
2. Do the individual disorders associated with relational problems (e.g., schizophrenia, affective disorders, adolescent delinquent behavior) show improvements in illness course when the relational problems are at least part of the focus of intervention?

Research suggests that family treatment is effective with schizophrenia, affective disorders, adolescent and child acting-out difficulties and eating disorders. In terms of strategies and techniques used in the family and marital treatment formats, there is substantial evidence for the effectiveness of cognitive-behavioral and psychoeducational techniques, with few data on the other approaches. Future studies should compare the efficacy of (and estimate the relative treatment effect sizes attributable to) family therapy versus competing therapies (i.e., individual or group therapies). Future research should also determine the optimal format in which to administer family treatment (i.e., home-based versus clinic-based; individual families versus multifamily educational groups).

### Medical Comorbidity

Relational problems can cooccur with virtually any general medical condition. In most cases, it can be convincingly argued that a medical condition in one member (e.g., cancer) can promulgate relational problems between this member and other members or between two other members of the family (e.g., a husband and wife who develop marital problems stemming from disagreements as to how to treat their daughter's juvenile-onset diabetes). In some cases, the relational problems may have prognostic value for the course of the medical condition and thus may become a focus of ancillary treatment.

Numerous attempts have been made to link the family constructs listed earlier (i.e., structure, communication, expression of affect and problem solving) to the concurrent severity or future outcome of various medical conditions. For example, Koenigsberg and coworkers (1993) examined levels of spousal EE in relation to glucose control in diabetic patients. The number of critical comments made by a spouse significantly predicted glycosylated hemoglobin levels (a measure of glucose control) in the patient, the latter having been measured for the 2- to 3-month period before the interview.

There is evidence that enhanced family problem-solving may be a protective factor in the course of certain medical conditions. Using a pattern-recognition procedure, Reiss and associates (1986) examined the problem-solving interactions of families in which one member had end-stage renal disease requiring long-term hemodialysis. High family scores on "delayed closure" during a problem-solving task indicated that a family was "environmentally sensitive", open to new information in choosing solutions, and willing to introduce new solutions when new information was available. The authors found these high scores predicted fewer medical complications in the affected family member during a 9-month follow-up period.

While family-based interventions for medical conditions have not been sufficiently investigated, there is some evidence of their utility, particularly for the treatment of chronic childhood diseases) where families are faced with numerous challenges in promoting health and adjusting to often-complex medical regimens. Family-based psychoeducational interventions in the treatment of sickle cell disease have resulted in greater disease knowledge among participating families when compared with treatment as usual. In a clinical trial, behavior family systems therapy with adolescents with insulin-dependent diabetes mellitus resulted in lower diabetes-specific family conflict and improvements in the parent–child relationship when compared with treatment as usual and to an educational support group.

It is clear that chronic and progressive medical illness co-occurs with a host of relational difficulties that may in some cases bode poorly for the outcome of the medical condition. In most instances, these relational disturbances seem to arise in reaction to the medical condition and are not apparently causally related

to the disorder itself. Family or marital intervention in medical conditions may, however, reduce the tension in the household and the level of burden and psychosocial stress experienced by the caretaking family member(s), which could in turn provide a more protective environment for the ill family member.

# Individual Psychoanalytic Psychotherapy

Psychoanalytic theory provides the modern clinician with a comprehensive system for the understanding of personality development, the meaningfulness of human conflict and emotional pain, and the mutative factors within the doctor–patient relationship. Psychoanalysis is a general psychology, a developmental theory and a specific treatment. Since its inception, psychoanalytic theory has undergone numerous and substantial revisions. Its history and the movements that contributed to its evolution are described in Chapter 18. With respect to psychoanalysis as a treatment approach, its history has been punctuated by persistent attempts both to simplify psychoanalytic technique and to shorten its duration of treatment. The synonymous terms psychoanalytic psychotherapy, psychoanalytically oriented psychotherapy, psychodynamic psychotherapy and expressive psychotherapy have come to represent the most coherent of these attempts.

## What is Psychoanalytic Psychotherapy?

It is customary to define psychotherapy in a broad fashion as being composed of three distinct components: a healing agent, a sufferer and a healing or therapeutic relationship (Frank and Frank, 1991). Strupp (1986) specified that psychotherapy is the systematic use of a human relationship for therapeutic purposes of alleviating emotional distress by effecting enduring changes in a patient's thinking, feelings and behavior. The mutual engagement of the patient and the psychotherapist, both cognitively and emotionally, is the foundation for effective psychotherapeutic work.

Whereas there are many different types of psychotherapy (Figure 66.1), the core task of the psychoanalytic psychotherapist is to make contact with and comprehend, as thoroughly as possible, the patient's subjective inner world to engage in an analytical (i.e., interpretive) conversation about it (Ornstein and Kay, 1990). This core task implies that all psychoanalytic psychotherapies may be further defined in terms of three operations: accepting, understanding and explaining (Ornstein and Ornstein, 1985) (Table 66.1). First, and more specifically, the therapist must engage with the patient by accepting the subjective experience of the patient's emotional pain and conflict. This is achieved through the establishment of a therapeutic dialogue based on an empathic, nonjudgmental rapport. Secondly, within the process of listening to, and feeling with, the patient, the therapist will begin to develop an understanding of the intricacies of the patient's plight. Much of what the therapist observes may at first remain outside of the patient's conscious awareness, manifested in the form of reenactments and reliving of earlier experiences within

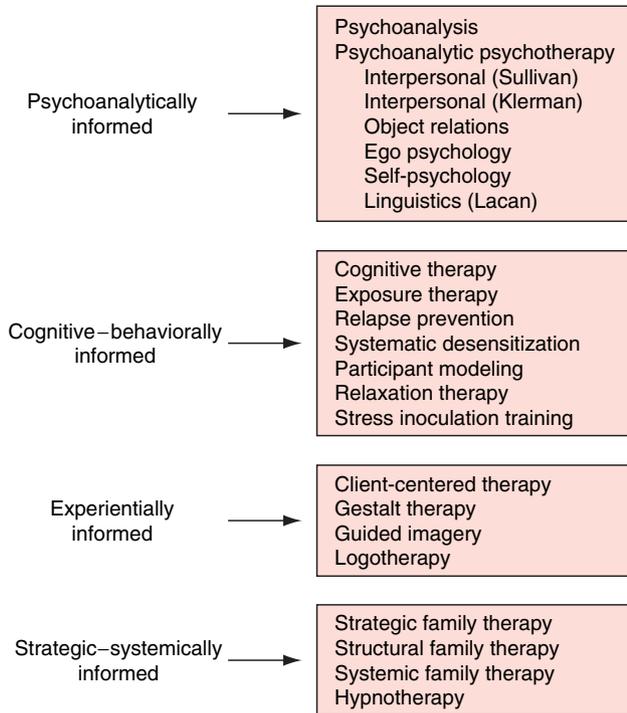

the therapy, rather than in deliberate, conscious, descriptive communication. Last, by the sharing of this beginning understanding with the patient through a simultaneously empathic and interpretive mode, both arrive at a deeper appreciation for the genesis of, and the reasons for, the patient's symptoms. The shared relationship in which understanding is gained is no less instrumental in achieving change than are the insights and modified perceptions that may result from the psychotherapeutic experience.

It is appropriate to conceptualize psychoanalytic psychotherapy as being on a continuum of expressive to supportive (Luborsky, 1984; Gabbard, 1994). Traditionally, to the degree that psychoanalytic psychotherapy has focused on the recovery of repressed psychological material, it has been called “expressive” and has been distinguished from the supportive psychotherapies which have concentrated on the shoring up of certain defense mechanisms. This implies that any given treatment might employ more or less expressive and supportive interventions, depending on what is transpiring within the psychotherapeutic process. An important skill of the psychoanalytic psychotherapist is then the ability to employ the appropriate balance of both expressive and supportive interventions as dictated by the needs of the patient. Finally, the conceptualization of an expressive–supportive continuum also facilitates the establishment of therapeutic goals, interventional plans and indications for individual psychoanalytic psychotherapy (Gabbard, 1994) (Table 66.2).

The theoretical concepts that derived from the theory reviewed in Chapter 18 constitute, more or less, the assumptions behind all psychoanalytic psychotherapy. These include, most importantly, the role of the unconscious; the centrality of transference; the characterological defense mechanisms; and the resistance to self-awareness and thereby to progress in the therapeutic setting. Of secondary importance, but nevertheless closely related to the unconscious, is the concept of psychic determinism, namely, that people behave in specific ways for specific reasons. No experience or memory, according to psychoanalysis, is ever lost but resides in the unconscious, which continues to influence current and future ways of experiencing feelings, thoughts and behaviors. Advances in cognitive neuroscience have supported the notion that many significant experiences throughout life remain outside of awareness.

## Transference and Resistance, Countertransference and Counterresistance

Transference and resistance constitute the two most distinctive features of psychoanalytic psychotherapies. Transference is

**Figure 66.1** Some types of psychotherapy.

defined as those perceptions of, and responses to, a person in the here and now that more appropriately reflect past feelings about, or responses to, important people earlier in one's life, especially parents and siblings. Psychoanalytic psychotherapy stresses the importance of transference within the treatment relationship, but it differs from psychoanalysis in that it does not, to the same degree, promote the depth and intensity of the transference.

Countertransference is variously defined as 1) the analyst's or psychotherapist's transference reactions to the patient; 2) his or her reactions to the patient's transferences; and 3) any reactions, feelings and attitudes of the analyst or therapist toward the patient, regardless of their source. These responses are manifestations of the requisite engagement by the therapist or analyst in the emotional process of treatment. Moreover, these reactions are a rich source of understanding of the patient's experience as

**Table 66.1** Essential Operations of Psychoanalytic Psychotherapy

Accepting	The therapist affirms the patient's past and present subjective experience
Understanding	The therapist appreciates both the conscious and the unconscious contributions to the patient's emotional problems
Explaining	The therapist expresses, through interpretations, his or her understanding to the patient

Adapted with permission from Ornstein PH and Ornstein A (1985) Clinical understanding and explaining: The empathic vantage point, in *Progress in Self Psychology*, Vol. 1 (ed. Goldberg A). Guilford Press, New York, pp. 43–61.

**Table 66.2** Comparative Interventions

Expressive	←Continuum→	Supportive
Confrontation		Suggestion
Clarification		Reassurance
Interpretation		Advice giving
Interpretation of transference		Praise
		Environmental intervention and manipulation

it touches the therapist affectively. Although countertransference feelings are at times uncomfortable for the therapist and a challenge to monitor and process, they are understood as a reflection of the glue of the relationship without which no real connection or significant change can occur.

Resistance is broadly defined as the conscious or, more often, unconscious force within the patient opposing the emergence of unconscious material. Resistance must be understood not as something the patient does to the therapist, but rather as the patient's attempt to protect herself or himself by avoiding the anticipated emotional discomfort that accompanies the emergence of conflictual, dangerous, or painful experiences, feelings, thoughts, memories, needs and desires. Resistance occurs through the use of unconscious mental operations called defense mechanisms, for which there is substantial research support (Vaillant, 1992; Horowitz *et al.*, 1995) (Table 66.3). The recognition, clarification and interpretation of resistance constitute important activities of the psychoanalyst and the psychoanalytic psychotherapist, both of whom must first appreciate how a patient is warding off anxiety before understanding why he or she is so compelled.

Counterresistance refers to those psychological processes within the therapist that impede therapeutic progress. These are reactions to some aspect of the treatment experience that unconsciously create anxiety in the therapist. Such occurrences become accessible first to conscious awareness and then to self-study or self-analytical work often in the form of a mistake or a symptom experienced in a therapy session. As an example, the therapist might forget the patient's appointment time or feel sleepy or bored during a therapy session. Countertransference feelings may also be manifested in dreams or fantasies about the patient. Analysis of such symptoms of countertransference not only can facilitate progress in a stalled treatment but may lead to significant growth in self-understanding by the therapist, as well as improved understanding of the patient.

### Basic Technique

The analysis of transference by the interpretation of resistance is important for the psychoanalytic psychotherapist. To promote the patient's examination of the phenomena of transference and resistance, both the analyst and the therapist are guided by principles that establish a confidential, safe and predictable environment geared toward maximizing the patient's introspection and focus on the therapeutic relationship. The patient is encouraged to free associate, that is, to notice and report as well as she or he can whatever comes into conscious awareness (Tables 66.4 and 66.5).

**Table 66.3** Some Common Defense Mechanisms\*

Repression	Relegation of threatening wishes, needs, or impulses into unawareness
Projection	Attribution of conflicted thoughts or feelings to another or to a group of people
Denial	Refusal to appreciate information about oneself or others
Identification	Patterning of oneself after another
Projective identification	Attribution of unacceptable personality characteristics onto another followed by identification with that other
Regression	A partial return to earlier levels of adaptation to avoid conflict
Splitting	Experiencing of others as being all good or all bad, i.e., idealization or devaluation
Reaction formation	Transformation of an unwanted thought or feeling into its opposite
Isolation	Divorcing a feeling from its unpleasant idea
Rationalization	Using seemingly logical explanations to make untenable feelings or thoughts more acceptable
Displacement	Redirection of unpleasant feelings or thoughts onto another object
Dissociation	Splitting off thought or feeling from its original source
Conversion	Transformation of unacceptable wishes or thoughts into body sensations
Sublimation	A mature mechanism whereby unacceptable thoughts and feelings are channeled into socially acceptable ones

\*All defense mechanisms are involuntary and unconscious.

Therapeutic neutrality and abstinence are related concepts. Both foster the unfolding and deepening of the transference, as well as the opportunity for its interpretation. The psychoanalytic psychotherapist assumes a neutral position *vis-à-vis* the patient's psychological material by neither advocating for the patient's wishes and needs nor prohibiting against these. The patient is encouraged in the therapeutic relationship to develop the capacity for self-observation. Neutrality does not mean nonresponsiveness; it is nonjudgmental nondirectiveness.

Abstinence refers to the position assumed by the psychoanalytic psychotherapist of recognizing and accepting the patient's wishes and emotional needs, particularly as they emanate from transference distortions, while abstaining from direct gratification of those needs through action. Abstinence is a principle that guards against the therapist's gratification at the patient's expense. For example, as the treatment experience deepens into a more consolidated transference neurosis, there may be a strong tendency by the patient to experience the therapist as **the** important person in the patient's life around whom the characteristic conflictual issues are manifested. By maintaining a neutral and abstinent position with respect to the patient's needs and wishes, the psychotherapist creates a safe atmosphere for the experiencing

**Table 66.4** Characteristics of Psychoanalysis

Goals	Personality reorganization Resolution of childhood conflicts
Patient's characteristics	Psychoneuroses and mild to moderate personality disorders Psychological mindedness Introspectiveness Can experience and learn from intense affects or conflicts without acting them out Reasonable object relationships High motivation Can tolerate frustration and therapeutic regression
Techniques	Use of couch Four or five sessions weekly Free association Neutrality Abstinence Analysis of defenses Analysis of transference Dream interpretation Genetic reconstruction Less frequent use of medication
Length of treatment	3–6 yr or longer

**Table 66.5** Characteristics of Psychoanalytic Psychotherapy

Goals	Partial personality reorganization Appreciation of conflicts and related defense mechanisms Partial reconstruction of the past Symptom relief Improved interpersonal relationships
Patient's characteristics	Includes all criteria for psychoanalysis Moderate to severe personality disorders (e.g., borderline) Some affective disorders with and without medication (e.g., major depression, dysthymia)
Techniques	Active therapeutic stance Face to face (sitting up) One to three sessions weekly Limited free association Active focus on current life issues Limited transference analysis Some supportive techniques Liberal use of medication Clarification and interpretation
Length of treatment	Months to years (may or may not be shorter than psychoanalysis)

and expression of even highly charged affects, the safety required for the patient's motivation for continued therapeutic work. The position held by the psychiatrist is neither sterile nor overstimulating and promotes the establishment of a meaningful therapeutic relationship.

The rule of free association dictates that the patient should verbalize to the best of her or his ability whatever comes into awareness, including thoughts, feelings, physical sensations, memories, dreams, fears, wishes, fantasies and perceptions of the analyst. Whereas at first glance this requirement appears to be unscientific, in fact, the psychiatrist and patient quickly come to appreciate that no thought or feeling is random or irrelevant but rather that all mental content is relevant to the patient's emotional problems. Indeed, much productive therapeutic work is focused on those instances when the patient is not able to speak about what is on his or her mind.

Many psychoanalytic psychotherapists also use the technique of dream interpretation, although recently there may be less emphasis on this. Freud placed great emphasis on the interpretation of dreams because he discovered that such a technique provided insights into the working of the unconscious. In a similar fashion, slips of the tongue, jokes, puns and some types of forgetfulness are attended to carefully by the therapist because they are nonsleep activities that also provide insight into the patient's unconscious mental processes. Good technique does not necessarily include pointing out to the patient these events each time they occur, for they may often be a source of intense embarrassment. Rather, the slips are noted as helpful data in assessing the patient's inner thoughts.

All of these techniques are embedded in a unique manner of listening to the patient's verbalizations within the context of the treatment situation. In particular, two related but specific components initially attributed to the listening process are worthy of note. First, the concept of the evenly hovering or evenly suspended attention implies that listening to the patient requires of the therapist that he or she be nonjudgmental and give equal attention to every topic and detail that the patient provides. It also embraces the notion that the effective therapist is one who can remain open to her or his own thoughts and feelings as they are evoked while listening to the patient. Such internal responses often supply important insights into the patient's concerns. Secondly, empathic listening is of equal importance to both parties. Empathy permits the patient to feel understood, as well as provides the therapist with a method to achieve vicarious introspection. Indeed, one of the major contributions of self-psychology has been the identification of empathic listening and interpretation (the immersion by the therapist into the subjectivity of the patient's experience) as basic to the methodology of psychoanalysis and psychoanalytic psychotherapy (Kohut, 1978, 1971). Interferences to successful empathic listening are often the product of countertransference reactions, which should be suspected whenever, for example, the therapist experiences irritation, strong erotic feelings, or inattention during a treatment session.

### How Does Psychoanalytic Psychotherapy Work?

Psychoanalytic psychotherapy helps by permitting the patient to become increasingly conscious of troublesome feelings, conflicts and wishes that heretofore had remained out of awareness and that produced unhappiness by promoting repetitive self-defeating behaviors, that is to gain "insight".

Whereas insight has always been valued as a goal, insight by itself is insufficient. The process whereby insight is acquired is a lengthy and arduous one that is inextricably linked with the recall of painful affects, memories and traumatic experiences. For treatment to be effective, there must be both cognitive and affective experiences for the patient. Neither a purely intellectual nor a purely cathartic experience is likely to result in relief or behavioral change. The support provided by the treatment relationship, which includes commitment, respect, reliability, honesty and care, is a powerful factor in the curative process. It is this atmosphere that makes bearable the emotional pain that accompanies the healing of the wounds first experienced in isolation, so often inflicted by the first objects of the patient's love, need and trust. All of these considerations are central to psychoanalytic psychotherapy as well.

The concept of "working through" is helpful in appreciating the often lengthy and complex psychotherapeutic processes. Working through is that stage or aspect of treatment characterized by repeated identification of reenactment and reliving of earlier experiences through confrontation, clarification, and interpretation of resistance and transference that ultimately promotes the patient's self-awareness. In effect, the working through process frees the patient from the position of being at the mercy of unconscious conflicts and fears that have compromised interpersonal relationships and achievement. This is accomplished not only through the analysis of the transference but also of current interpersonal relationships outside of the psychotherapy. Ultimately, a thorough understanding of the transference and of current relationships can permit the patient to appreciate their relationship to important early experiences and ultimately to ameliorate the influence of the past on the present.

### Therapeutic Alliance

A great deal of research in the outcome of psychoanalytic psychotherapy has focused on the importance of the therapeutic alliance (Docherty, 1985). Increasing appreciation for the role of supportive factors, such as the rapport between the patient and therapist that constitutes the therapeutic relationship, has balanced the earlier and more narrowly defined position that attributed therapeutic success exclusively to insight resulting from specific interpretive activity. The clinical consequences of this appreciation of the helpfulness of nonspecific factors have been the psychoanalytic psychotherapist's paying much greater attention to the initial phases of engaging the patient in psychotherapy and a greater respect for those positive and negative factors that the therapist brings to the working relationship. Currently, approaches to psychoanalytic psychotherapy hold that the psychiatrist's personality and interventional technique have equal influence on the therapeutic process. In essence, the contemporary view is more dyadic, and places greater importance on the contributions of the therapist (both the conscious and the unconscious), as well as of the patient with respect to progress and impasse in the psychotherapeutic process.

Contemporary psychoanalytic psychotherapists still emphasize elucidation of the unconscious, especially within the transference, and still use interpretation as a primary clinical intervention, but recognizes more fully the important role of the mutual emotional engagement of therapist and patient and the curative role of this relationship in addition to other supportive factors. They adhere to a much broader perspective on human development and psychiatric disorders. Psychological problems

**Table 66.6** Indications for Psychoanalysis

Psychoanalysis is the treatment of choice for repetitive, longstanding, maladaptive problems involving personality or character and chronic, repetitive behavioral, affective, or mental disturbances or symptoms that do not respond to cheaper or quicker forms of treatment. In general, it is used for all the character disorders or personality disorders, except antisocial and schizotypal disorders, as well as numerous symptom disorders.

The chronic symptoms must reflect both:

1. Intrapsychic conflict
2. Developmental arrest or inhibition

As well, the psychiatrist must expect that:

3. The patient's symptoms are likely to continue unless analysis is undertaken
4. Treatments that are less intensive than analysis would likely result in excessive personal or social cost for the patient or just provide temporary relief of acute symptoms related to a current stress, without dealing with underlying issues, hence predisposing the patient to difficulties in future.

Finally, the patient must be able to use psychoanalysis.

In general, this rules out the psychotic disorders and a number, but not all, of the borderline disorders.

Reprinted with permission from the American Psychiatric Association (1985) *Peer Review Manual*, 3rd edn. APA, Washington DC.

can result not only from early intrapsychic conflict but also from developmental deficits or failures as well as from psychological trauma (Table 66.6).

### How Does Psychoanalytic Psychotherapy Differ from Psychoanalysis?

The answer to this question has occupied many researchers and psychiatrists throughout the last 50 years. Efforts have been made continually not only to elucidate the differences between the two treatments but, more important, to define the underlying principles of psychoanalytic psychotherapy. Whereas some prefer definitions of psychoanalysis and psychotherapy as distinct separate entities, it is more useful to many psychiatrists to conceptualize psychoanalysis and psychoanalytic psychotherapy as residing on a therapeutic continuum. As discussed, there is much in the conduct of psychoanalytic psychotherapy that has been borrowed from psychoanalysis. Free association, clarification and interpretation in psychoanalytic psychotherapy are such examples. The centrality of transference is another, although early psychiatrists and researchers advocated that transferences were to be recognized and acknowledged in psychoanalytic psychotherapy and “managed” rather than interpreted so that patients were not subject to the intense therapeutic regressions characteristic of psychoanalysis. Today, such a distinction regarding the approach to transference in psychoanalytic psychotherapy is less rigid.

On the other hand, certain supportive and more directive techniques, such as greater activity of the therapist through focusing the patient on specific current problems and relationships, reassuring and affirming the patient, and the giving of advice, are used much more in psychoanalytic psychotherapy than in

**Table 66.7** Phases of Psychoanalytic Psychotherapy

Beginning phase	Patient is educated about roles of both parties Therapeutic alliance is formed → symptomatic relief from nonspecific relationship factors
Middle phase	Usually the longest phase of therapy Reexperiencing of patient's conflicts within dyad Interpretation of conscious and previously unconscious material → new insightfulness about current, past and sometimes previously forgotten experiences
Termination phase	Begins with agreed-on end of treatment Anxiety evoked by impending loss of therapist Initial symptoms may recur Integration and consolidation of therapeutic gains Therapist is viewed with less distortion

psychoanalysis. Therefore, the adherence to the therapist's neutrality is less strict, and as a result, there is often but not always less frustration for the patient in psychoanalytic psychotherapy. The length of treatment may not distinguish the two approaches, but the frequency of sessions (four or five per week) and the use of the couch, however, are characteristic of psychoanalysis (see Table 66.7).

Overall, it is fair to say that psychoanalytic psychotherapy

- Places greater emphasis on the here and now in terms of the patient's current interpersonal relationships and experiences outside of the therapy; whereas in psychoanalysis, there is greater emphasis on the experiences within the analysis and the relationship between analyst and analysand;
- Incorporates, more than does psychoanalysis, various other techniques from other dynamic and behavioral psychotherapies;
- Emphasizes the usefulness of focusing on current (dynamic) problems and less on genetic issues; and
- Establishes more modest goals of treatment.

The last point is particularly important in that it facilitated the development of brief dynamic psychotherapies which address focal problems generally in up to 20 sessions.

### Tasks of the Psychoanalytic Psychotherapist

What are the challenges of the psychotherapist in performing psychoanalytic psychotherapy? First, the therapist must ensure that the patient can feel both emotionally and physically safe within the therapeutic relationship. This is accomplished by acknowledging the goals of the treatment and defining the role of the therapist and through establishing professional boundaries. Boundaries refer to those constant and highly predictable components of the treatment situation that constitute the framework of the working relationship. For example, agreeing to meet with

the patient for a specified amount of time, in a professional office, and for an established fee are some of the elements of the professional framework.

Boundaries also have ethical dimensions best summarized as the absolute adherence by the therapist to the rule of never taking advantage of the patient: through sexual behavior; for personal, financial, or emotional gain; or by exploiting the patient's need and love for the therapist in any fashion (e.g., by using the therapy sessions to discuss the therapist's own problems). The concepts of neutrality, abstinence and confidentiality further define the role of the therapist. A critical task of the psychoanalytic psychotherapist is to detect when a breach in either role or boundary has occurred and to restore the patient's security through clarifying and interpreting the meaningfulness of such a breach.

The explication of a boundary violation is but one specific example of the technique of interpretation. Successful interpretation is based on a number of prerequisite skills. These include the capacity to empathize with the patient's plight, the ability to recognize the meaning of one's own fantasies about, and responses to, a patient (countertransference), the ability to maintain the patient's verbal flow through the use of open-ended or focused questions, and the capacity to tolerate a relatively high level of ambiguity within the therapeutic relationship. One important professional characteristic of the skilled psychotherapist is patience. Psychotherapy is often arduous, and the capacity to "stay in the chair" with the patient is critical.

The identification of repeated patterns of behavior both within the therapy and in the patient's outside life is a fundamental technique in making sense of the patient's emotional life. This, of course, involves the appreciation of transference and the art of knowing how and when to share this recognition with the patient. Interpretation relies on both appropriate timing and dosage. That is, the psychoanalytic psychotherapist must appreciate when the patient can best integrate the therapist's observations and must respect the patient's defenses, taking care not to overwhelm the patient by insisting that she or he confront more than is tolerable.

Psychoanalytic psychotherapy requires the successful engagement of the patient and the establishment of a therapeutic or working alliance. The alliance can be threatened by a number of phenomena including, but not limited to, the following:

- The therapist's countertransferences or other limitations in his or her capacity to tolerate the emotions stirred by the patient, resulting in empathic failures and mistakes.
- The emergence of intense feelings and needs within the patient, for example, when an accurate well-timed intervention evokes feelings in relation to the therapist of appreciation and love accompanied by feelings of vulnerability, erotic desire, or inferiority which the patient wants to flee.
- The patient's being reminded of the existence of others in the therapist's life, such as other patients or family (e.g., during interruptions due to the therapist's vacations), triggering painful and embarrassing feelings of jealousy and possessiveness.

The therapist's ability to appreciate and respectfully to acknowledge to the patient the impact of these temporal events is critical to the progress of treatment.

All of the psychotherapist's skills and techniques must be embedded in a consistent and coherent theoretical viewpoint that provides the therapist with a framework to understand the etiology and meaning of a patient's symptoms and dysfunctional

behaviors both in the past and in the present in each of the phases of psychotherapy (Table 66.7).

This includes an organized method for understanding the therapist's unconscious and conscious responses to the patient as well. It requires that the therapist listen to the patient's communications in a manner that is markedly different from other forms of social discourse. So-called "process communication" speaks to the therapist on multiple levels and through displacement, through passing remarks and jokes, through shifts in topics, and through metaphors and symbols. To assist in understanding complicated process communication, psychiatrists often ask themselves, Why is the patient telling me this now? What might the patient be trying to say about his or her uncomfortable feelings? Is something being said about the therapeutic relationship?

The objective of this type of treatment is to improve the patient's quality of life largely through enhancing interpersonal relationships by promoting greater insight into perceptual distortion and intrapsychic and interpersonal conflict. Psychoanalytic psychotherapy accomplishes this objective by focusing on the patient's current predicaments as manifested in both life activities and relationship with the therapist. It is at times less concerned with the analysis of transference and the complete discovery of the underlying genetic precursors of the patient's current psychological problems, depending on the specific clinical situation.

## Indications for Psychoanalytic Psychotherapy

Although current psychotherapy research attempts to ascertain which specific disorder in which type of patient is most effectively treated by what specific psychotherapeutic approach, studies have not as yet provided the answers to these questions. Conditions and disorders for which psychoanalytic psychotherapy appears to be indicated include personality disorders (except antisocial personality disorder); post traumatic stress disorders; symptom neuroses or neurotic conflicts; adjustment disorders; paraphilias; and **some** mood, anxiety, somatoform, sexual and gender identity, eating, substance abuse and dissociative disorders (Table 66.8). In addition, psychoanalytic psychotherapy is often employed in treating patients who present with relational problems and those

\*Not indicated for all disorders in these categories.

problems that are the result of abuse or neglect. It may also be useful to patients with certain impulse disorders and to patients whose psychological problems are affecting or are the result of their primary medical illnesses. In short, psychoanalytic psychotherapy, often in combination with medication, is an appropriate intervention in a broad range of disorders, conditions and psychiatric illnesses (Karasu, 1989; Gabbard, 1995).

The characteristics of the patient assumed to be correlated with positive outcome in psychoanalytic psychotherapy include introspectiveness (psychological mindedness); ability to establish and maintain human relationships, even “unhealthy” ones; vocational stability; high degree of motivation; absence of formal thought disorder; and psychological resources sufficient to withstand the possible frustration during the treatment and its characteristic therapeutic regression and accompanying strong affects. Patients with more severe disturbances may be best approached using supportive psychoanalytic psychotherapy discussed below.

### Contraindications to Psychoanalytic Psychotherapy

For the most part, contraindications to any psychoanalytic psychotherapy that is heavily weighted toward the expressive end of the therapeutic continuum are as follows (Table 66.9):

- Poor impulse control
- Significant cognitive deficits
- Severely dysfunctional interpersonal relationships
- Little ability to tolerate frustration, anxiety and depression
- Significant lack of introspective capacity

### Supportive Psychoanalytic Psychotherapy

Although only recently systematized, this form of psychotherapy provides psychological stabilization to the patient through the vehicle of a consistent and predictable caring therapist–patient relationship (Werman, 1984; Rockland, 1989; Novalis *et al.*, 1993; Hellerstein *et al.*, 1994; Misch, 2000). Supportive psychotherapy attempts to shore up the patient’s psychological defenses and enhance his or her ability to cope with the trials of illness or psychological deficits and the challenges they impose on the patient’s daily activities (Table 66.10). Not unexpectedly, it also strives to prevent decompensation and regression. As such, psychoanalytic supportive psychotherapy employs a psychodynamic understanding of the patient’s difficulties but does not emphasize

**Table 66.9** Contraindications to Expressive Psychoanalytic Psychotherapy

Major ego deficits  
 Poor motivation  
 Significant cognitive deficits  
 Inability to obtain symptom relief through understanding  
 Inability to verbalize affects  
 Lack of psychological mindedness  
 Minimal impulse control  
 No social support network  
 Low frustration tolerance  
 Inability to form therapeutic alliance

**Table 66.10** Characteristics of Supportive Psychoanalytic Psychotherapy

Goals	Maintain current level of psychological functioning Restore premorbid adaptation, if possible Enhance coping mechanisms Strengthen defense mechanisms unless they are maladaptive Support reality testing Relieve symptoms Decrease mental distress
Patient’s characteristics	Severe character disorders Chronic ego deficits Thought disorders Limited psychological mindedness Limited motivation Poor interpersonal relationships Poor impulse control Low frustration tolerance Regression proneness Some potential for therapeutic alliance Extreme passivity Inability to verbalize affects Those in crisis situations (catastrophic loss, acute psychic trauma, medical illness) Psychologically healthy Effective social network High premorbid adaptation Flexible defenses
Techniques	Predictability and consistency of therapist Conversational style Confrontation, clarification, education Problem-solving focus Provide encouragement, advice, praise, reassurance Environmental intervention Strengthen reality testing Shore up defense mechanisms Discourage regression Infrequent genetic reconstruction Infrequent transference analysis Less therapeutic neutrality Frequent use of medication
Length of treatment	Usually once weekly or less Duration of sessions flexible Varies from brief therapy for those reactive disorders in individuals who do not need or are not motivated for further help to lifelong treatment of patients with some chronic disorders

interpretation of the patient's internal world. Rather, supportive psychotherapy focuses on assisting the patient to address interpersonal and environmental challenges in the here and now.

Despite its noninterpretive emphasis, supportive psychotherapy can have a substantial impact in the lives of patients with significant ego deficits and those with major mental illness. These patients may include those with high levels of aggressivity, poor impulse control, overreliance on action rather than verbal expression of emotions, compromised reality testing and limited psychological mindedness. It is also highly effective with higher functioning patients who have experienced recent psychic trauma (e.g., through natural disasters, illness, physical or sexual assault, and unexpected devastating losses).

Supportive psychotherapy techniques consist predominantly of empathically listening to the patient's feelings and experiences; giving advice and reassurance; offering suggestion and helpful coping techniques; and for some patients with severe and chronic maladaptations, gently revealing their misperceptions and how they interfere in daily functioning. Although often unexpressed, the patient's identification with the therapist's values, ideals and approaches to problems is exceptionally therapeutic. Environmental interventions through helping agencies and the patient's significant others are also effective supportive techniques. Although nonspecific to some degree, these interventions are nevertheless based on a comprehensive understanding of the patient's strengths and weaknesses, and are frequently instrumental in curbing self-destructive and self-defeating behaviors. Transference is appreciated but the therapist rarely interprets it in supportive psychoanalytic psychotherapy, choosing rather to foster a positive working relationship through other means (Pinsker *et al.*, 1992).

Although frequently disparaged, effective supportive psychoanalytic psychotherapy is often more challenging to provide than some forms of expressive psychotherapy. Appreciating the psychological forces that are impinging on a marginally functioning patient whose communicative abilities are suboptimal requires a sophisticated clinical approach. Moreover, in supportive psychotherapy, the therapist must assist the patient to modulate intense affective states that are often frightening to the patient and to those in his or her environment. Needless to say, such affects can be directed at the therapist as well. The establishment with the patient of the requisite safe and caring relationship, which may be frequently disrupted by both internal and external forces, is often a significant clinical challenge.

Supportive psychotherapy can produce significant and lasting behavioral change through the reinforcement of health-promoting behaviors; increased capacity for self-reflection; anxiety reduction; and development of new defenses such as intellectualization that enable the patient to acquire a cognitive, anxiety-reducing conceptualization of her or his difficulties.

## Gender Issues in Psychotherapy

Does the gender of the psychotherapist have any effect on the psychotherapeutic relationship and treatment outcome? Are certain psychological problems best treated by therapists whose gender is different from that of the patient? Do different phenomena appear in the treatment of those patients whose therapists are of the same gender? Is the duration of treatment affected by the therapist's gender? Does gender have any influence on the choice of therapist by a patient? These are important questions that have been debated in psychotherapy and psychoanalytic literature for more than 50 years.

Although the literature regarding the advantages and disadvantages of gender matching of patients and therapists consists largely of anecdotal and negative reports (Zlotnick *et al.*, 1998), it is nevertheless evocative. A number of common themes have emerged, including that

- The gender of the therapist may be more critical in supportive treatments that rely on identification with the therapist (Cavennar and Werman, 1983).
- The therapist's gender may be less important in psychoanalysis than in face-to-face psychoanalytic psychotherapies because, in the latter, the transference can be less intense (Mogul, 1982).
- Beginning women therapists have less difficulty with empathy but more difficulty with authority issues than do their male counterparts (Kaplan, 1979).

Although there is only one controlled study and it showed no difference regarding the influence of the therapist's gender on the therapeutic process (Zlotnick *et al.*, 1996), there is much to consider about the influence of actual gender and gender-related beliefs of both patient and therapist on the emergence of transference and countertransference. However, the best psychoanalytic psychotherapies will include ample opportunities for the working through of the patient's issues related to important figures of both genders.

## Ethnocultural Issues in Psychotherapy

Culture refers to meanings, values and behavioral norms that are learned and transmitted in the dominant society and within its social groups. Culture powerfully influences cognitions, feeling and "self" concept, as well as the diagnostic process and treatment decisions. Ethnicity, a related concept, refers to social groupings which distinguish themselves from other groups based on ideas of shared descent and aspirations, as well as to behavioral norms and forms of personal identity associated with such groups (Mezzich *et al.*, 1993).

Given the increasing multiculturalism of many cities in the USA, how should the psychoanalytic psychotherapist treat patients from cultures other than his or her own? Whereas therapists are obligated to be culturally informed, Foulks and colleagues (1995) have argued against the promotion of culturally specific psychotherapies. Although acknowledging that some cross-cultural psychiatrists believe expressive-supportive psychotherapy to be an ethnotherapy appropriate only to the citizens of the Western world, they emphasized the overwhelming problems in establishing separate therapies and clinics devoted to patients from a multitude of specific cultures. Also, they stated that the principles of psychotherapy elucidated in this chapter – accepting, understanding and explaining – are appropriate for the culturally diverse patient.

## Is Psychoanalytic Psychotherapy Effective?

The short answer to this question is yes. Meta-analytical studies of psychotherapy have demonstrated unequivocally that psychotherapy is effective (Luborsky *et al.*, 1975; Smith *et al.*, 1980; Lambert *et al.*, 1986). The study by Smith and coworkers (1980), for example, demonstrated that 80% of those patients treated in psychotherapy fared better on outcome measures than those who received no treatment. Psychological growth achieved through psychotherapy is also enduring (Husby, 1985).

Cost-offset studies have repeatedly demonstrated the helpfulness of psychotherapy in reducing general health care services by as much as one-third (Mumford *et al.*, 1984; Krupnick and Pincus, 1992; Olfson and Pincus, 1994). These include reduction in hospital stays for surgical and cardiac patients (Mumford *et al.*, 1982) and decreased treatment costs for those with respiratory illnesses, diabetes and hypertension (Schlesinger *et al.*, 1983). Brief psychotherapy has also been shown to be effective in general medical clinics, where those patients with significant medical and psychiatric problems improve substantially more than those treated by primary care physicians alone (Meyer *et al.*, 1981).

Luborsky and coworkers (1993) have demonstrated that psychoanalytic psychotherapy is as effective as cognitive, behavioral, experiential, and group therapies and hypnotherapy. For this meta-analysis, rigorous inclusion criteria were established including, but not limited to, adequate sample size with random assignment, suitable length and frequency of sessions, sound outcome measures, adherence by therapists to treatment manuals, and comparable skill levels among therapists. A number of other studies have demonstrated positive benefits in panic disorder depression, personality disorder, drug abuse, eating disorders and others (Willborg and Dahl, 1996; Bateman and Fonagy, 2001.)

The important research questions with respect to brief psychoanalytic psychotherapy have been summarized by Barber (1994) and are relevant to all psychoanalytic psychotherapies (Table 66.11).

### Towards a Neurobiology of Psychotherapy

Exciting new research in psychiatry, brain imaging, cognitive neuroscience, genetics, and molecular biology has provided striking insights into how psychotherapy actually changes both brain structure and function (Liggan and Kay, 1999; Gabbard, 2000; Lehrer and Kay, 2002). Learning and memory are associated with alterations in central nervous system (CNS) neuronal plasticity including increased synaptic strength and number of synapses. Neurogenesis, or the creation of new brain cells, occurs daily in the human hippocampus (Eriksson *et al.*, 1998),

the central location for the formation of new explicit memories. Not only does memory consolidation lead to persistent modifications in synaptic plasticity, but psychotherapy, a form of learning, also produces changes in the permanent storage of information acquired throughout an individual's life and provides new resources to address important psychobiological relationships between affect, attachment and memory which is of fundamental importance in psychiatric disorders. Rapidly accruing knowledge about the different types of memory and the role of the amygdala now support the influence of memories that reside outside of the awareness of our patients (LeDoux, 1996). Implicit memories formed in infancy and childhood persistently affect the manner in which patients experience themselves and their worlds as manifested, for example, in transference reactions within and outside of the therapeutic relationship.

The study of psychotherapy from a neurobiological perspective is likely to provide greater understanding of how words in the context of therapeutic relationships can heal. It may be that there are similar mechanisms and anatomical regions that are involved in the successful treatment of psychiatric illness with psychotherapy and pharmacotherapy as monotherapies, as well as in the combined treatment situation (Sacheim, 2001). It is also likely to yield a greater understanding of pathogenesis and delineate helpful interventions to decrease genetic vulnerability to emotional disorders.

### Conclusion

At this time, the theory and technique of psychoanalytic psychotherapy provide the most comprehensive orientation to the continuum of expressive–supportive psychotherapy. Psychoanalytic psychotherapy is a potent intervention and, as such, holds great promise when it is used in a sophisticated fashion for appropriate patients with appropriate psychiatric problems. Like medication, psychoanalytic psychotherapy has specific indications, contraindications and, undoubtedly, potentially negative effects. As an effective therapeutic intervention, it requires that the therapist be highly skilled in assessing the inner experience of those who come for help. It also requires extensive training and education in techniques of this treatment modality. As well, the therapist must acquire significant self-knowledge, sophistication and dedication in working so intensively with human pain.

Human beings live in a social world in which their ability to gain self-esteem and self-definition significantly follows from their success in personal relationships. Psychotherapy in a group setting provides a social arena in which members can learn about their assets and deficits through interactions with peers (fellow members) and authority (the therapist). Members also have opportunities to experiment with newly learned behaviors in the protected atmosphere of the group in preparation for using them in their external world.

A broad spectrum of theoretical approaches informs therapists about which aspects of group behaviors they should attend to. Some focus on individuals as seen through the psychoanalytic lens of transference and resistance; others stress interpersonal transactions in which distortions arising from childhood are played out within the group and are subject to feedback, while others focus on properties of the group as a whole, which emphasize group dynamics and systems theories as the central organizing concepts. Learning principles are contained in almost all of these orientations and are the central emphases in cognitive-behavioral approaches. Successful integration of these approaches has not been accomplished. Therapists may maintain a central theoretical orientation and pragmatically adapt elements from other orientations to address particular problems as they emerge in the treatment process.

The concepts in this chapter primarily address working with adults in an outpatient setting in the psychodynamic tradition. Individuals' internal psychopathologies emerge in the microcosm of the group. They are expressed in interpersonal transactions, which are influenced by the dynamics of the therapeutic system.

### Group Development and Group Dynamics

The basic science informing group treatment is group development and dynamics. Understanding of these concepts provides a foundation for the therapist's integration of individual, interpersonal and intrapsychic dynamics with those of group membership (Table 67.1).

### Group Development

The seminal work of Bennis and Shepard (1956) produced a spate of studies demonstrating that groups have a natural developmental sequence. Groups must accomplish certain tasks as they move from a collection of individuals to a functioning and working organization. In this discussion, the focus is on developmental sequences in groups conducted along psychodynamic principles.

**Table 67.1 Stages of Group Development**

Stage	Theme	Dynamics
Orientation (forming)	Engagement	Dependency Safety Norms
Differentiation (storming)	Power	Testing Competition Autonomy
Maturation (performing)	Work	Affect tolerance Leadership Self-reflection
Termination (departing)	Separation	Loss Hope

### Initial (Engagement, Orientation) Phase

Individuals entering a psychotherapy group are faced with two major tasks: they have to decide how they will use the treatment to accomplish their goals and simultaneously they have to determine the limits of emotional safety. Members turn to the therapist in hope of gaining information on how to proceed. They anticipate that the leader, a person they already know and who fulfills a traditional role, will provide guidance and smooth the way in getting to know the strangers in the room. In the main, these "dependency" strivings are frustrated. Members tentatively reveal themselves to others. Gradually, unwritten and primarily unconscious rules (norms) develop, which help contain anxiety and set standards for acceptable behavior. Therapists help shape behavior by providing information on how to proceed and by clarifying (interpreting) underlying anxieties. Common themes and concerns may be highlighted, which serve to diminish members' sense of isolation and enhance cohesion.

### Reactive (Power, Differentiation) Phase

Many groups move into this phase by rebelliously rejecting their leader. This may be followed by a relatively short-lived sense of well-being and harmony. However, norms are often experienced as restrictive and members may begin to feel as though they are controlled by the group (group tyranny). In response, they assert individuality and demonstrate their own power. Struggles between members emerge, and angry exchanges are not uncommon. Usual norms against expression of intense intragroup affects are tested and modified in accordance with members' personal capacities. Some members may threaten to quit, or they remain silent during this phase as they grapple with their ability to tolerate

conflict. The therapist assists in helping members understand and tolerate responses to intense feelings and differences.

### Mature (Working) Phase

In this phase, groups have developed considerable cohesion. Members can tolerate differences and they can contain anxiety and allow conflicts to emerge without having to interrupt exchanges. They have learned to provide and receive feedback from others without undue defensiveness. A considerable portion of the group transactions is focused on the here and now, and exchanges are appreciated as containing both reactions to the present and vestiges from prior relationships (transferences). Members attempt to understand one another at both surface and in-depth levels. The therapist no longer is the sole expert, and members are valued for their emotional and cognitive uniqueness. Therapists continue to help patients understand their in-group reactions and assist in broadening their perspectives to include the sources (genetic) of their feelings and their manifestations in their outside world.

### Termination Phase

Ending treatment is the final stage. It is filled with mixed feelings: those of success and looking to the future and those surrounding separations (Schermer and Klein, 1996). Often there is a regression as anxieties over departing are addressed. This provides an additional opportunity to explore the problems that emerge. Members respond with pleasure at seeing someone “graduate”, but they also experience loss of a valued contributor to the work and envy over a colleague’s achievement. A successful termination also offers hope for those who remain. The therapist monitors the dynamic forces and enables members to say their farewells within a context of therapeutic accomplishments and continuing psychological work. In the process, remaining members experience and integrate their responses to the departure.

### Summary

Groups do not uniformly traverse these developmental phases, and they undergo shifts to earlier stages under stress, such as vacations or change in membership. A considerable amount of therapeutic work takes place at each developmental level. For instance, a group of individuals experiencing problems with basic trust may spend a good deal of time in an initial stage, where these feelings may be explored. Patients who need to address competitive feelings may alternate between the reactive and the working phases. Understanding group development provides a framework for therapists to appreciate the forces that have an impact on members’ feelings and behavior.

### Group Dynamics

Group dynamics refer to norms and cultures that are unique to each group. They are influenced by group size, members’ race, gender, age and the social environment. Group dynamics are also a product of members’ personalities, the leader’s functioning and their subsequent interactions. The dynamics emerge as members go about their tasks of determining how they will achieve their goals and maintain personal safety. Norms are rules defining what is acceptable, that is, how people express themselves, what one can do or say. Illustrative of norms are the pressures of using “politically correct” (PC) expressions. There are sanctions, both conscious and unconscious, against violating norms. In part, norms are initially defined in the therapeutic agreement

(discussed later) as presented by the therapist, but they are modified as a result of group development.

The concept of role is intimately linked with group therapy. Roles are essential functions that help the group achieve its goals and support members’ emotional tasks. Four general roles can be defined for groups (MacKenzie, 1997): structural, sociable, divergent and cautionary roles. The structural or leadership role helps the group address its work. The therapist is the primary occupant of this role, but members also function in keeping the group on task, organizing the experience and maintaining a perspective of the group process. The social or emotional role helps contain feelings and assists in managing social relationships among the members and with the leader. Some individuals relieve group tensions by changing the topic, making a joke, smoothing ruffled feelings, or by encouraging others to express their less acceptable and/or painful feelings. The divergent role is filled by persons who seem oppositional, who “don’t go along with the crowd”, or seem to fight authority. They are likely to become a container for unacceptable thoughts or emotions. Such individuals are vulnerable to becoming scapegoated, a process in which inadmissible feelings are seen (or placed) in one person and thereby kept out of awareness in the others. The cautionary or silent role may be played by a member who seldom speaks or keeps his thoughts and feelings hidden. These persons are often a threat to the others because they keep secrets or avoid painful affects. When a group is ready to take action, members often attempt to “recruit” the silent person into their ranks; this process is most frequently seen when there is preparation for fight-or-flight (see discussion of Bion below). Roles may be filled by one or several persons. They are essential for group functioning, and, theoretically, each member has the psychological potential to fill varying roles.

### Theories of Group Therapy

The theoretical spectrum informing the practice of group therapy is broad. Within psychodynamics, some emphasize drive theory, object relations, or self-psychology. Other therapists favor interpersonal theory and cognitive-behavioral approaches. Transactional analysis, originating from the work of Berne (1966), and Gestalt therapy (Perls *et al.*, 1951) emphasize interpersonal transactions arising from more traditional psychodynamic theory.

Group theoreticians are generally categorized along a continuum of group as a whole, interpersonal and intrapsychic. Moreover, therapists using object relations, self-psychology or psychodynamic theories integrate their theoretical preferences along this continuum (Kibel, 1992; Harwood and Pines, 1998; Rutan and Stone, 2001). There are few purists and varying degrees of integration is the norm (Table 67.2).

A common thread in many of these theories is that individuals in their interaction and discourse within the group will exhibit their difficulties in relationships, which in turn provides a window into their internal world. In short, the group becomes a microcosm of their external world (Slater, 1966).

### Group-as-a-Whole Approaches

These theories emphasize whole-group processes as the primary therapeutic vehicle. They subscribe to notions that members are influenced by the group dynamics and that one or more persons may speak for the entire group, including those who are silent.

**Table 67.2 Group Theories**

Theory	Authors	Key Phrases
Group-as-a-whole	Bion	Basic assumption, Work group
	Whitaker and Lieberman	Group focal conflict
	Ezriel	Required, Avoided, Calamitous relationship
	Foulkes	Group analysis, Group matrix, Figure/ ground
Interpersonal	Horwitz	Integrative, Inductive
	Yalom	Cohesion, Therapeutic factors, Feedback
Intrapsychic	Gustafson and Cooper	Unconscious planning
	Slavson	Limited regression, Transference
	Wolff and Schwartz	Standard analytic, Alternate sessions
	Durkin	Group-as-preoedipal mother, Transference neurosis
General system	Glatzer	
	Durkin	Exchange across boundaries
	Agazarian Ettin	Subgrouping Social and cultural values and attitudes
	Hopper	Social unconscious

### Interpersonal Approaches

On the basis of Sullivanian principles, Yalom (1995) emphasized the centrality of transactions in the here and now of the group as the primary, but not exclusive, therapeutic force for change. His formulation of “therapeutic factors” brought into sharp focus the importance of cohesion (which is a dynamic concept that implies that the group is attractive, “safe”, and that members have a commitment to the group goals and ideals). Yalom pays particular attention to members’ capacity to give and receive feedback. He asserts that maladaptive interpersonal transactions are the consequence of parataxic distortions (having some similarity to transference responses, i.e., arising from childhood experiences) that can be therapeutically altered by authentic human interaction, that is, feedback and consensual validation.

### Intrapsychic Approaches

Intrapsychic theories are primarily application of dyadic theory into the group setting. The emphasis is on unconscious processes with the group providing opportunities for patients to regress to a level of internal conflict or developmental arrest. These theories explore individual transferences, resistances and developmental arrests as the primary therapeutic focus. Peers may be experienced as siblings or as displacement objects from parental figures (Slavson, 1950; Wolf and Schwartz, 1962).

Groups may either dilute or intensify transferences to the leader (Horwitz, 1994), which enables “stuck” patients to resolve impasses occurring in dyadic treatment. Regression is limited, and the presence of others creates a balance between the external and the internal worlds (Durkin, 1964). Integration of an intrapsychic framework with that of the group as a whole is contained in descriptions of members’ transferences to the group as a preoedipal maternal experience (Glatzer, 1953; Scheidlinger, 1974).

### General Systems Approaches

General systems theory is based on open systems theory (von Bertalanffy, 1966). Emphasis is placed on the boundaries separating the group from the external world and members or subgroups from one another (Durkin, 1981). Emphasis on boundaries as worthy of therapeutic concern is evident in the group agreement. Agazarian (1997) elaborated systems concepts into a model of group treatment that focused on subgroups as the primary site of therapeutic attention. She asserted that by focusing on subgroups, which contain individual differences and similarities, members are more prepared to address intrapsychic defenses and resistances.

### Beginning a Group

#### Group Organization

Forming a psychotherapy group is a complex task and attention to organizational details will anticipate some of the potential hazards and smooth the path. Composition, size, fees, place, duration and time of meetings are elements that require decisions in advance of recruiting and preparing potential members.

The size of dynamically-oriented groups ranges from six to 10 members. Groups at the upper size range generally meet for lengthier periods to provide sufficient “airtime” for each person. Smaller groups (four members or less) may be threatened by fears of dissolution (Fulkerson *et al.*, 1981). The duration of meetings is set for 75 to 120 minutes, the norm being 90 minutes. Most groups meet once weekly. Attention must be paid to the group space. An optimal room will comfortably seat eight to 10 persons with unobstructed views of one another. Seats do not have to be identical. Both the position and the type of seat members choose may assume considerable emotional significance. Access to the room needs consideration. Is there time for members to gather in the group room before the meeting, or is a waiting room necessary? In private settings, meetings are occasionally held in a waiting room and therapists must ensure that others do not intrude on that space.

Careful thought must be given to optimal group composition (Table 67.3). Patients chosen for groups that will explore intrapsychic elements should have a capacity for self-reflection and empathy with others. If possible, members with different personality styles should be selected to provide a spectrum of interactive patterns. Other long-term groups may be established with supportive goals and include patients with significant ego deficits. (Groups for the chronically mentally ill are discussed separately later.) Groups designed with a specialized format (e.g., women survivors of sexual abuse, male perpetrators, or individuals with eating disorders) generally are more focused on a symptom or a specific behavior and in such cases balanced membership is of lesser importance.

**Table 67.3 Selection of Patients**

Type of Group	Positive Attributes	Negative Attributes
Dynamic	Ego strength	Crisis situation
	Motivation for change	Active substance abuse-related disorder
	Capacity for insight	Sociopathy
Supportive	History of satisfying relationship	Cognitive disorder or mental retardation
	Diminished ego strength	Acute psychosis
	Limited reflective capacity	Disabling cognitive disorders
Specialized focus	Motivation for support	Substance abuse
	Most relationships problematical	
	Common characteristic	Psychosis
	Focus on single problem	Motivation for personality change

### Recruiting, Selecting and Preparing Patients

Few applicants requesting psychotherapy consider group treatment. Thus, gathering six to 10 individuals together may not be a simple task. Patients are more likely to agree to enter a group if the rationale is explained to them in some detail. Thus, the therapist needs to be clear about the relationship between group goals and patient goals (to be discussed below). The therapist also needs to be familiar with the patient's history, coping style, symptoms and personality configurations. In obtaining a patient's developmental history, the therapist can specifically search for the person's interaction in group settings, such as school, church, recreation and family. Discussion of the person's typical reactions to group situations helps engage the patient in examining his or her roles in interpersonal situations. The screening and preparatory interviews have five major tasks (Rutan and Stone, 2001):

1. Establish a preliminary alliance between patient and therapist.
2. Define the patients' therapeutic goals.
3. Provide information about the nature of group treatment.
4. Explore the patients' anticipatory anxiety.
5. Discuss the group agreement and gain the patient's acceptance.

Careful screening helps patients anticipate the tasks of entering a group. Such preparation will decrease, but not eliminate premature termination which may range from 20 to 50% of members in newly formed groups.

### The Group Agreement

The agreement represents the framework in which treatment will proceed. It promotes a structure that defines boundaries between

**Table 67.4 The Group Agreement**

Attend all meetings, be on time and remain throughout the session
Actively work toward treatment goals, remain until they have been achieved and discuss plans to stop treatment
Observe one's inner reactions to interactions in the group and comment on them
Use the group for therapeutic and not social purposes
Put feelings into words and not action
Be responsible for fees
Understand the therapist's role
Protect the confidentiality of the meetings and the anonymity of members

the group and the environment, among the members and with the therapist. Although members accept the agreement, they also break it. Such disruptions are valuable windows into understanding a person's inner world. The therapist must distinguish between acts that are disruptive to the group and those that carry more benign communications (Nitsun, 1996).

Rutan and Stone (2001) list the elements of the agreement as shown in Table 67.4.

The initial element in the agreement addresses patients' ability to attend all sessions. Those who have responsibilities that interfere with attendance should not be admitted into the group (e.g., executives whose conflicts make them unavailable once every third or fourth week). Similarly, persons who have time conflicts and would consistently come late or leave early should delay entry until their schedule can be adapted to that of the group.

In establishing goals, the patient and therapist enter into a conscious agreement to work toward specified change. However, unconscious elements contributing to a patient's behaviors are likely to emerge in the therapeutic process that may point to additional goals worthy of pursuit. Instructions regarding termination are an additional part of this agreement element. Patients generally have little idea how to stop treatment, and leaders can indicate that sufficient time to take leave of the group is an important part of the therapy. Plans to leave should be discussed and then a date for departure established that allows sufficient time to say goodbye.

The succeeding three elements in the agreement address patient behaviors within the group. Patients slowly learn that one of the major benefits of therapy follows from addressing feelings and reactions to one another and to the therapist. Consistent attainment of this goal suggests that the group is functioning at a mature level. Physical contact and verbal abuse are prohibited. Patients unable to contain these behaviors may be asked to leave the session temporarily. Although physical touching or hugging may seem soothing and reassuring to some individuals, for others it is a threat to their personal boundaries. Those behaviors are open to analysis.

### Therapist's Role

The group leader assumes a major, but not the sole, responsibility for the treatment. The therapist's special role is established in part by the agreement. Within that framework, clinicians begin to shape the group to provide participants a way of using their experience to learn about themselves. Assuming that patients'

**Table 67.5 Therapist's Focus**

Past	(here and now)	future
In group		out of group
Group as a whole	(subgroup)	(interpersonal)
	individual	
Affect		cognition
Process		content
Understanding		corrective emotional experience

optimal learning begins with a focus on transactions within the group, psychodynamically-oriented therapists try to find ways of helping members examine resistances and defenses against such engagement. In contrast, clinicians using a more strictly interpersonal (Yalom, 1995) or a system-centered orientation (Agazarian, 1997) may actively instruct members to address one another directly in the here and now of the meeting. The goals of the different approaches are similar: to use the intragroup processes to promote personal change. Therapists always benefit from examining their own contributions to the construction of the group dialogue. The therapist's focus, however, is not exclusively on in-group processes. Rutan and Stone (2001) list six foci for the therapist's attention (Table 67.5):

The major but not exclusive focus promoting change is members learning from the here and now of treatment. Groups develop a rhythm in which members might address outside events as a warm-up to exploring in-group interactions, or they might focus on current feelings and then expand on those experiences in respect to their outside lives, now, in the past, or in the future. Integration of a person's experiences across an extended period enhances feelings of continuity and stability of the self.

The therapist monitors the ebb and flow of affects which reflect the group developmental stage. Members' capacity to tolerate intense feelings is enhanced as trust and cohesion increase. The dialectical tension between affect and cognition is seen in members' roles as they attempt to contain dysphoric states and sustain emotional contacts with one another. Patients may find ways of managing intense feelings through scapegoating or externalizing. These are group-wide processes and should be addressed as such. Some individuals require cognitive understanding before risking immersion into feelings, whereas others search for affective connections before integrating their experience cognitively.

The therapeutic process is fueled by members' searching for new solutions to their developmental arrests and conflicts. In general, members communicate feelings about their in-group experience through associations (not always conscious) to events in their outside world. As such, the associations can be understood as metaphoric communication that informs the treatment process. After a successful interpretation or clarification, associations to external or historical events may represent integration of those experiences into members' psychic structure.

Considerable individual change takes place via the group relationship without overt cognitive integration. The sense of sharing, of being understood, of having needs met, of being responded to in an empathic (corrective) manner may stabilize a shaky psychic structure and, some patients, to their therapist's surprise, may successfully terminate treatment without having achieved understanding (Stone, 1985). These are the powerful forces for change, labeled "corrective emotional" experiences. Patients also strive for cognitive integration of their thoughts and

feelings and, through experiencing and then understanding the here-and-now, external and developmental incidents, they consolidate their learning. Patients are then more prepared to transfer their learning from therapy to situations in their outside world (Ezriel, 1973).

Members' level of self and ego development influence the course of the group as a therapeutic agent. Persons suffering from archaic conflicts of trust or psychic safety, as expressed in a variety of personality disorders (the difficult patient), may require an extended period of therapy exploring these issues. Transferences to the group, leader, or peers emerge that reflect these developmental levels.

## Special Treatment Considerations

### Scapegoating

Group psychotherapy has been called a hall of mirrors (Foulkes, 1961) where aspects of oneself are seen reflected in others. Scapegoating is the process in which individuals, by "observing" characteristics in another that are unacceptable in themselves, try to deny their feelings and place them in the "offending" person. This process, involving projective identification, is universal and frequently activated during treatment. It is by no means entirely conscious but patients often have an initial awareness that they are attempting to rid themselves of unacceptable feelings or behaviors.

Scapegoating may lead to the "scapegoat's" extrusion from the group. It depletes the group, in the sense that specific emotional responses are not available for examination. Many affects may serve as the stimulus to evoke scapegoating, such as anger, envy, or romantic feelings. Scapegoating becomes virulent because of affect contagion (Freud, 1955), in which feelings become greatly magnified in the communication process and adds a destructiveness to scapegoating.

The therapist's task of protecting the scapegoat is primarily accomplished through assisting members in "taking back" feelings that they are attributing to the scapegoat. A simple illustration is members' anger with an individual who habitually arrives late. That person might be accused of wanting to avoid the group. Analysis of the members' vitriol may reveal that they are also avoiding other intense group feelings. Such an analysis enables the scapegoat to become linked with the others rather than have an isolating experience.

### Nonverbal Communication

Patients communicate powerful feelings nonverbally. Discrepancy between verbal and nonverbal messages is confusing, but frequently the latter element is received as the "truth". Patients may tell sad stories and laugh, or they may relate a success in a dreary manner. Members may pull their chairs outside the group circle, sit close to or opposite the therapist, shift position in their chair, or not look at one another during emotionally laden interchanges. White knuckles, crimson blushing, or a black dress are additional colorful communications.

Patients learn to address these meaningful communications as they become comfortable examining in-group behaviors. However, many times the person may be unaware of sending nonverbal messages, and confrontations can be experienced as intrusive and threatening. Stereotyping certain behaviors as carrying predetermined meanings is a common error, and patients learn, sometimes through painful experience, that the sender may have highly personal meanings attached to the behavior.

Exploration of nonverbal behaviors is often a powerful entry into the recipient's and the sender's current and past feelings.

### Difficult Patients

A number of individuals appear to be good group candidates, but they prove to benefit little from participation or they seem to obstruct the treatment process. These individuals, generically labeled "difficult patients", can be conceptualized as having significant relational problems that interact with a particular group culture (Roth *et al.*, 1990; Stone and Gustafson, 1982). Although such individuals are often diagnosed as having borderline or narcissistic personality disorder, not all such patients can readily be given those specific diagnoses. Nitsun's (1996) felicitous expression, "the anti-group", characterizes these individuals as having the potential to disrupt the entire therapeutic endeavor.

The difficult patient should be seen in context. Some groups can accept individuals who seldom speak, whereas others see such a person as seriously harming cohesion and, therefore, as "difficult". Difficult patients fill roles and are frequently labeled "monopolizer", "help-rejecting complainer", or "the silent one". The role embodies both the individual personality and a group function. Evidence for this assertion is found when the difficult individual is removed and another rises to fill his or her place, which suggests that, in part, the role was necessary to deal with members' anxieties.

A more careful examination of the processes involved in the emergence of a difficult patient may expose that such individuals are covertly coconstructed by others in the group (Gans and Alonso, 1998). Interactions among members and the therapist tend to evoke and/or exaggerate particular character tendencies of members who often have underlying issues of forming intimate relationships. The therapeutic challenge is to deconstruct the processes so all can see their contributions to the difficult individual. This is similar to scapegoating described previously.

Nevertheless, some patients persist in behaviors that do not change and that become destructive to the treatment process. They evoke responses in others, including the therapist, that interfere with a sense of safety and limit members' willingness to expose their inner thoughts and feelings. Many difficult patients seem unable to process their interactions cognitively but remain enmeshed in emotional exchange. Others may interrupt emotional exchange with intellectual dissertations.

Not infrequently, these individuals prematurely terminate treatment, leaving those remaining with feelings of relief, frustration and anger. Other difficult patients remain in the group and at times the therapist is faced with making a decision that favors the group over an individual. The patient is informed that she or he is not benefiting from the treatment modality and is asked to leave. Such a decision should be reached only after the therapist has completed a thorough self-scrutiny and has sought consultation to explore countertransference contributions to the impasse.

## Alternative Treatment Formats

### Cotherapy

In some settings, groups are conducted by cotherapists. This format provides opportunities for clinicians to learn from one another, share leadership responsibilities, more readily recruit members and provide continuity in the absence of one leader. Cotherapy uniquely offers therapists chances directly to observe another clinician's work and to learn about countertransferences. The model is utilized for training neophyte group therapists who

can be paired with a more experienced therapist. For patients, this model is thought to offer a recreation of the family, as therapists are cast in parental roles, whether or not the therapists are of the same or different gender.

The conduct of cotherapy is not without special problems (Lang and Halperin, 1989). Cotherapists need to attend to their relationship because they are susceptible to a variety of transference responses to one another, most commonly competitive and narcissistic strivings. They will need to predetermine under what circumstances they might address their inevitable disagreements directly in the session.

### Pharmacotherapy and Group Therapy

The inclusion of patients receiving pharmacotherapy in dynamic psychotherapy groups is common practice. Eighty-three percent of surveyed psychiatrists included patients requiring medication in group therapy (Stone *et al.*, 1991).

Combining medications with psychotherapy has become widespread. The evidence for modification, if not cure, of major debilitating symptoms is substantial and yet patients will be left with emotional responses and unexplored meaning of their illness. Moreover, discontinuation of medication is highly correlated with recurrence of symptoms. In my opinion, clinicians' and patients' objections to the combined treatment approach can be sensitively addressed and inclusion of patients receiving medications in groups offers opportunities effectively to treat a wider patient population.

### Time-limited Groups

As pressure mounts to conduct therapy in briefer periods, interest in time-limited groups has increased (MacKenzie, 1997). The number of sessions may range from 12 to 30. Many insurance companies limit coverage to 20 sessions and thus a 16-session model allows for preparatory interviews and, if necessary, one or two sessions after termination of the group.

Time-limited goals are established by the therapist. Groups may be organized along specific symptom constellations, such as bereavement, sexual abuse, bulimia, or anorexia nervosa, or they may explore a personality sector with the expectation that the individual will continue to utilize the learning after termination.

Selection of patients for time-limited groups is of central importance. Therapists may opt to organize groups with ability to work with interpretations or one that is primarily supportive. Members should be assessed for their degree of psychological mindedness, that is, are they able to reflect on themselves and their interactions and on their ability to find a focus, not necessarily of recent origin. Difficulties should be formulated in interpersonal terms to facilitate the exploration of the problems in the group setting (e.g., a delayed grief reaction).

In most circumstances, once treatment begins additional members are not accepted. The agreement is similar to that of longer-term groups with the exception that the number of sessions is limited. Using this format, the therapist needs to be more active in defining the focus for the members. In the context of group development, interventions are made that focus on the interpersonal aspects of the particular dynamic stage. These groups can be particularly useful in addressing issues of engagement, trust, unfulfilled hopes, separation and loss. The combination of time pressure, maintaining focus on interpersonal processes and providing encouragement to apply learning in the external world has produced a treatment format that may be as effective as individual treatment (Budman *et al.*, 1988).

## Chronically Mentally Ill

This special population of patients requires modification of traditional dynamic approaches (Kanas, 1996; Stone, 1996; Schermer and Pines, 1999). The population is broader than individuals with major psychiatric disorders (schizophrenia or bipolar disorders) and includes some disabling anxiety or personality disorders. Indeed, chronicity is determined primarily by duration and disability rather than by diagnosis. In some instances, groups are organized homogeneously for patients with schizophrenia or bipolar disorder (Cerbone *et al.*, 1992). These groups often emphasize the importance of continuing with medication and include important educational components. They may have greater structure and focus on particular topics, such as managing hallucinations, paranoid thinking, or social relations (Stone, 1996).

More typically, groups are structured to include a spectrum of patients within a relatively small range of disability. Patients are prone to attend erratically and a flexible format that accepts this propensity may serve these individuals well (Stone, 1996). The sessions are usually shorter, 45 to 60 minutes and the group census may range from 12 to 16 persons. In the flexible format, core and peripheral subgroups develop and, over extended periods, groups develop a sense of continuity and cohesion.

Treatment goals should be concordant with patients' strengths and are generally formulated to help in adaptation to everyday problems, improving social relations and managing feelings. The agreement is modified and patients may be encouraged to socialize outside of the meetings. Therapists attempt to help patients manage their isolation and sense of shame over their illness.

Countertransferences require particular attention in part due to the difficulty patients have in linking to their therapists, which may leave the clinician expecting more than the patients can deliver. Moreover, in the current climate, particularly for major mental illness, medications are valorized and therapy is depreciated, a state of affairs that affects the therapist (Della Badia, 1999).

## Conclusion

While, historically, group psychotherapy was sometimes misrepresented as a less expensive, watered-down treatment, work by many has helped establish it as an effective, cost efficient and rigorous therapeutic modality applicable to a wide variety of patient problems. It provides a more direct experience for patients working with peers, as well as with those in "authority". The individual's difficulties with people is not limited to the experience of a particular individual therapist but emerges in the relational context of a number of individuals, thereby broadening the entire treatment context. In this era of emphasis on cost containment and efforts to provide rapid, brief therapies, groups can provide for some a positive time-limited treatment and for others an extended opportunity to address and alter significant intrapsychic and interpersonal difficulties.

# Time-limited Psychotherapy (Including Interpersonal Therapy)

In this chapter, we offer an overview of the field of TLP. Given the explosive growth in the field of brief psychotherapy research, it is impossible to review all extant, empirically supported TLPs. Instead, we focus on concepts common to second generation TLPs, practical strategies associated with brief treatments, and problems typical to this modality. To illustrate these principles, we use examples from several evidence-based treatments, with a focus on interpersonal psychotherapy (as it is not covered elsewhere in this text) as a paradigm of TLP.

## What is Time-limited Psychotherapy?

Time-limited psychotherapy refers to a psychosocial intervention, usually an individual psychotherapy, of relatively brief duration. Many of the defining features of TLPs follow from the fact that these treatments are intensive or compressed. Over a short period of time, the therapist identifies necessarily circumscribed treatment goals, working actively to maintain the treatment focus and preserve the treatment structure. Thus, TLPs are characterized by 1) specified treatment duration or time limit; 2) narrow treatment focus; 3) rapid and succinct case formulation; 4) structured treatment format; and 5) active therapist role.

Despite these similarities, TLPs comprise a heterogeneous array of treatments used to treat a plethora of conditions over quite variable time periods. “Brief” treatments can last anywhere from a single session to a year, and the therapeutic techniques deployed may range from transference interpretation (in brief psychodynamic psychotherapy) to a fear hierarchy (in behavioral therapy). Brief therapies are not indicated for the management of longstanding character disorders or chronic and persistent mental illness such as schizophrenia or bipolar disorder.

Given that (a) not all TLPs are the same and (b) experience in delivering one treatment does not confer expertise in all TLP modalities, it would be overwhelming to attempt mastery of TLPs in general. Thus, a reasoned approach to acquiring “competence” in brief interventions might include acquainting oneself with the general principles of TLP, learning the techniques and strategies associated with one evidence-based therapy, and then obtaining clinical training (including expert supervision that involves review of audio-recorded or videotaped sessions) in the selected TLP modality. Although standards for “competence” vary across TLP modalities (in some cases, they are not defined

at all), true competence is typically obtained after completion of a course in a specific psychotherapy followed by several carefully supervised cases (Markowitz, 2001). This chapter will facilitate the first step in this process: familiarity with the concepts common to most evidence-based TLPs.

## Overview of Interpersonal Psychotherapy

Throughout the chapter, we use examples from interpersonal psychotherapy (IPT) to illustrate many of the general principles of TLP. In order to acquaint the reader with IPT, we offer a brief overview of this modality, introducing IPT-specific concepts such as the interpersonal inventory, the four interpersonal problem areas and the interpersonal formulation. The reader is referred to the treatment manual (Weissman *et al.*, 2000) for a more thorough discussion of IPT.

IPT was developed in the 1970s by Klerman and Weissman as a 16-session psychotherapy for outpatients with nonpsychotic depression (Klerman *et al.*, 1984). IPT grew out of the interpersonal theories of Harry Stack Sullivan and Adolf Meyer as well as several empirical studies demonstrating the bidirectional link between interpersonal stresses and onset of depression. In its original form IPT is an acute treatment for depression. It can be used alone or in combination with medication to treat the patient’s depressive symptoms and the interpersonal problems that contribute to or are affected by the depression. IPT makes no inference about causality, simply linking the depressive symptoms to a patient’s particular interpersonal issues. Regardless of which came first, IPT assumes, based on empirical evidence, that one can achieve improvement in mood by addressing interpersonal problems.

IPT uses a medical model of psychiatric illness. The therapist explains to the patient that he or she has “major depression” which is a medical illness, like diabetes or heart disease, and instills the hopeful and empirically validated idea that IPT is a good treatment for this specific disorder. Using Parsons’s concept of the “sick role” (Parsons, 1951), the patient is assigned the responsibility to work toward better health in exchange for being relieved of unmanageable social obligations. The patient is also educated about the relationship between depression and interpersonal problems and, in collaboration with the therapist, selects an “interpersonal problem area” (see later) as the focus of treatment.

In the process of assessing the patient, the IPT therapist conducts the “interpersonal inventory”. The interpersonal inventory consists of a review of all important past and present relationships as they relate to the current depressive episode. The therapist asks about the patient’s life circumstances and requests a description of the important people in his or her life. In addition to outlining the “cast of characters” in the patient’s life, the therapist probes the quality of those relationships, asking the patient to describe satisfying and unsatisfying aspects, unmet expectations with others, and aspects of relationships that the patient would like to change. The interpersonal inventory helps the therapist establish the “interpersonal problem area”.

One of four interpersonal problem areas – grief, role dispute, role transition, or interpersonal deficits – serves as the explicitly agreed upon focus of treatment. It typically consists of issues such as the incompletely mourned loss of a loved one (i.e., complicated bereavement), conflict with a spouse or an employer (i.e., role dispute), an important life event (i.e., role transition) or, in the absence of one of these acute precipitants, longstanding, impoverished interpersonal relationships (i.e., interpersonal deficits). The therapist offers the patient an “interpersonal formulation”: having emphasized that depression is a medical disorder with a constellation of psychological and physical symptoms, the therapist links the patient’s current interpersonal problem to the depression and offers IPT as a powerful treatment for both the depression and the interpersonal problems. In the ensuing weeks (total of 16 weekly sessions), the therapist uses a variety of techniques outlined in the manual to help the patient work through these “real-life” problems.

### General Principles of Time-limited Psychotherapy

The hallmark of TLP is its specified treatment duration. Because of this compression, TLPs share attributes that both link them to

one another and distinguish them from long-term treatment modalities. These general principles are summarized in Table 68.1.

### Time Limit

Table 68.2 groups psychotherapies commonly administered in a time-limited format by treatment approach and lists representative examples of strategies and typical treatment durations.

TLPs differ from truncated long-term treatments that are interrupted by attrition, noncompliance, or the pressures of managed care organizations. The duration of these latter therapies may coincide with that of a TLP, but they do not constitute fully formed brief treatments. TLPs have distinctly defined beginnings, middles, and ends – regardless of their absolute duration. Knowledge from the outset that therapy has a defined end-point indeed may constitute a key active ingredient of time-limited therapy. It suggests that relief may be near at hand. Marmor speculates that this approach “counters the patient’s impulse to see himself as helpless, inadequate, and in need of dependent support” (Marmor 1979, p. 153). Our experience with IPT as a treatment for depression in individuals who are HIV-seropositive suggests that these individuals, despite shortened life spans, use the brevity of treatment as an impetus to effect radical, rapid changes in their lives (Swartz and Markowitz, 1998). The time limit, in a variety of ways, seems to provide an important motivation to speed the patient toward health.

A meta-analysis of many psychotherapy studies (none of them TLPs) found that most (75%) patients achieve symptom relief within 26 sessions of an open-ended treatment (Howard *et al.*, 1986). Most treatments included in this meta-analysis were naturalistic (e.g., not controlled) studies of patients suffering from very heterogeneous symptoms (diagnoses are not specified). This finding suggests that many patients may respond quickly, even if psychotherapy is open-ended. Although no studies have com-

**Table 68.1** General Principles of Time-limited Versus Open-ended Psychotherapies

Principle	Time-limited Psychotherapy	Open-ended Psychotherapy
Duration of treatment	Specified time frame, 1–40 sessions	Duration not specified; may last several years
Scope of treatment	Well-defined treatment focus; circumscribed goals	Flexible treatment goals, varying over time, often not well-defined
Treatment goals	Remission of specific symptoms or intrapsychic conflict	Character change, improved functioning, or ongoing support
Case formulation	Rapid; succinct; drives treatment goals; often explicitly stated to patient	Strives for depth of understanding; subject to ongoing revision and reassessment as treatment unfolds
Characteristics of suitable patients*	Acute illness; good premorbid functioning; limited resources; focused problem area	Chronic illnesses; poor premorbid functioning; extensive resources; multiple targets of change
Treatment structure	Defined stages of treatment; clearly specified termination phase; often specified in a manual	Flexible structure; no specified end point; treatment stages vary widely; not codified as a manual
Therapeutic stance	Active; direct suggestion may be permitted; functions to maintain treatment focus	Less directive; neutral

**Table 68.2 Major Models of Time-limited Psychotherapy**

Psychotherapy Type/Major Theorists	Techniques	Typical Time Duration
Interpersonal psychotherapy (IPT) Klerman Weissman	<ul style="list-style-type: none"> <li>• <i>Medical model</i> of illness.</li> <li>• Life events affect mood, and <i>vice versa</i>.</li> <li>• Link symptoms to one of four <i>interpersonal problem areas</i>.</li> <li>• Work through an affectively meaningful problem area using role-play, communication analysis, and direct suggestion.</li> <li>• Focus on the <i>here and now</i>, outside rather than inside the office.</li> </ul>	12–16 wk
Cognitive-behavioral therapy (CBT) Beck Rush Barlow	<ul style="list-style-type: none"> <li>• Identify distorted thoughts that lead to maladaptive feelings and behaviors.</li> <li>• Homework assignments to recognize, test, and challenge underlying <i>automatic negative thoughts</i> or maladaptive behaviors.</li> <li>• <i>Relaxation techniques</i> to manage anxiety.</li> <li>• Encourage <i>rational</i>, scientific, collaboration between patient and therapist.</li> </ul>	12–16 wk
Behavior therapy (BT) Foa Mynors-Wallis	<ul style="list-style-type: none"> <li>• Based on principles of operant conditioning, social learning theory.</li> <li>• Gradual <i>exposure</i> to anxiety-producing stimuli.</li> <li>• Self-monitoring, graded task assignment.</li> </ul>	8–12 wk
Brief psychodynamic psychotherapy Balint Davanloo Luborsky Malan Mann Sifneos Strupp	<ul style="list-style-type: none"> <li>• Identify problematic relationship themes that are resolved through <i>transference interpretations</i>.</li> <li>• Offer <i>support</i> through the formal aspects of treatment such as regular appointments and collaboration.</li> <li>• Select central issue that has current relevance and past antecedent.</li> <li>• <i>Transference interpretations and clarification</i> to develop insight and resolve conflict.</li> <li>• <i>Confront defenses</i> – despite emergence of anxiety – to uncover underlying impulse.</li> <li>• Explore past <i>conflicts</i>, <i>ego defenses</i> and <i>resistances</i>.</li> </ul>	12–20 sessions
Motivational interviewing Miller Rollnick	<ul style="list-style-type: none"> <li>• Patient-centered, directive method for <i>enhancing motivation</i> to change.</li> <li>• Encourage articulation and resolution of <i>ambivalence</i>.</li> <li>• Diminish resistance and strengthen patient's <i>commitment to change</i>.</li> </ul>	2–4 sessions
Psychodynamic-interpersonal Hobson Shapiro	<ul style="list-style-type: none"> <li>• Less emphasis on interpretation than most psychodynamic treatments.</li> <li>• Greater emphasis on patient-therapist relationship than in IPT.</li> <li>• Help patient learn new ways of relating to therapist and, by extension, others.</li> <li>• Enhance interpersonal skills.</li> </ul>	3–8 sessions

pared prospectively response rates of TLPs to open-ended treatments, we predict that treatment response would be more rapid for patients receiving time-limited interventions because of explicit expectations that therapy will conclude within a specified time frame. TLPs are generally dosed with a frequency of once a week, although this varies as well.

The optimal duration and dosage of TLP, although empirical questions, remain largely unanswered to date. In practice, treatment duration is often defined by convention, the exigencies

of a research protocol or managed care organization, or even the inclinations of the therapist.

### **IPT: Duration of Treatment**

IPT was originally designed as a 16-week intervention so that it could be administered over the same period as an acute course of pharmacotherapy, allowing an assessment of the relative efficacy of the two interventions (DiMascio *et al.*, 1979). IPT is also administered as a 14-session intervention (Markowitz

unpublished data), a 12-session intervention (Mufson *et al.*, 1999; O'Hara *et al.*, 2000) and an eight-session intervention (Swartz *et al.*, 2002), but there are no data comparing the relative benefits of varying doses of acute IPT.

### Treatment Focus

An important characteristic of TLP is careful definition of treatment goals, which are usually agreed upon by the patient and therapist, and often specified at the beginning of treatment. Because therapy is brief, the scope of the treatment is circumscribed and focused. TLPs do not attempt sweeping changes in character. Rather, treatments target a specific diagnosis, set of symptoms, or a narrow aspect of character. Typical and appropriate treatment goals for TLPs include remission of depressive symptoms, reduction in frequency of binge-eating, and resolution of a specific interpersonal conflict.

Most TLPs define treatment goals by diagnostic criteria, in much the manner of pharmacotherapies. IPT focuses on two discrete goals: remission of depressive symptoms and resolution of an interpersonal problem area (Weissman *et al.*, 2000). Cognitive-behavioral therapy for panic disorder focuses on reduction in frequency of panic attacks and relief of general anxiety symptoms (Barlow, 1997). Motivational interviewing, a brief intervention designed to facilitate behavior change, is often administered for the sole purpose of helping patients reduce or eliminate their alcohol consumption (Miller and Rollnick, 1991). Thus, although the treatments vary in their focus, in all cases their treatment goals are narrow and usually specified from the outset.

### Case Formulation

Treatment focus is closely allied with the broader concept of case formulation. According to Eells, psychotherapy case formulation is “a hypothesis about the causes, precipitants, and maintaining influences of a person’s psychological, interpersonal, and behavioral problems.... It should serve as a blueprint, guiding treatment” (Eells, 1997, pp. 1–2). In TLP, because time is short, the process of generating a case formulation is also compressed. The therapist must identify the most important components of the patient’s narrative, balancing the urge to learn more about the patient’s life circumstances with the time constraints of the TLP. Thus, the TLP therapist typically conducts an overview of the patient’s psychosocial circumstances and then selects a few “hot” topics – relevant both to the current complaint and the nature of the therapy – to consider in greater depth. This approach allows the therapist to develop an informed, timely case formulation. The ability rapidly to develop and deliver such a formulation is for many therapists among the more difficult but also most valuable aspects of learning a TLP.

### IPT: Case Formulation

Case formulation in IPT builds on two core IPT concepts: 1) depression is a treatable illness and 2) events in one’s psychosocial environment affect one’s mood, and vice versa. The IPT therapist defines depression as a medical illness that, like asthma, is both treatable and affected by the patient’s circumstances. The therapist notes that, in a biologically vulnerable individual, when painful events occur, mood worsens and depression may result. Conversely, depressed mood compromises one’s ability to handle one’s social role, generally leading to negative events. IPT therapists use the connections among mood, environment and social

role to help patients understand their depressions within an interpersonal context, and to teach them to handle their social role and environment so as to both solve their interpersonal problems and relieve their depressive syndrome.

The therapist’s formulation includes a diagnosis of depression as a medical illness, the provision of reassurance and hope, the assignment of the sick role and, most importantly, the identification of one (or at most two) interpersonal problem areas that become the agenda for the remainder of the treatment. The therapist directly states this case formulation to the patient and elicits his or her agreement with the proposed strategy before moving ahead with the next phase of treatment. Thus, in IPT, case formulation constitutes an important treatment tool that links the patient’s mood symptoms to life events and introduces a specific interpersonal problem area as the focus of treatment for the ensuing sessions (Markowitz and Swartz, 1997).

The brevity of treatment leaves little room for error in formulating the IPT case – or any TLP case, for that matter. The therapist must use the initial treatment sessions aggressively to pursue all potential areas and to determine the treatment focus prior to embarking on the middle phase of treatment. If a covert and imposing problem area should arise in the middle phase, however, the therapist would have to renegotiate the treatment contract to address it.

### Structured Treatment

In TLP, the structure of the intervention is clearly delineated and referenced throughout the treatment period. The therapist will often call the patient’s attention to important landmarks in the treatment: “Today we’ve reached the halfway point” or “We only have three sessions left”. In manualized treatments, each of these time intervals has specified tasks or strategies. For instance, in IPT, the initial phase can last up to three sessions. During that time, the therapist has specific tasks (*viz.*, obtain a psychiatric history and interpersonal inventory, offer a case formulation). Similarly, the middle and end phases of treatment have a specified duration and associated tasks.

In support of the treatment structure, TLP requires the therapists to make formal or informal “treatment contracts” in which the patient and therapist explicitly or implicitly agree to goals, duration and other parameters of treatment. The therapist may discuss with the patient the exact number of sessions planned, rules for missed sessions or rescheduled sessions, fees and so on. Although some aspects of treatment contracts are common to all psychotherapies, TLPs tend to specify more elements in the contract from the outset, including expected treatment responses (e.g., “At the end of 16 weeks, your mood will likely be much better”) and specific requirements of the patient (e.g., homework assignments in Prolonged Exposure and CBT). Patients often find the transparent structure of TLPs reassuring, removing some of the unnecessary mystery (and perhaps stigma) historically associated with psychotherapy.

Most TLPs call for serial assessments of symptoms. In clinical practice (and in clinical trials), it is often practical to administer a self-report measure such as the Beck Depression Inventory (Beck and Steer, 1993) or the Beck Anxiety Inventory (Beck and Steer, 1990). Regardless of the instrument chosen, it is important to build into the weekly therapy session time to complete and review a standardized symptom measure and track change over time. Serial symptom assessment provides the patient with additional psychoeducation (*i.e.*, symptom recognition) and a reliable means of tracking improvement (or lack thereof).

## Active Therapist

In order to maintain the treatment focus, the therapist must be active in TLP. He or she must move the treatment process forward under the pressure of an inexorably ticking clock. This demands constant attention to the treatment focus and redirection of the patient if the focus falters. The therapist gently keeps the patient on task, shaping the treatment rather than simply following the patient's lead. A challenge in TLP is to balance strict adherence to the treatment focus with an empathic stance that supports the treatment alliance. Although it is important to attend to the agreed upon problem area in IPT, it is also important that the patient feel "heard" and that the therapist allows time in the session for the patient to express his or her feelings unimpeded.

## Practical Issues in Time-limited Therapy

### Patient Selection

Because of their limited focus, TLPs are ideally suited to patients with acute symptomatology and relatively favorable baseline functioning. Resource availability may also influence decisions to use a time-limited or open-ended approach. Most evidence-based treatments are designed for and have been tested in samples of patients who meet DSM-IV criteria for Axis I disorders (predominantly mood and anxiety disorders, as well as specific behavioral problems such as substance abuse or eating disorders). Thus, it is important to conduct a thorough diagnostic interview, identify target diagnoses and symptoms and select, if possible, a TLP that has been empirically validated for that population. It would be inappropriate to treat a patient with a primary diagnosis of a specific phobia with IPT, as IPT has not been tested in this population; a behavioral approach would be preferable. A patient suffering from major depression, however, might reasonably be treated with CBT, IPT, or brief dynamic therapy.

### Engagement

The closely allied concepts of engagement and treatment alliance respectively refer to the patient's commitment to the treatment enterprise and the relationship between therapist and patient. Positive treatment alliance typically correlates with better treatment adherence and engagement. Given the brevity of treatment, one challenge of TLP is to establish rapidly a relationship with the patient in order to facilitate engagement in treatment. Maintaining this alliance throughout treatment is also important because nonattendance, while disruptive to any psychotherapy, is particularly costly in a time-limited treatment.

### IPT: Therapeutic Relationship

While many of the so-called "common" factors of psychotherapy function to facilitate this process, in IPT the therapist's stance is specifically intended to create a positive relationship with a depressed patient. The IPT therapist maintains a warm, encouraging stance that counters the depressed patient's pessimism with an equal and opposite optimistic realism. In psychodynamic terms, the IPT therapist cultivates a positive transference. He or she handles negative transference as illness-derived, treatment-interfering behaviors: for instance, tardiness or lack of participation would be defined as sequelae of depression. The therapist might intervene by saying, "It's hard to feel enthusiastic about therapy when your depression makes it hard to enjoy anything". In addition, the therapist might address it on a practical level, saying, "We only have five sessions left. We need all the remaining time

to get to the bottom of your problem with your wife and to treat your depression". These strategies both promote the therapeutic alliance and enhance treatment engagement.

### Maintaining the Focus

As previously discussed, it is imperative that the TLP therapist identify clear treatment goals and maintain focus during the brief treatment period. It can be challenging to keep the patient on task and manage material that emerges in sessions unrelated to the primary treatment goal. To address this important issue, the therapist must clarify from the outset the goals and potential limitations of treatment.

### IPT: Treatment Focus

In IPT, treatment goals are specifically stated during the initial phase of treatment. The IPT therapist might say, "The goal of this treatment is to help you with this depression and your unresolved feelings about your mother's death last year. At the end of 16 weeks, we can discuss whether you need additional treatment for your bulimia, but let's first see how you feel when the depression has lifted". It is important that the patient explicitly agree to the stated treatment goals. In the case described above, the patient would need to agree to defer treatment for a possible eating disorder, focusing on her depression and grief for the immediate future.

In IPT, a clear treatment contract helps the patient and therapist remain focused. For instance, if the patient brings up feelings of dissatisfaction in the workplace during a therapy designed to address problematic relationships with a spouse (role dispute), the therapist may first briefly explore whether these complaints relate to the treatment focus. Thus, if demands from the spouse lead the patient to accept an unsatisfactory job, or if a dispute at work parallels that at home, the therapist can refocus the comments in light of the ongoing marital dispute. However, if there is no obvious connection to the main treatment focus, the therapist might gently redirect the patient by saying, "Although your work concerns are important too, at the beginning of therapy we agreed that we should spend these few months working through your problems with your spouse. I wonder how that has been going".

### Termination

As the end of treatment nears, the therapist reiterates the date and time of the final session, actively eliciting responses to the end of treatment if the patient does not spontaneously offer them. Termination provides an opportunity to review treatment gains (which are often impressive), support the patient's sense of competence and independence, grieve the end of treatment and identify unaddressed problems. The termination phase is more crucial and more complicated in psychodynamic psychotherapies because of their emphasis on the importance of the therapeutic relationship.

### IPT: Termination

In IPT, termination is handled as a graduation or role transition. In the termination phase of IPT (typically the last two to three sessions), the therapist helps the patient express expectable sad feelings (which are distinguished from recrudescing depressive affect) about the end of treatment, but underscores patient progress in having treated the depressive episode and problems at work, love relationships, and so on. While concerns about the patient's ability to manage without the therapist's help are inevitable, the therapist counters with examples of the patient's hard

therapeutic work outside of the office. The therapist commends the patient's "real world" victories, reminding the patient that IPT has helped him or her to develop new skills that he or she will continue to use after treatment ends. Termination promotes patient independence while grieving the loss of the treatment relationship. The therapist and patient also review the symptoms of depression and identify "warning signs" which might lead the patient to a reevaluation in the future.

In the event of partial response or nonresponse, the therapist suggests alternative treatments and makes appropriate referrals for follow-up. If the therapist judges that additional treatment is warranted for management of persistent symptoms, it is critically important that the therapist blames the therapy rather than the patient for failing to bring about a full remission. The therapist can gently point out that all of our treatments for depression are imperfect and that we cannot yet predict which treatments will work for any individual patient. The therapist confidently reassures the patient that there are other options (i.e., medication, other forms of psychotherapy), helping the patient select follow-up treatment that fits his or her needs. Another reasonable strategy (though not backed by any empirical data) would be to extend the treatment duration of IPT by a fixed number of sessions (e.g., six or eight additional sessions). This option would probably be best for a patient who has had at least a partial response to IPT and may need a few extra sessions to complete therapeutic work that is already underway. In keeping with the spirit of IPT, it would be important to explain this rationale to the patient explicitly and to set a second termination point to help maintain the focus of treatment. See the later section on "nonresponse and partial response" for a fuller discussion of treatment options for patients who are not well at the end of 16 sessions.

When the patient experiences a remission of symptoms by the end of 16 sessions, it may be tempting to refer the patient for additional psychotherapy such as marital treatment or an insight-oriented psychotherapy to address residual interpersonal issues or longstanding personality problems. However, it may be preferable to encourage a treatment-free period of 3 to 6 months to help clarify and consolidate treatment gains, particularly if the patient has presented with a first episode of relatively acute illness. Greater symptom chronicity and number of episodes suggest the need for continuation and maintenance treatment.

## Common Problems in Time-limited Psychotherapy

### Nonresponse and Partial Response

There are no clear guidelines to determine the optimal next step for patients who fail to respond or do not respond fully to an initial course of psychotherapy. In the case of nonresponse to a given treatment, which may be defined as failure to achieve at least a 25% decrease in baseline symptoms over a 6- to 8-week time period (Nierenberg and DeCecco, 2001), the usual approach would be to stop the unhelpful therapy and consider alternatives. Patients who show no benefit from a TLP should be evaluated for the typical sources of treatment failure such as misdiagnosis, the presence of a comorbid psychiatric disorder, or comorbid general medical conditions (Kornstein and Schneider, 2001), and referred for appropriate treatment. If the TLP psychotherapist is also a physician, it would be reasonable at this point to consider pharmacotherapy. If the clinician decides that it is in the best interest of the patient to abandon a course of TLP, it is important

that the therapist help the patient understand that the "fault" lies with the TLP rather than the patient. The therapist should be certain to offer the patient support during the transition to an alternate treatment, instilling hope that the new treatment will offer relief and making sure that continuity of care is preserved.

In most cases of partial response to a TLP, clinicians choose to add medication as their first strategy. Unless the therapist suspects that psychotherapy may have worsened the patient's condition, continuing psychotherapy usually makes sense. The preexisting therapeutic relationship can provide a supportive holding environment for the patient while medication is initiated that may help the patient tolerate initial medication side effects and the delayed onset of action associated with antidepressant medication. Among depressed patients who fail to respond to an initial course of pharmacotherapy, response rates to a second antidepressant hover around 50% (Marangell, 2001). By contrast, in a sample of depressed women, the addition of an SSRI to IPT among those who failed to respond to IPT alone brought about remission in almost 80% of subjects (Frank *et al.*, 2000). Thus, depressed patients who do not remit with psychotherapy alone may be excellent candidates for combination treatment with psychotherapy and medication.

If a patient refuses medications or prefers a trial of a different psychotherapy, it may be reasonable to change TLP modalities or consider an open-ended treatment. Issues to consider include whether it makes sense to switch therapists, the qualifications of the therapist to administer multiple types of psychotherapy, and the availability of alternate treatments in the patient's geographic area. Whereas psychopharmacologists can easily change prescriptions and proceed with a consistent therapeutic approach, a psychotherapist who suddenly begins acting differently may confuse an already uncomfortable patient.

### IPT: Handling Nonresponse to Treatment

In IPT, we make every effort to blame the treatment rather than the patient when symptoms persist beyond termination. Depressed patients are inclined to blame themselves, so it is important for therapists to maintain their objective stance, pointing out treatment successes (there are usually some) and underscoring the fact that not all patients respond to any single treatment. Patients with histories of chronic or recurrent depression who respond to an acute course of IPT are generally considered candidates for continuation and/or maintenance of IPT sessions (usually administered at a reduced frequency) to help achieve a full remission and prevent relapse and/or recurrence (Frank, 1991; Markowitz, 1998).

### Mid-treatment Crises

During the course of any psychotherapy, unanticipated crises may occur in the patient's life, temporarily derailing treatment. For instance, if the patient suddenly developed new, life-threatening symptoms such as active suicidal ideation or frank psychosis, the case formulation would be abandoned in order to attend to patient safety. Alternately, if the patient experienced an unexpected life crisis mid-treatment (i.e., the death of an important person, significant changes in socioeconomic status, etc.), it would be reasonable to reevaluate the treatment focus in order to attend to the patient's pressing needs.

Regardless of treatment modality, patient safety supersedes the treatment paradigm. In TLP, it is desirable to address the crisis as quickly as possible in order to return to the treatment focus and complete the treatment within the specified time

frame. If the therapist can address the crisis rapidly and resume the prior focus, it may be possible to regain the original treatment trajectory. If multiple sessions are required to address the crisis, the therapist must ask, “Is this TLP salvageable?” and “Can we meet our treatment goals within the remaining allotted time?” If not, the therapist should consider altering the treatment focus or abandoning the current treatment approach entirely. As we have emphasized throughout, changes in treatment approach should be handled carefully, reassuring the patient that they are not to blame and providing support as the patient shifts to a new intervention.

### Contraindication to Time-limited Psychotherapy

For all psychoactive treatments it is important to consider instances in which a specific therapy is **not** indicated for a disorder or kind of patient. Unfortunately, thus far there are no well-designed empirical studies of a psychotherapy’s potential “toxicities”, although there is speculation about the kinds of individuals who would be predicted to respond poorly to time-limited treatments.

In the brief psychodynamic psychotherapy literature, time-limited treatments are generally not recommended for those individuals who might have difficulty in quickly forming a therapeutic alliance or might develop severe difficulties in the face of termination (Marmor 1979). In practice, this usually translates into a reluctance to treat borderline, suicidal, substance abusing, or psychotic patients with brief psychotherapy (Davanloo, 1980; Mann, 1974; Sifneos, 1979). Also excluded are “acting out”, cognitively impaired, very dependent, or “unrestrainably” anxious patients (Koss and Shiang, 1994).

Although Sifneos (1979) and Mann (1974) consider severe psychopathology a contraindication to their brief psychodynamic psychotherapies, other time-limited treatments specifically target serious mental disorders. IPT and CBT, for example, were developed for the treatment of major depression; these and other brief psychotherapies have been used to treat a spectrum of significant pathologies including bulimia (Fairburn, 1998), alcohol dependence (Miller *et al.*, 1998), panic disorder (Barlow, 1997; Milrod *et al.*, 2000), and post traumatic stress disorder (Foa *et al.*, 1991).

**Table 68.3 Summary of Empirical Evidence Supporting Efficacy of TLPs for Mood Disorders (Randomized Trials Only)**

Diagnosis	N	Study Design	Results	Reference
Major depressive disorder	81	16 wk of IPT, amitriptyline (AMI), IPT plus AMI, or nonscheduled control	IPT plus AMI > IPT = AMI > control	DiMascio <i>et al.</i> (1979)
Major depressive disorder in the elderly	91	16–20 wk of behavioral (BT), cognitive (CT), or brief psychodynamic (BPT) therapy or wait-list control (WLC)	BT = CT = BPT > WLC	Thompson <i>et al.</i> (1987)
Major depressive disorder	250	16 wk of IPT, CBT, imipramine (IMI) or placebo (PLA) plus clinical management (CM)	IMI > IPT > CBT > PLA plus CM (differences were nonsignificant)	Elkin <i>et al.</i> (1989)
Recurrent major depressive disorder	128	3 yr of maintenance treatment: monthly maintenance IPT (IPT-M), IMI plus IPT-M, IPT-M plus PLA, CM plus PLA, IMI plus CM	IMI plus IPT-M = IMI plus CM > IPT-M = PT-M plus PLA > CM plus PLA	Frank <i>et al.</i> (1990)
Major depressive disorder	107	12 wk of CT, IMI, or CT plus IMI	CT plus IMI > IMI = CT (differences were nonsignificant)	Hollon <i>et al.</i> (1992)
Depressive symptoms in HIV-positive individuals	101	16 wk of IPT, CBT, IMI plus supportive therapy (SP), or SP alone	IMI plus SP = IPT > CBT = SP alone (differences were nonsignificant)	Markowitz <i>et al.</i> (1998)
Recurrent major depressive disorder in the elderly	180	3 yr of maintenance treatment: nortriptyline (NTP), IPT-M, IPT-M plus NTP, IPT-M plus PLA, or CM plus PLA	NTP plus IPT-M > NTP > IPT-M plus PLA > CM plus PLA	Reynolds <i>et al.</i> (1999)
Major depressive disorder in adolescents	48	12 wk of IPT or CM	IPT > CM	Mufson <i>et al.</i> (1999)
Severe, refractory, nonpsychotic illness	110	8 wk of psychodynamic interpersonal therapy (PI) or usual care (UC)	PI > UC	Guthrie <i>et al.</i> (1999)
Postpartum depression	120	12 wk of IPT or WLC	IPT > WLC	O’Hara <i>et al.</i> (2000)
Chronic depression	681	12 wk of nefazodone (NFZ), cognitive-behavioral-analysis system of psychotherapy (CBASP), or NFZ plus CBASP	NFZ plus CBASP > NFZ = CBASP	Keller <i>et al.</i> (2000)

Although it is unlikely that a personality disorder will remit following a course of brief psychotherapy, we also know that it is often difficult accurately to diagnose personality disorders in the presence of an Axis I disorder (Hirschfeld *et al.*, 1983). Hence **seeming** Axis II pathology should rarely be an exclusion in the presence of an appropriate Axis I target disorder. Furthermore, the structure and brevity of time-limited treatments may help the therapist to manage or circumvent some of the treatment-interfering behaviors characteristic of cluster B personality disorders. Thus, it may be reasonable to treat patients with moderate character pathology for an Axis I disorder with a TLP and then refer them for a different kind of psychotherapy once the acute symptoms have remitted.

### Empirical Data

Because these treatments are relatively short, it is easier (though by no means easy) to conduct psychotherapy outcome studies with TLPs than with longer-term psychotherapies. The past decade has witnessed the publication of relatively large numbers of TLP studies. Because of these studies, we have more confidence that TLPs work, at least for particular indications, than other forms of psychotherapy. In Table 68.3, we summarize findings from empirical studies of TLPs as treatments for mood disorders. In Table 68.4 we summarize population-specific indications for selected TLPs.

### Conclusion

In 1975, Luborsky asked the question, “Is it true that ‘everyone has won and all must have prizes’?” (Luborsky and Singer, 1975).

In other words, are all psychotherapies equally efficacious for all conditions and all patients all of the time? In the ensuing decades, through more systematic studies of TLPs, we have begun to establish the efficacy of specific psychotherapies for specific disorders. Moving beyond the first generation TLPs that used psychodynamic principles to treat mildly ill patients with heterogeneous diagnoses, the second generation of TLPs are characterized by written manuals that specify treatment interventions for defined disorders and populations.

In the process of focusing the lens, however, we may have lost sight of the big picture. As Guthrie (2000) points out, although patients in real world settings experience chronic symptoms and multiple disorders, psychotherapy researchers have typically excluded these patients from outcome studies. There have been great strides in the field of TLP research over the last two decades, but much work remains. The next challenge will be to develop strategies to disseminate these evidence-based (**efficacy** proven) TLPs into general clinical settings and to conduct new (**effectiveness**) psychotherapy studies of their relevance in general psychiatric populations.

Future empirical work may focus on further defining psychotherapy duration, with the dual goals of establishing the fewest number of sessions that can be used to treat a given problem and identifying those patients for whom longer courses of therapy are indicated.

### Acknowledgment

The authors would like to thank Danielle Novick for her assistance in the preparation of the chapter.

**Table 68.4 Time-limited Therapies with Demonstrated Efficacy for Specific Disorders**

Disorder	Psychotherapy	Efficacy
Major depression, acute	IPT	1*
	CBT	1
	PI	2
Major depression, recurrent	Maintenance IPT	1
Major depression in the elderly	Cognitive therapy	2
	Behavior therapy	2
	Horowitz’s stress-response psychotherapy	2
Depressive symptoms in HIV seropositive men	IPT	2
Chronic depression	Cognitive-behavioral analysis system of psychotherapy	1
Dysthymia	CBT	2
	IPT	2
Opiate addiction	Luborsky’s SE plus drug counseling	2
	CBT plus drug counseling	2
Alcohol addiction	CBT	1
	Motivational enhancement therapy	1
	Twelve-step facilitation	1
Bulimia	CBT	1
	IPT	2
PTSD	Prolonged exposure	2
Panic disorder	CBT	1
	Panic-focused psychodynamic therapy	2

\*tentative classification; 1, rigorously proven; 2, promising results.

Preparation of this chapter was supported, in part, by a grant from the National Institute of Mental Health, MH-64519 (H.A.S.).

# Cognitive and Behavioral Therapies

---

The family of cognitive and behavioral therapies includes a diverse group of interventions. Nevertheless, the treatments share several pragmatic and theoretical assumptions. First, these therapies emphasize a psychoeducational orientation, by which patients learn about the nature of their difficulties and the rationale for use of particular treatment strategies. Secondly, the cognitive and behavioral therapies typically employ homework and self-help assignments to provide patients the opportunity to practice therapeutic methods to enhance generalization outside of the therapy hour. Thirdly, objective assessment of psychiatric illness is considered an integral part of treatment, and selection of therapeutic strategies derives logically from such assessments. Fourthly, the therapeutic methods used are generally structured, are directive, and require a high level of therapist activity. As such, the cognitive and behavioral therapies tend to be easier than other approaches to describe in treatment manuals. Fifthly, for most disorders, the cognitive and behavioral therapies are time-limited interventions. Sixthly, and perhaps most important, these therapies are built on empirical evidence that validates the theoretical orientation and guides the choice of therapeutic techniques. Specifically, learning theories (i.e., classical, operant and observational models of learning) and the principles of cognitive psychology are relied on heavily in constructing cognitive–behavioral treatment models.

## Cognitive Model

The basic theories of the cognitive model are rooted in a long tradition of viewing cognitions as primary determinants of emotion and behavior. For excellent reviews of the historical bases of cognitive therapy, see Dobson and Block (1988) Clark *et al.* (1999). The description of cognitive theories given here is based largely on Beck's concepts. This model of therapy tends to give somewhat more emphasis to cognitive than behavioral factors in treatment interventions, but both are considered to be integral parts of the model (Figure 69.1).

Depending on the case formulation and the phase of therapy, attention may be directed primarily at cognitive or behavioral aspects of the disorder. In most cases, a combination of cognitive and behavioral techniques is used. For this reason, we use the term cognitive–behavioral therapy (CBT) throughout the chapter unless referring to a specific form of behavioral treatment.

Figure 69.2 displays a simplified model for understanding the relationships between environmental events, cognitions, emotion and behavior (Wright and Beck, 1994; Wright, 1988; Thase and Beck, 1993). This model is based on the theoretical assumption

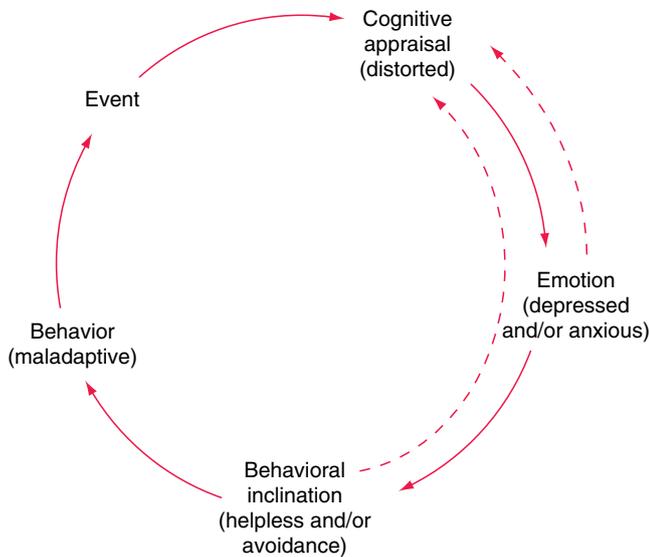

that environmental stimuli trigger cognitive processes and the ensuing cognitions give the event personal meaning and elicit subsequent physiological and affective arousal. These emotions, in turn, have a potent reciprocal effect on cognitive content and information processing, such that cascades of dysfunctional thoughts and emotions can occur. The individual's behavioral responses to stimuli and thoughts are viewed as both a product and a cause of maladaptive cognitions. Thus, treatment interventions may be targeted at any or all components of the model.

Of course, many other factors are involved in psychiatric disorders, including genetic predisposition, state-dependent neurobiological changes and various interpersonal variables. These influences are also included in the case conceptualization in CBT. Wright and Thase (1992) have outlined an expanded cognitive–biological model that can be used for synthesizing cognitive and neurobiological factors in a combined therapy approach. Contemporary psychiatric research is striving to understand how best to combine and/or sequence CBT and pharmacotherapy, and relate CBT technique to new understandings in cognitive neuroscience. Nevertheless, the working model in Figure 69.2 can be used as a practical template to guide the therapist's case formulation and interventions.

## Automatic Thoughts and Schemas

Dysfunctional information processing is apparent in many psychiatric disorders at two major levels of cognition—automatic thoughts and schemas (Beck, 1976; Dobson and Shaw, 1986; Teasdale, 1983; Segal, 1988; Alford and Correia, 1994). Automatic thoughts are cognitions that stream rapidly through an individual's mind, whether spontaneously or in response to some prompt or stimulus. Automatic thoughts may be triggered by affective arousal (i.e., anger, anxiety, or sadness), or conversely, affective shifts are generally accompanied by automatic negative thoughts (Teasdale, 1983). Their automatic nature refers to their speed of entry into awareness and their implicit believability. In this way, automatic thoughts have emotional validity (Thase and Beck, 1993). For most people, before therapy, automatic thoughts are usually not examined carefully for validity. In fact, many people susceptible to anxiety or depression are likely to use an affectively focused logic referred to as emotional reasoning (i.e., "I *feel* that this is correct, therefore it is correct"). Although we all experience automatic thoughts, in depression, anxiety and other psychiatric disorders the thoughts are distinguished by their greater intensity and frequency (LeFebvre, 1981).

Beck (1967) coined the term **cognitive triad** to describe the content of automatic negative thoughts. Typically, automatic

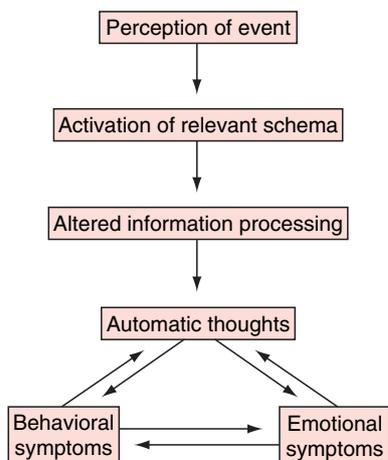

**Figure 69.1** A working model for cognitive-behavioral therapy. Reprinted with permission from the American Psychiatric Press *Review of Psychiatry*, Vol. 7, pp. 554–590. *Cognitive therapy of Depression*, Wright JH. Copyright 1988, American Psychiatric Press.

negative thoughts may be grouped by themes pertaining to self, world (i.e., significant others or people in general) and future. As described subsequently, the themes revealed in one’s characteristic automatic negative thoughts may be used to infer deeper levels of cognition: beliefs, rules and schemas. Patients can be taught to examine their beliefs and their operational rules. Although patients are not fully aware of their schemas, these cognitions are usually accessible through the questioning techniques used in CBT (Wright and Beck, 1994).

Beck and coworkers (Beck *et al.*, 1979; Beck and Emery, 1985; Wright and Beck, 1983) have noted that stereotypic errors in logic (termed cognitive errors or cognitive distortions) also shape the content of automatic thoughts (Table 69.1).

Schemas represent the sum of one’s beliefs and attitudes. They are the basic assumptions or unspoken rules that act as templates for screening and decoding information from the environment (Segal, 1988; Wright and Beck, 1983; Young and

**Figure 69.2** Cognitive model of information processing.

**Table 69.1** Common Patterns of Irrational Thinking in Anxiety and Depression

Cognitive Error	Definition
Overgeneralization	Evidence is drawn from one experience or a small set of experiences that reach an unwarranted conclusion with far-reaching implications.
Catastrophic thinking	An extreme example of overgeneralization, in which the impact of a clearly negative event or experience is amplified to extreme proportions, e.g., “If I have a panic attack, I will lose <b>all</b> control and go crazy (or die).”
Maximizing and minimizing	The tendency to exaggerate negative experiences and minimize positive experiences in one’s activities and interpersonal relationships.
All-or-none (black or white, absolutistic) thinking	An unnecessary division of complex or continuous outcomes into polarized extremes, e.g., “Either I am a success at this, or I am a total failure.”
Jumping to conclusions	Use of pessimism or earlier experiences of failure to prematurely or inappropriately predict failure in a new situation; also known as fortune-telling.
Personalization	Interpretation of an event, situation, or behavior as salient or personally indicative of a negative aspect of self.
Selective negative focus – “ignoring the evidence” or “mental filter”	Undesirable or negative events, memories, or implications are focused on at the expense of recalling or identifying other, more neutral or positive information; in fact, positive information may be ignored <i>or</i> disqualified as irrelevant, atypical, or trivial.

Adapted with permission from Beck AT, Rush AJ, Shaw BF *et al.* (1979) *Cognitive Therapy of Depression*. Guilford Press, New York.

Lindermann, 1992). Psychological well-being may be understood in part by development of a set of schemas that yield realistic appraisals of self in relation to world (e.g., “I’m reasonably attractive, but looks aren’t everything”, “I can be loved under the right circumstances”, or “I must work harder to compensate for an average intellect”). Although unspoken, schemas may be inferred from one’s beliefs and attitudes. In the cognitive model, dysfunctional attitudes are the structural “bridge” between pathological schemas and automatic negative thoughts. Schemas pertaining to safety, vulnerability to threat, self-evaluation, one’s lovability, and one’s competence or self-efficacy contain the ground rules for personal behavior that are particularly relevant to the understanding of disorders such as anxiety, depression, or characterological

**Table 69.2 Proposed Maladaptive Schemas**

Autonomy	
Dependence	The belief that one is unable to function with the constant support of others
Subjugation/lack of individuation	The voluntary or involuntary sacrifice of one's own needs to satisfy others' needs
Vulnerability to harm or illness	The fear that disaster (i.e., natural, criminal, medical, or financial) is about to strike at any time
Fear of losing self-control	The fear that one will involuntarily lose control of one's own impulses, behavior, emotions, mind, and so on
Connectedness	
Emotional deprivation	The expectation that one's needs for nurturance, empathy, or affect will never be adequately met by others
Abandonment/loss	The fear that one will imminently lose significant others or be emotionally isolated forever
Mistrust	The expectation that others will hurt, abuse, cheat, lie, or manipulate you
Social isolation/alienation	The belief that one is isolated from the rest of the world, is different from other people, or does not belong to any group or community
Worthiness	
Defectiveness/unlovability	The assumption that one is inwardly defective or that, if the flaw is exposed, one is fundamentally unlovable
Social undesirability	The belief that one is outwardly undesirable to others (e.g., ugly, sexually undesirable, low in status, dull, or boring)
Incompetence/failure	The assumption that one cannot perform competently in areas of achievement, daily responsibilities, or decision-making
Guilt/punishment	The conclusion that one is morally bad or irresponsible and deserving of criticism or punishment
Shame/embarrassment	Recurrent feelings of shame or self-consciousness experienced because one believes that one's inadequacies (as reflected in the preceding maladaptation schemas of worthiness) are totally unacceptable to others
Limits and Standards	
Unrelenting standards	The relentless striving to meet extremely high expectation of oneself, at all costs (i.e., at the expense of happiness, pleasure, health, or satisfactory relationships)
Entitlement	Insistence that one should be able to do, say, or have whatever one wants immediately

Reprinted with permission from Thase ME and Beck AT (1992) An overview of cognitive therapy, in *Cognitive Therapy with Inpatients: Developing a Cognitive Milieu* (eds Wright JH, Thase ME, Beck AT *et al.*). Guilford Press, New York, p. 9; adapted from Young (1999) *Cognitive Therapy for Personality Disorders: A Schema-Focused Approach*. Professional Resource Exchange, Sarasota, FL.

disturbances (Segal, 1988; Young and Lindermann, 1992; Blackburn *et al.*, 1986b; Beck *et al.*, 1990). A number of schemas relevant to psychiatric illness are listed in Table 69.2. Bowlby (1985) has noted that most psychopathologically relevant schemas are developed early in life, when the individual is relatively powerless and dependent on caregivers.

The cognitive model of psychiatric illness emphasizes the concept of stress-diathesis (Thase and Beck, 1993; Metalsky *et al.*, 1987). From this perspective, a schema such as "I must be loved to have worth", might remain latent until activated by a relevant life stressor (i.e., a romantic breakup).

Underlying schemas may be buttressed by either maladaptive or adaptive attitudes (e.g., "No matter how hard I try, I'm bound to fail" versus "I'm a survivor; if I just hang in there things will be okay"), but many of these cognitive structures have mixed features (Wright and Beck, 1994). Schemas such as "If I'm not perfect, I'm a failure" may lead to driven obsessional behavior, rigid attitudes and beliefs, and frequent bouts of dysphoric or irritable moods. However, basic perfectionistic beliefs such as these can also result in high levels of performance and success.

The concept of attributional style (Hammen *et al.*, 1989) describes an alternative view of cognitive vulnerability. Derived from human studies of the learned helplessness paradigm (Seligman, 1975), attributional style refers to the characteristic way that people explain the causality, controllability and impact of events. People susceptible to depression are more likely to have an attributional style in which negative events are perceived to be personally controllable (i.e., internality), far-reaching (i.e., globality), and enduring (i.e., stability) (Peterson *et al.*, 1985; Abramson *et al.*, 1989; Sweeney *et al.*, 1986).

The results of many studies suggest that disturbances in information processing are essential features of depression and anxiety (see Chapter 15 on Cognitive Neuroscience).

### Behavioral Model

The behavioral model is based on the relatively straightforward chain of events and responses illustrated in Figure 69.3. Through the years, considerable effort and debate have concerned whether stimulus–response and response–reinforcement relationships

**Figure 69.3** Chain of events.

could be invoked to account for the complexity of human behavior (Kazdin, 1982; Staats, 1964). In its maturity, behavioral therapy has broadened beyond an exclusive focus on observable behaviors (i.e., radical behaviorism) and now incorporates cognitive processes and other individual variables that affect one's preparedness to learn (Bandura, 1977b; Goldfried and Davison, 1994). For example, in observational learning, the stimulus–response contingency relationship is established vicariously, by watching, reading about, or imagining the event in question. Reinforcement does not have to take place explicitly; it may occur vicariously, or it may simply be imagined. Other factors, such as the individual's past history, inherent talents, or skillfulness of his or her pertinent response repertoire, help account for the wealth of interindividual variability in stimulus–response relationships. Bandura's cognitive–behavioral formulation of self-efficacy is one example of a “mental” construct that has abiding behavioral implications. This modifiable attitude or belief (roughly akin to self-confidence) influences persistence, willingness to try new things, optimism and capacity to endure setbacks (Bandura, 1977a).

## Cognitive and Behavioral Treatment Strategies

The cognitive and behavioral therapies are well known for their use of specific treatment techniques. Commonly used CBT procedures are directly linked to the theoretical constructs and empirical research of this school of therapy. Although techniques are given somewhat more emphasis in CBT than in other forms of psychotherapy, there is still considerable room for therapists to be creative and flexible in developing a treatment plan. In fact, novice therapists sometimes focus too much on applying techniques at the expense of nurturing the therapeutic alliance and case formulation. Development of a productive therapeutic relationship and an individualized case conceptualization should always take precedence over the implementation of specific cognitive or behavioral techniques. A number of the more important CBT strategies are described briefly here. More detailed accounts of CBT interventions can be found elsewhere (Beck *et al.*, 1979; Beck 1995; Barlow and Cerny, 1988; Freeman *et al.*, 1989; Persons, 1989).

## Collaborative Empiricism

The therapeutic relationship is as important in CBT as in any of the other effective psychotherapies. However, interchanges between therapist and patient often differ from those observed in supportive or dynamically oriented treatment. One difference is that the therapist is responsible for managing the pace of the session and uses an agenda to help make each session as efficient as possible. Cognitive–behavioral therapists strive for a therapeutic relationship that emphasizes: 1) a high degree of collaboration and 2) a scientific attitude toward testing the validity or usefulness of particular cognitions and behavior. This therapeutic stance is referred to as collaborative empiricism. The empirical nature of the relationship reflects that therapist and patient work together as an investigative team to develop hypotheses about cognitive or behavioral patterns, examine data, and explore alternative ways of thinking or behaving. At first, therapists usually spend more time

teaching and explaining in CBT than in other forms of therapy, yet in the course of therapy, patients are actively engaged to become increasingly involved in the work of treatment.

The collaborative empirical stance requires that the therapist and patient work together to make an **honest** appraisal of the validity of cognitions as well as of the adaptive or maladaptive nature of beliefs and behaviors. If a negative assessment proves to be accurate (e.g., the patient actually has made serious mistakes, the individual's spouse is highly likely to leave, or the patient has engaged in a repetitive self-defeating behavior pattern), then the therapist and patient need to work together in a problem-solving mode to develop a plan to cope with the problems at hand or practice more adaptive strategies for use in the future.

Wright and Beck (1994) and others (Clark *et al.* 1999) have recommended several strategies for enhancing collaborative empiricism. These include: 1) adjusting the therapist's level of activity to match the patients' symptom severity or the phase of treatment; 2) encouraging use of self-help procedures; 3) attending to the “nonspecific” variables important in all therapeutic relationships (e.g., empathy, respect, equanimity, kindness and good listening skills); 4) promoting frequent two-way feedback; 5) devising coping strategies to help deal with real losses or implementing a plan of action to address maladaptive behavior; 6) recognizing transference phenomena; 7) customizing therapeutic interventions; and 8) using humor judiciously. It is also important to recognize and account for the wide variety of individual differences in cultural backgrounds, social attitudes and expectations that each patient brings to the therapy encounter (Wright and Davis, 1994).

## Psychoeducation

Most forms of CBT integrate explicit psychoeducational procedures as a core element of the treatment process. Psychoeducational procedures are typically blended into treatment sessions in a manner that de-emphasizes formal teaching. There is a concerted effort to teach the patient why it is important to challenge automatic thoughts, identify cognitive errors and practice implementing a more rational thinking style. Behavioral interventions are also preceded by psychoeducation to convey the background for principles such as extinction, reinforcement, self-monitoring, exposure and response prevention.

In the early phases of treatment, special attention is paid to socializing the patient to CBT. The basic cognitive–behavioral model is demonstrated, and expectations for both patient and therapist are conveyed. Some of the frequently used psychoeducational procedures in CBT include brief, impromptu explanations (often written on a chalkboard or a pad of paper to increase the chances of comprehension and retention) and reading assignments, such as *Coping with Depression* (Beck and Greenberg, 1974), *Feeling Good* (Burns, 1980), *Mind Over Mood* (Greenberger and Padesky, 1995) or *Getting Your Life Back* (Wright and Basco, 2001). Psychoeducational initiatives typically become more complex as therapy proceeds. For example, detailed explanations and repeated exercises may be needed before the patient fully grasps abstract concepts such as attributional style or schemas. As therapy progresses, homework assignments continue explicitly to reinforce material covered during therapy sessions.

## Modifying Automatic Thoughts

The first step in changing automatic thoughts is to help the patient recognize when she or he is having them. The therapist is often

able to illustrate the presence of automatic negative thoughts during the initial session by gently calling attention to a change in the patient's mood. Such "mood shifts" can be excellent learning experiences that give personally relevant illustrations of the linkage between cognitions and feelings.

One common misconception of CBT is that its practitioners disregard the role of affect or feelings in the etiology and treatment of psychiatric disorders. Actually, one of the principal components of CBT is the stimulation and modulation of emotion (see Figure 69.3). In fact, Beck referred to emotion as "the royal road to cognition" (Beck, 1991). In contrast to experiential therapies, variations in emotion are used in CBT to establish links with cognition and identify errors in information processing. Getting in touch with feelings is thus not a goal in CBT but only a means by which therapy helps patients to gain greater control over the processes that influence their moods and behaviors.

### Socratic Questioning

The most frequently used technique to uncover and modify automatic negative thoughts is Socratic questioning (or guided discovery) (Beck *et al.*, 1979; Overholser, 1993a, 1993b, 1993c). Socratic questioning teaches the use of rationality and inductive reasoning to challenge whether what is thought or felt is actually true. The therapist models the use of Socratic questioning and encourages the patient to start raising questions about the validity of his or her thinking. There are few formal guidelines for Socratic questioning (Overholser, 1993a). Rather, therapists learn to use their experience and ingenuity to frame good questions that engage the patient in a process aimed at recognizing and modifying a biased or distorted cognitive style. Typical questions include: What ran through your mind at that time? What is the evidence that your impression is accurate? Could there be any alternative explanations? If this were true, what would be the worst thing that would happen? When guided discovery methods are not sufficient to draw out automatic thoughts, the therapist may turn to several alternative ways of eliciting dysfunctional cognitions, as described in the following.

### Imagery Techniques and Role-playing

Imagery techniques and role-playing are used when direct questioning does not fully reveal important underlying cognitions. When imagery is used, the therapist sets the scene by asking the patient to visualize the situation that caused distress. Although some patients can readily imagine themselves in a previous scene, many need prompts or imagery induction to encourage their active participation in the exercise. Several types of questions can be used to help frame the scene. These include inquiries about: 1) the physical details of the setting, 2) occurrences immediately before the interaction, and 3) descriptions of the other people in the scene (Wright and Beck, 1994). In role-playing exercises, the therapist and patient act out an interpersonal vignette to uncover automatic thoughts or to try out a revised pattern of thinking. This technique is used less frequently than imagery by most cognitive-behavioral therapists and may be reserved for situations in which transference distortions are unlikely (Wright and Beck, 1994).

### Thought Recording

Thought recording is one of the most useful procedures for identifying and changing automatic thoughts. This technique is first presented in relatively simple two- or three-column versions in the early stages of therapy. When the two-column procedure is

used, patients are instructed to write down events in one column and thoughts in the other. Alternatively, they can record events, thoughts and emotions in the three columns. The purpose of this exercise is to encourage patients to begin to use self-monitoring to increase awareness of their thought patterns. Next, the strength of the emotion and the believability of the automatic negative thoughts are rated on a scale of 0 to 100. In subsequent sessions, a more complex five-column thought record, the Daily Record of Dysfunctional Thoughts (DRDT) is introduced (Figure 69.4). The fourth column of the DRDT encourages the patient to develop rational alternatives that rebut the automatic negative thoughts; the fifth column is used for a reevaluation of the mood and cognitive ratings. Work on identifying cognitive errors can also be included in this form of thought recording.

### Examining the Evidence

The examining the evidence procedure is a collaborative exercise used to test the validity of automatic negative thoughts. Cognitions are set forth as hypotheses rather than established facts. The patient is encouraged to write down evidence that either supports or refutes the automatic thought using a two-column form (i.e., pros and cons). Cognitive errors such as magnification, personalization and all-or-nothing thinking are frequently revealed in these situations.

Next, the therapist helps to guide revision of the automatic negative thought in light of the evidence (e.g., "I often feel inferior to others, even when there's no good evidence that they feel that way" or "I have had a number of difficulties with my teachers and employers, but not all relationships have been bad"). The process thus moves from the patient's general and globally negative interpretations to more specific, factually based statements.

When an honest appraisal uncovers evidence in support of negative cognitions, the therapist may choose to focus on the patient's attributions of causality or internality. The patient who posits a negative attribution for poor work evaluation (e.g., "My performance was poor because I don't have what it takes") can usually be aided to consider a more neutral attribution (e.g., "My performance was poor because I was underprepared... my depression also prevented more energetic preparation"). The treatment plan may also be revised to develop better methods of coping in similar situations or to work on ways of remediating skill deficits. Sometimes, particular difficulties cannot be changed (e.g., physical handicaps, markedly unattractive physical looks, or severe financial limitations).

### Generating Alternatives

If automatic thoughts prove to be largely dysfunctional, the patient is encouraged to generate alternatives that are more accurate or factual. Many of the techniques discussed earlier can be used to help generate alternatives to automatic thoughts. Socratic questioning is used in therapy sessions to help the patient start to think more creatively. Also, psychoeducational procedures may be employed to teach brainstorming techniques. For example, the patient may be taught to use "expert testimony" or the opinions of someone who knows her or him well (i.e., a sibling, spouse, or best friend) to help develop more rational alternatives. Thought records are often used to record alternatives to automatic thoughts. We often encourage patients to collect their thought records in notebook form for ongoing use. Figure 69.4 illustrates the use of rational alternatives during CBT for a depressed patient.

Date	Event	Automatic thoughts	Emotions	Rational thoughts	Outcome
	a. Describe actual event preceding unpleasant emotion or b. Stream of thoughts, daydream, or memories preceding unpleasant emotion.	a. Write automatic thought(s) that led to emotion(s). b. Rate of belief in automatic thought(s), 0–100%.	a. Specify sad, anxious, angry, tense, and so on. b. Rate degree of emotion, 0–100.	a. Identify cognitive errors. b. Write rational response to automatic thought(s). c. Rate belief in rational response, 0–100%.	a. Specify and rate subsequent emotion(s), 0–100.
1/30/95	My boss asks for a progress report.	I'm in big trouble. (85) I can't handle this job. (90) I've messed everything up. (95)	Anxious (95) Sad (80)	Magnification, ignoring the evidence, overgeneralization.  I'm slightly behind schedule, but I can catch up. (95) I've had a good track record with this job. (100) I'm doing O.K. in some other areas of my life. (95)	Anxious (40) Sad (20)
	My son comes home late from a party.	Nobody listens to me. (90) He doesn't care. (75) What's the use of trying? (80)	Angry (75) Sad (85)	All or none thinking, ignoring the evidence, personalizing.  My son pays attention a fair amount of the time, but he doesn't always do what I want. (90) There's plenty of evidence that he cares about me. (100) We need to improve how we communicate. (95) I need to tell him that I'm angry. (100)	Angry (30) Sad (25)

**Figure 69.4** *Daily record of dysfunctional thoughts.*

Many patients with depression, anxiety and related conditions have relatively rigid cognitive styles that perpetuate dysfunctional thought and behavior patterns. These individuals frequently experience “second-order” automatic negative thoughts, that is, negative thoughts that are triggered by rational alternatives (“that’s a cop-out...quit making excuses”). These thoughts about thoughts tend to undermine the credibility of the rational responses and may dampen the patient’s enthusiasm for using the procedure. The therapist may notice a particular facial expression or a change in the patient’s posture that suggests the existence of second-order thoughts. In such cases, more active therapeutic assistance may be needed. For example, the therapist may need to act as a teacher or coach in the area of adaptive cognitive functioning, rapidly rebutting automatic thoughts as they arise. Coping cards, which are index cards with helpful reminders on the use of CBT methods (in this case, rational responses to repetitive automatic negative thoughts), may be written during sessions and carried by the patient in his or her pocket, wallet, or purse for later use.

### Cognitive–Behavioral Rehearsal

Cognitive–behavioral rehearsal is a treatment strategy that is particularly useful for preparing patients to put their experiences in CBT to work in real-life circumstances. After automatic thoughts have been elicited and modified through procedures described before, the therapist guides the patient in a series of rehearsal

exercises to try out alternative cognitions in a variety of situations. By using imagery and role-playing scenarios to practice generating more adaptive cognitions, the patient may become aware of problems that could interfere with implementation of the new style of thinking. Further practice and targeted homework assignments may then be needed before alternative cognitions can be fully used. For example, the effects of cognitive–behavioral rehearsal may be extended to real situations by assigning homework to test use of the modified automatic thoughts.

### Modifying Schemas

The emphasis in the early phases of therapy is usually on behavioral activation, identifying and changing automatic thoughts, and the reduction of symptoms. However, as the patient gains knowledge of cognitive–behavioral principles and acute symptoms begin to subside, the focus of the treatment sessions usually shifts toward work on the schema level. Because schemas serve as underlying templates for making sense of new information, they play a major role in the modulation of more superficial cognitions (automatic thoughts), regulation of affect, self-esteem and control of the behavioral repertoire. Thus, schema modification is an important component of cognitively oriented therapies.

With Axis I disorders such as major depressive disorder and panic disorder, schema revision efforts are directed at correcting dysfunctional attitudes that may predispose the patient

to symptomatic recurrences. After several months of productive therapy, schema modification may be placed in the context of reducing future vulnerability. CBT of personality disorders typically requires that a major portion of therapy be devoted to modifying schemas and related patterns of behavioral dysfunction (Beck *et al.*, 1990). When schematic work cannot be fully addressed in time-limited therapy, the model of ongoing change may be introduced. Thus, the patient may begin to change her or his “life course” by development of a long-term self-help plan. Jarrett and colleagues (2001) have proposed continuation and maintenance phases of CBT treatment of depression, and they argue for focusing on schema change in these phases of treatment if it is not accomplished in the acute phase of treatment.

Many of the techniques used to test and modify automatic thoughts are also used to identify and revise schemas. Psychoeducational interventions are usually required as a first step. Most patients are not aware of their “guiding principles”, so the therapist may need to begin by introducing and illustrating this concept. It is often useful to use synonyms for the term schema (such as basic assumptions or core beliefs) and to demonstrate how schemas are linked to automatic negative thoughts using material from the patient’s own experience (Wright and Beck, 1994). Socratic questioning is the core procedure used for schema modification (Beck *et al.*, 1979; Overholser, 1993c).

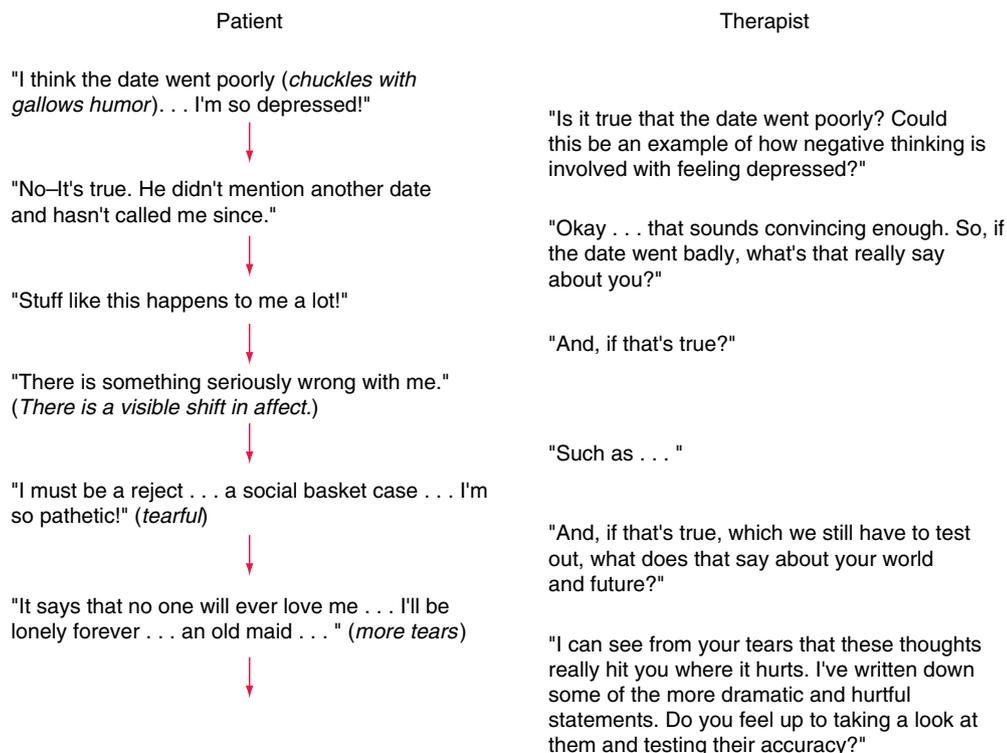

The downward arrow technique (Figure 69.5) is a particularly powerful way to move from surface cognitions to deeper cognitive structures (Thase and Beck, 1993). This technique describes asking the patient a question such as: “If this automatic thought were true, what would it mean about you as a person?” Another useful approach is to examine patterns of automatic thoughts from thought records to sort out common themes. The therapist may suggest a thematic collation based on her or his knowledge of the patient’s automatic negative thoughts. In some

situations, it may be helpful to have patients review a description of common pathological schemas to recognize some of their core beliefs (see Table 69.2). On occasion, it may be useful to have the patient write a brief autobiography to help elucidate the historical antecedents of the schema. Computerized learning programs can also be employed to help patients uncover their schemas (Wright *et al.*, 1995, 2002a).

Because schemas are so strongly held (in essence, they have helped define reality and mold behavior for years), they may require intensive work in a number of therapy sessions to undergo significant change. Sometimes long-term continuation and maintenance CBT is required to accomplish schematic restructuring. Therapists can select from a number of CBT techniques, including examining the evidence, listing advantages and disadvantages, generating alternatives, cognitive response prevention and cognitive-behavioral rehearsal, as they attempt to modify schemas (Wright and Beck, 1994). Examining the evidence, generating alternatives and cognitive-behavioral rehearsal were described earlier as methods of changing automatic thoughts.

### Cognitive Response Prevention

In cognitive response prevention, the patient agrees to complete a homework assignment in which she or he must behave in a way that is inconsistent with the pathological schema. For example, a person with perfectionistic attitudes may be engaged in an assignment in which she or he must perform in a “so-so” manner. This is intended to activate the schema which is triggering automatic negative thoughts (e.g., “They’ll think I’m a sloth” or “I’ll never be trusted with an important assignment again”). By not responding to the perfectionistic demands dictated by the schema, the individual thus has the opportunity to cope with the automatic negative thoughts consequent to this “rule violation”.

**Figure 69.5** *The downward arrow technique.*

## Listing Advantages and Disadvantages

The listing advantages and disadvantages procedure is particularly useful when a schema appears to have both adaptive and maladaptive features. Schemas that have damaging effects are often maintained because they also have a positive side. For example, the schema “I must be perfect to be accepted” can have significant benefits (e.g., hard work and attention to detail often lead to success in work or school). Nevertheless, because perfection is seldom possible, the individual may remain vulnerable to setbacks. Other schemas, such as “I’m a complete loser”, may not seem to have any advantages at first glance. However, even such a markedly negative basic assumption can have certain behavioral reinforcers associated with it. For example, a person who believes that he or she is a loser may avoid making commitments, withdraw from challenging assignments, or refuse to exert a sustained effort to solve a difficult problem. This strategy may thus protect the person from painful setbacks. The advantages and disadvantages analysis provides the patient and therapist with essential information for planning modifications. Revised schemas are most likely to be used when they take into account both the maladaptive and the adaptive features of the old basic assumption.

In general, it is recommended that patients keep a list of the schemas as they have been identified. The schema list helps to focus the patient’s attention on the overarching nature of these maladaptive principles. Because schemas often become manifest only during periods of increased stress or symptom expression, they may appear to fade in significance as the patient begins to improve. For example, behavioral treatment programs that neither endorse nor aim to modify schemas are generally as effective as CBT in the short run. However, there may be a false security engendered by symptom relief. The cognitive model posits that the individual will remain vulnerable to the depressogenic impact of “matching” life events unless schema revision is accomplished (Thase and Beck, 1993).

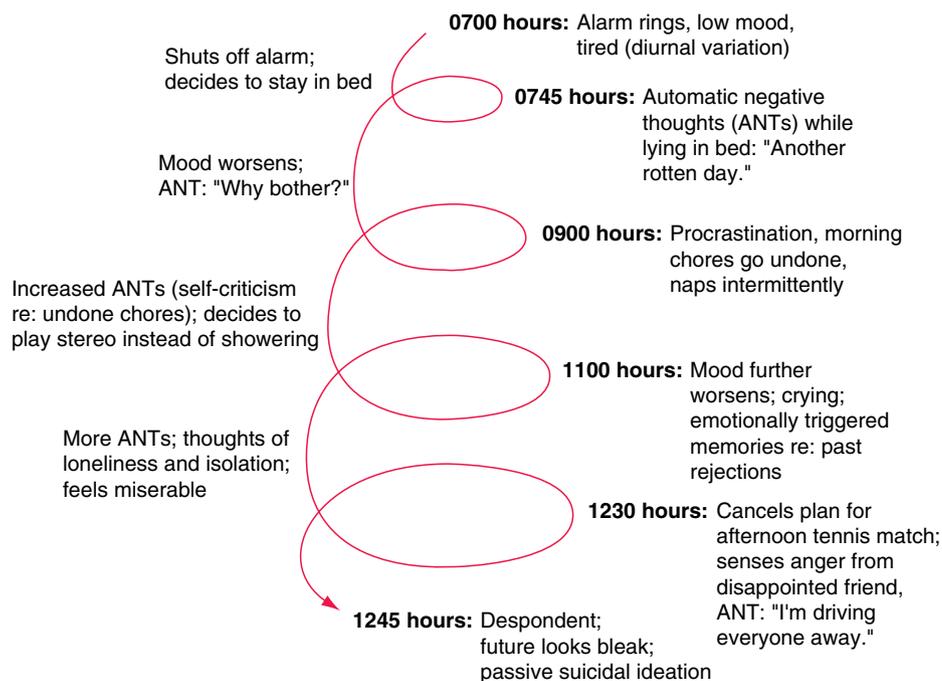

## Behavioral Techniques

In CBT, behavioral methods are usually integrated with cognitive restructuring in a comprehensive treatment plan. Behavioral strategies may be given a greater emphasis earlier in therapy with more severely symptomatic patients such as those with intense depression, bipolar symptoms, or schizophrenia (Beck *et al.*, 1979; Thase and Wright, 1991; Kingdon and Turkington, 1995; Basco and Rush, 1996; Scott and Wright, 1997). Some cognitive–behavior therapists may rely primarily on behavioral interventions for conditions such as obsessive–compulsive disorder (OCD) or simple phobias. Commonly used behavioral strategies are described here in alphabetical order.

## Activity Scheduling, Graded Tasks and Mastery–Pleasure Exercises

One key to the behavioral approach for treatment of depression is the interruption of the downward spiral linking mood, inactivity and negative cognition (Beck *et al.*, 1979; Lewinsohn *et al.*, 1982) (Figure 69.6). Completing an activity schedule is often the first behavioral homework assignment used in CBT (Beck and Greenberg, 1974). Depressed patients are asked to begin to keep a daily log that is used to chart the relationship between their moods and their activities (Figure 69.7).

The nature of the activities is examined, and deficits in activities that might elicit pleasure or feelings of competence are identified. Next, assignments are made to engage in discrete pleasurable activities (or, in the case of an anhedonic individual, activities that were rewarding before becoming depressed). If needed, a “menu” of reinforcers can be generated by having the patient fill out a Pleasant Events Schedule (Lewinsohn *et al.*, 1982). Following operant principles, activities that have been “high-grade” reinforcers in the past are scheduled during times of low moods or decreased activity. Next, subjective ratings of

mastery or competence and pleasure are added to the activity schedule by use of a simple scale (i.e., 0–5), to avoid the tendency of dichotomous thinking. In this way, achieving a small degree of pleasure or mastery during a scheduled activity may be framed as an accomplishment, particularly early in the course of therapy.

### Breathing Control

An important component of CBT for anxiety disorders involves teaching the patient breathing exercises that may be used to counteract hyperventilation and/or reduce tension (Clark *et al.*, 1985). Slow, deep breathing can have a calming effect not unlike progressive muscle relaxation (Bernstein and Borkovec, 1973). These exercises also help to distract the patient from autonomic cues. After initial instruction and practice, the breathing skills are then applied in progressively more anxiety-provoking situations.

A note of caution is in order when teaching patients breathing control exercises. We have seen many patients who have misunderstood instructions and who have developed a pattern of deep overbreathing in response to stress. Instead of helping reduce anxiety, their breathing changes may increase the chances of hyperventilation. Thus, we typically recommend that patients be taught about the pace and form of normal breathing patterns. Next clinicians can model normal, calm breathing as compared with overbreathing during an anxiety attack. The second hand of a watch can be used to time breaths so that they can be slowed to a normal rate. Positive, calming images can also be used to reduce anxiety during the breathing exercises. Finally, we suggest that

patients practice breathing exercises regularly to gain mastery of this anxiety management technique.

### Contingency Contracting and Behavior Exchange

These strategies use the principles of operant conditioning (Skinner, 1938) to modify the probability of occurrence of either undesired or desired behaviors. An excellent introduction to these methods is presented by Malott and colleagues (1993). One key to applied behavioral analysis is control over the contingencies or reinforcers. Another important factor is that the terms of the contract are negotiated and should be specific and relatively straightforward. The positive contingency or reinforcer should be desirable and available shortly after the terms of the contract have been met. A paycheck is a good example of a contingency contract. Another common strategy is to chain, or pair, a high-frequency behavior (e.g., reading, watching television, or listening to music) to a low-frequency one (e.g., doing paperwork, doing housework, spending time with the children). Contingencies should generally start out relatively “rich” (e.g., 1 hour of video game time after 15 minutes of paperwork) and may be progressively “thinned” in time (Malott *et al.*, 1993). Punishments or “response cost” contingencies are less widely used because of their negative affective responses (Azrin and Holz, 1966).

Behavioral contracts may be particularly useful for assisting patients with medication adherence. For example, the

therapist may help the patient identify barriers to taking medication as prescribed and then work out behavioral solutions which are written in contract form. Behavioral methods may include pairing medication taking with routine activities such as brushing teeth or meals, reminder systems and reinforcement from significant others. We recommend explicit discussion of adherence problems and mutual agreement on a plan for taking medications when patients have difficulty in following the pharmacotherapy plan.

### Desensitization and Relaxation Training

Systematic desensitization (Wolpe, 1958) was one of the first behavioral strategies to gain wide acceptance. Systematic desensitization relies on exposure through a progressive hierarchy of fear-inducing situations. This procedure may use pairing of progressive deep muscle relaxation and visualization of the target behavior to decondition fearful responses. Systematic desensitization is useful for treatment of simple phobias, social phobia, panic attacks and generalized anxiety (Wolpe, 1982). Some evidence suggests that the active ingredient of systematic desensitization is exposure to the feared situation, first in imagination and later in reality, rather than an actual counterconditioning through the relaxation response (Kazdin and Wilcoxin, 1976). Progressive deep muscle relaxation is also useful as a self-directed coping strategy and for treatment of sleep-onset insomnia (Goldfried and Davison, 1994; Bernstein and Borkovec, 1973).

### Exposure and Flooding

The purpose of these strategies is to speed extinction of conditioned fear or anxiety responses. Behavioral theory dictates that fearfulness is reinforced by avoidance and escape behaviors (Rachman *et al.*, 1986). Because the basis of the fear or phobia is irrational, the optimal strategy is to increase exposure to the feared activity without aversive consequences. In obsessive-compulsive disorder, the ritualistic behavior (e.g., handwashing or checking) is presumed to be reinforced by the relief of the anxiety associated with the compulsion (e.g., handwashing temporarily relieves the fear of contamination) (Rachman *et al.*, 1986). In exposure, there are at least three means of fear reduction: autonomic habituation, recognition that the fear is irrational and explicit enhancement of morale or self-efficacy that accompanies mastering the previously dreaded activity.

In graded or progressive exposure, a hierarchy is established, ranging from least to most anxiety-provoking situations. The individual is taught one or more ways to cope with anxiety (e.g., relaxation or self-instruction), and with the help of the therapist, the items on the hierarchy are worked through, one item at a time. Mastery is predicated on maintaining a sufficient duration of exposure for the fear to extinguish or dissipate. In some cases, imagery (exposure *in vitro*) is used before moving to exposure to the actual feared stimulus. Exposure may also be enhanced by guided support (i.e., the therapist's presence during the session) or by use of coping cognitions for the duration of the exposure exercise.

Flooding, which relies on the same principles, dispatches with the hierarchical approach. The individual is exposed to the maximal level of anxiety as quickly as possible. The rationale for this accelerated approach is that it may hasten autonomic habituation. To be effective, flooding needs to be accompanied by response prevention. In response prevention treatment of

OCD, the individual agrees not to perform the compulsion despite strong urges to do so. Because obsessions are more private than compulsions, there can be less certainty that the individual has fully participated in response prevention exercises (Stern, 1978).

Simple phobias may be rapidly treated by an accelerated form of exposure referred to as participant modeling or contact desensitization. The therapist serves as a supportive coach or guide and assists the patient through a progressively more demanding level of exposure to the feared situation. In most cases, lifelong fears of air travel, tunnels, heights, matches, dogs, water, or insects can be fully treated in a few hours of guided exposure.

### Social Skills Training

Satisfactory interpersonal relationships require a complex set of skills, including reciprocity, respect for another's opinion, appropriate modulation of self-disclosure, the tempered ability to yield on some occasions and to set limits at other times, the natural use of social reinforcers, and the capacity to express anger and resolve conflicts in a constructive manner (Lewinsohn *et al.*, 1982; Hersen *et al.*, 1984). Many people with psychiatric disorders suffer from either a state-dependent deterioration of these social skills or lifelong deficits of such skills. Once established, social skills deficits can increase the likelihood of experiencing stressful life events as well as "turn off" family members and other sources of social support that may help to buffer people against stressors (Coyne *et al.*, 1987).

Problems as diverse as underassertiveness, temper "attacks", excessive self-disclosure, monopolistic conversational style, underreinforcement of significant others and splitting (i.e., playing one against another) are amenable to social skills training. The methods employed include modeling (i.e., the therapist demonstrates a more effective alternative approach), role-playing and role reversal, behavior rehearsal and specific practice assignments. Often, the interpersonal anxiety and lack of self-confidence that go hand in hand with social skills deficits lessen in response to successful mastery of targeted assignments.

### Thought Stopping and Distraction

Automatic negative thoughts and repetitive, intrusive ruminations are sometimes too intense to address with purely cognitive interventions. The technique of thought stopping capitalizes on the individual's ability to use a selectively narrowed attentional focus to suppress the intrusive cognitions. For example, a ruminative individual may be asked to visualize a large red "stop" sign, including its octagonal shape and white lettering. The command "Stop!" is paired with the image. The image and command are then used to interrupt a "run" of ruminations. At first, the technique is practiced in sessions at times when automatic thoughts or ruminations are mild. After initial success, the technique is next applied to more intensely disturbing cognitions. For individuals who find visualization difficult or ineffective, a rubber band may be worn on the wrist as a distractor. In a manner similar to that described before, the command "Stop!" is paired with a brisk snap of the rubber band.

### Indications for Treatment

The cognitive and behavioral therapies are indicated as primary treatments for adults suffering from several nonpsychotic, nonorganic disorders including major depressive disorder,

dysthymic disorder, panic disorder, social phobia, OCD, post traumatic stress disorder (PTSD), generalized anxiety disorder and bulimia nervosa (Wright *et al.*, 2002b). Cognitive and behavioral therapies are also useful as adjunctive treatments for patients with bipolar disorder (Basco and Rush, 1996; Basco and Thase, 1998; Lam *et al.*, 2000) and schizophrenia (Mueser, 1998; Kingdon and Turkington, 1995; Senky *et al.*, 2000). Although not extensively studied, cognitive and behavioral therapies incorporating coping skills training and relapse prevention strategies may also improve the outcome of individuals with substance abuse disorders (Wright *et al.*, 2002b).

Cognitive and behavioral therapies, like most other types of treatment, have not been studied widely in patients with Axis II disorders. However, the CBT approach to problem specification and explicit training in coping skills may be well suited for treatment of individuals willing to work on changing these habitual, ingrained patterns of thinking and behavior (Beck *et al.*, 1990). Specific cognitive-behavioral formulations have been developed for each of the personality disorders, and modifications of CBT methods have been described for working with patients with Axis II problems (Beck *et al.*, 1990). Linehan's model of CBT (dialectical behavior therapy) has been shown to be efficacious in reducing parasuicidal behavior in patients with borderline personality disorder (Linehan *et al.*, 1991, 1993).

### Selection of this Modality

Selection of CBT for an individual patient should be based on the appropriateness of CBT for the treatment situation. Relevant questions include: Is the patient psychotic? If so, are there specific target behaviors and has psychopharmacological treatment been optimized? Does the patient suffer from a disorder known to be responsive to CBT? Within groups of patients with potentially treatable disorders, other indicators of responsivity include chronicity, severity and comorbidity (Whisman, 1993; Thase *et al.*, 1993). A good general rule is that patients with acute, mild to moderately severe, mood and anxiety disorders are the best candidates for treatment with CBT alone (Thase, 1995). Patients with more chronic, severe, or complicated illnesses may be better candidates for combined treatment strategies than for CBT alone (Wright and Thase, 1992; Thase and Howland, 1994; Friedman, 1997). McCullough (2000) has developed a variant of CBT for chronic depression that has shown much promise alone and combined with antidepressant medication.

### Preparation of the Patient

The cognitive and behavioral therapies explicitly incorporate strategies to increase involvement and preparedness of the patient for therapy. Patients are typically encouraged to read relevant written materials describing the theory and strategies of the therapy; for common disorders, such as major depressive disorder and panic disorder, self-help manuals for patients are now available (Burns, 1990; Greenberger and Padesky, 1995; Wright and Basco, 2001). Patients beginning CBT need to become acculturated to the following: 1) they will be active participants in trying out new strategies; 2) they will be expected to do homework; 3) the outcome of therapy will be measured and strategies will be altered if they are not helping; 4) therapy will be focused on symptoms and social functioning and generally will be time limited in nature; and 5) the chances of success after treatment termination can be gauged by the patients' incorporation of the therapy into their day-to-day life.

### Phases of Treatment

Most cognitive and behavioral therapies may be viewed as using a three-stage process. The initial phase includes the processes of clinical assessment, case formulation, establishment of a therapeutic relationship, socialization of the patient to therapy, psychoeducation and introduction to treatment procedures. The middle stage involves the sequential application and mastery of cognitive and behavioral treatment strategies. The second stage ends when the patient has obtained the desired symptomatic outcome. The final phase of therapy is characterized by preparation for termination. The frequency of sessions is reduced, and there is a steady transfer of the responsibility for the continued use of therapeutic strategies from the therapist to the patient. The third stage of treatment also focuses on relapse prevention. Strategies used at this point include anticipation of reaction to future stressors or high-risk situations, identification of prodromal symptoms, rehearsal of self-help procedures and establishment of guidelines for return to treatment (Otto *et al.*, 1993; Thase, 1993). The failure to achieve a remission of depressive symptoms after 16 to 20 weeks of treatment may indicate a need for continuation phase treatment to achieve these goals and maintenance phase treatment for relapse prevention. Incomplete symptomatic remission after 20 weeks of CBT may also indicate the need for adding pharmacotherapy to the treatment plan as we discuss in greater detail below.

### Intensity of Treatment

Outpatient CBT is normally conducted once or twice a week. In selected cases, three-times-weekly or even daily sessions may be useful, but the cost-effectiveness of such a labor-intensive approach is uncertain. Therapists should adjust the frequency and intensity of treatment in concert with the needs of patients as well as the therapy resources that are available.

### Duration of Treatment

In most cases, treatment is conducted in a period of 3 to 6 months. For those who begin therapy as inpatients, a similar period of aftercare is strongly recommended (Thase, 1993). Unsuccessful therapy (e.g., failure to effect significant symptomatic improvement) should generally not continue past 12 to 16 weeks for outpatients. Therapy should not be terminated until patients have achieved symptomatic remission. Ideally, at least two or three sessions are planned on an every-other-week basis in preparation for termination.

### Outcome Assessment

Cognitive and behavioral therapies are, in part, distinguished by their integrated use of objective assessment methods. For depression and the anxiety disorders, a number of well-established rating scales are available. Therapist-administered scales include the Hamilton Anxiety Rating Scale (Hamilton, 1959) and the Hamilton Depression Rating Scale (Hamilton, 1960) as well as the Yale-Brown Obsessive-Compulsive Scale (Goodman *et al.*, 1989). Self-report assessments of symptoms include the Beck Depression Inventory (Beck *et al.*, 1961), the Beck Anxiety Inventory (Beck *et al.*, 1988), the Fear Survey Schedule (Wolpe and Lang, 1964), the Fear Questionnaire (Marks and Matthews, 1979) and the Hopkins Symptom Checklist (Derogatis *et al.*, 1974). These scales are typically administered before treatment

and repeated periodically (e.g., weekly or monthly) to monitor progress. The Dysfunctional Attitudes Scale, the Attributional Style Questionnaire and the Automatic Thoughts Questionnaire may be used to evaluate distorted cognitions (Dobson and Shaw, 1986). As suggested earlier, high residual levels of cognitive symptoms most likely convey an increased risk for relapse after termination of treatment (Thase *et al.*, 1992; Simons *et al.*, 1986). Similarly, high scores on the Hopelessness Scale (Beck *et al.*, 1974) have been associated with a high risk for subsequent suicidal behavior (Beck *et al.*, 1985b).

### Augmentation of Therapy

One of the major methods of augmenting a cognitive and behavioral therapy is to add an appropriate form of pharmacotherapy. For example, a depressed or agoraphobic person who has not benefited much from 8 weeks or more of CBT alone should probably be considered for pharmacotherapy. There are no contraindications to combining CBT and pharmacotherapy (Hollon *et al.*, 1991; Wright and Thase, 1992).

### Continuation and Maintenance Phase CBT

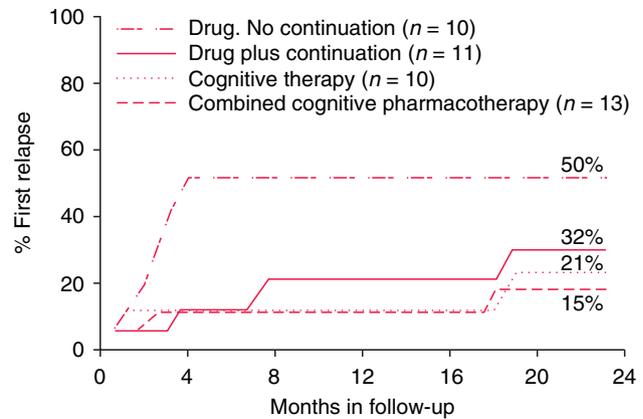

Because some patients do not completely achieve a remission of symptoms (their return to premorbid well state) and because many patients experience depression as a recurring illness, there is a need for longer-term treatment methods for major depression (Kupfer *et al.*, 1986). Furthermore, incomplete remission of depression leads to recurrence, and this has many adverse economic, interpersonal and medical consequences (Thase, 1992).

### Efficacy of CBT

The cognitive and behavioral therapies are, as a class, the best studied type of psychotherapy. Numerous research studies have demonstrated the efficacy for a variety of Axis I DSM IV disorders including mood disorders (Thase, 1995; Dobson, 1989; Depression Guideline Panel, 1993), anxiety disorders (Wolpe, 1982; Clum *et al.*, 1993; Beck and Zebb, 1994; Chambless and Gillis, 1993; Durham and Allan, 1993; Butler *et al.*, 1991; Barlow *et al.*, 2000) and eating disorders (Agras *et al.*, 1992, 1994, 2000; Fairburn *et al.*, 1991, 1992, 1993, 1995; Garner 1992; Goldbloom *et al.*, 1997; Walsh *et al.*, 1997; Wilson, 1999; Ricca *et al.*, 2000). CBT approaches have also been used to treat personality disorders and as part of multimodal treatments for schizophrenia and bipolar disorder.

### Conclusion

The cognitive and behavior therapies are based on well-articulated theories that have a strong empirical basis. These therapies emphasize objective assessments and use of directive interventions aimed at reducing symptomatic distress, enhancing interpersonal skills, and improving social and vocational functioning. Cognitive interventions are focused primarily on identifying and modifying distorted thoughts and pathological schemas. Behavioral techniques to increase exposure, increase activity, enhance social skills and improve anxiety management are useful modalities, and can complement or amplify the effects of cognitive strategies. Similarly, the cognitive perspective can add depth to behavioral models for therapy by teaching patients how to recognize and modify their attitudinal vulnerabilities.

**Figure 69.8** Risk of relapse after cognitive therapy and pharmacotherapy, singly or in combination. Reproduced with permission from Evans MD, Hollon SD, DeRubeis RJ *et al.* [1992] Differential relapse following cognitive therapy and pharmacotherapy for depression. *Arch Gen Psychiatr* 49, 802–808. Copyright 1992, American Medical Association.

The cognitive and behavioral therapies are the best-studied psychological treatments of major depressive, panic, generalized anxiety and obsessive-compulsive disorders. Overall, there is good evidence for the effectiveness of these interventions within these indications. Cognitive and behavioral therapies are being adapted for adjunctive use with pharmacotherapy for treatment of bipolar disorder and schizophrenia. There are no contraindications for use in combination with pharmacotherapy. The cognitive and behavioral therapies have become one of the standard psychosocial treatment approaches for mental disorders.

Family therapy is psychotherapy that directly involves family members in addition to the identified patient, and/or explicitly attends to the interactions among family members (Pinsof and Wynne, 1995). Family therapy thus engages relational and communicational processes of families and social networks as a primary context for solving clinical problems or treating psychiatric disorders, even though one family member may be the sole bearer of distress or symptoms. By educating family members or altering family patterns of relating or communicating, such clinical problems as depression, anxiety, marital conflict, or disruptive childhood behavior can be resolved or attenuated.

The different family therapy traditions can be usefully contrasted by comparing how each structures perceptual, cognitive, and executive processes when clinicians work with families – from each of these perspectives:

- What does a therapist look for?
- What does a therapist think about?
- What does a therapist do?

Different family therapy traditions are themselves best regarded as different sets of ideas and interventions to be valued as potential tools within comprehensive, multimodality treatment programs. We will illustrate the range of perspectives and interventions available in the different traditions by examining, in turn, how psychodynamic, structural, strategic, cognitive-behavioral and postmodern family therapy traditions each might approach a clinical problem.

### Psychodynamic Family Therapy

Psychodynamic psychotherapy helps family members solve relational problems by understanding better how emotional processes influence the perceptions, feelings and actions of those involved. The early psychoanalysts noted that intrapsychic processes of an individual powerfully shape his or her interactions with other people, and most so in emotionally intimate relationships of couples and families. Extending the concepts and language of psychoanalysis to family behavior was a logical next step for those who began meeting with parents and children, couples and whole families. In particular, object relations theory provided a bridge from the individual intrapsychic processes to the interpersonal processes of families (Scharff and Scharff, 1987; Framo, 1991; Slipp, 1991).

#### What to Think About

In order to understand how one family member acts in relation to other family members, psychodynamic family therapy concen-

trates upon motivations, conflicts, defenses and relationships from the past that currently influence the present. Family interactions are explained in terms of internal processes within individual family members. Therapeutic change is sought through family members gaining conscious insight into previously unconscious processes that have been generating problems in family relationships.

#### What to Look For

Psychodynamic family therapy grounds its work in historical information. Extensive individual and family histories are elicited in order to understand family members' experiential models of the world. These experiential models govern how meanings are attributed to such family patterns as rules for how people should respond and models for being a man or a woman, husband or wife, or mother or father. These models have developed out of each family member's personal history, the family's history and mythology, and their cultural history. Some of the diagnostic patterns upon which psychodynamic family therapists focus when assessing families include the following:

- **Projective Identification** Projective identification is an ego defense to which psychodynamic family therapists have attributed a crucial role in conflictual family relationships. In projective identification, one family member (a parent or couple partner) relates to another family member (a particular child or the other couple partner) as if he or she embodied a projected part of self. The projecting family member then interacts with, or relates to, the projected part of self as if that part were an internalized part of himself or herself. The projecting family member unconsciously prompts the other to conform to the way in which he or she is being perceived, evoking in the other the associated feelings and behaviors as if they were authentic. When viewed from the outside by the therapist, it appears as if the two are in collusion with one another in order to sustain these mutual, projected perceptions. Projection of disavowed elements of the self, whether positive or negative, has the effect of charging the relationship with emotion that has been transposed from an intrapsychic sphere into an interpersonal one. Acted out interpersonally, it serves to decrease psychic anxiety at the expense of an increase in tension and impasse in the relationship.
- **Unresolved Grief** When a family member, or the family as a whole, has not fully grieved losses, the family can become developmentally frozen. While so preoccupied with the past, it can be difficult to focus enough time and energy on current problems.
- **Clarity of Ego Boundaries and Capacity for Intimacy/Separateness** Conflicted family relationships can represent an alternative method for stabilizing emotional distance when

the involved family members lack the emotional maturity to regulate closeness and distance in more differentiated ways. This has been a common model for understanding couples who chronically fight yet never separate.

### What to Do

Psychodynamic family therapists employ the fundamental tools of psychodynamic psychotherapy (opening emotional expression, clarifying communications, encouraging family members to speak from the “I” position, and interpretation of unconscious conflicts) to resolve projective processes, cutoff relationships, and difficulties in modulating closeness and distance in family relationships. Psychodramatic techniques, such as doubling and role reversal, can play useful roles in implementing these interventions (Blatner, 1994). Therapeutic rituals are particularly useful in facilitating grief over losses and in facilitating developmental transitions, such as a young adult leaving home or a couple moving into retirement years (Imber-Black and Roberts, 1992).

### Structural Family Therapy

Structural family therapy considers problems involving a particular family member to be inextricably linked to the organizational context of the entire family. It solves problems by changing the family’s organizational context. Structural family therapy thus emphasizes an understanding of a family in terms of the family roles and roles that shape its members’ actions.

Family structure is the internal organization of the family that dictates how, when and to whom family members relate while carrying out the various functions of the family (Aponte and VanDeusen, 1981; Colapinto, 1991). Some important elements of family structure for clinical work are boundaries, hierarchy, alliances and coalitions:

- **Boundaries** Rules defining who participates and how, in particular moments of family life. For example, a boundary around the parental couple means that the children are included in discussions of certain topics but not in others;
- **Hierarchy** Relative influence of each family member upon the outcome of an activity. For example, all family members may have opinions about spending money, but the parents as a couple typically have the final say;
- **Alliances** Family members joining together to support another family member. For example, older children may join the well-parent in organizing to parent younger children if the other parent were to become seriously ill;
- **Coalitions** Family members joining together in opposition to another family member. For example, a grandchild and grandmother might quietly ally together for the child to stay up late at night against the mother’s wishes when the child is at grandmother’s house.

The family structure should provide cohesive and flexible responses to life stresses so that important family functions – parenting, providing income, marital intimacy, recreation and other activities – can be carried out successfully, and family members can grow and mature in their individual lives.

### What to Look For

A structural family therapist observes closely the flow of family structures as family members talk about and interact together

around the presenting problem of the therapy. The therapist wishes to witness how sequences of family behaviors are enacted during interactions in the sessions, particularly the occurrence of a symptom as it is embedded within different configurations of organized family interactions. The therapist observes how boundaries, hierarchy, alliances and coalitions are associated with the presenting symptom, as well as any repetitive-behavioral sequences (verbal or nonverbal) that involve symptomatic behavior.

### What to Think About

The structural family therapist considers the problem to be sustained by the current family structure and its community ecosystem. Important questions to answer in assessing these relationships include:

- To what elements of family structure – boundaries, hierarchy, alliances, coalitions – do occurrences of the presenting problem appear linked?
- What family functions are blocked by the problem? If not for the problem, what would be happening that is not happening now?
- For whom is the problem a concern? Who is most affected? Who would need to change for the symptom to disappear?

### What to Do

Structural family therapists ameliorate symptoms by shifting family structure. Boundaries can be strengthened or weakened by behavioral assignments that exclude a particular family member from certain moments of family life (e.g., an assignment for parents to leave children with a baby sitter to go on a date alone) or include a particular family member where that person had been absent (e.g., involving both parents in collaborative disciplining of a misbehaving child when the father had been only peripherally involved). Alliances are encouraged when they support the individual development of family members and strengthen the family as a whole. Secret coalitions, particularly when they cross generational boundaries, are targeted for therapeutic disruption as when one parent covertly supports a child’s oppositional behavior with the other parent.

### Strategic Family Therapy

Strategic therapy is built upon the premise that a therapist is responsible for planning a strategy that solves successfully the family’s presenting problem. The therapist sets clear goals that intervene by changing relational and communicational processes in the family (Madanes, 1981; Stanton, 1981). Strategic therapy was designed as a counterpoint to psychodynamic psychotherapy by emphasizing “how” people can behave differently in order to solve problems, rather than “why” they behave as they do.

### What to Think About

The focus of strategic therapy is upon problem solving. Problems are viewed as persistent efforts by one or more family members to apply a solution that makes sense but is inadequate for the problem at hand, such that “the solution becomes the problem”. Common-sense understandings often lead people to pursue unsuccessful strategies even though it ought to be apparent that the problem is not resolving. For example, people intuitively attempt to cheer up a person who is depressed, even though cheering up (a solution) usually makes the depression (the problem) worse.

Strategic therapists commonly view clinical problems as emerging out of difficult life-cycle transitions, both predictable ones (e.g., marriage, birth of a child, separating/individuating of an adolescent) and unpredictable ones (e.g., loss of job, sudden illness, a death in the family) that necessitate shifting to new patterns of perceiving and acting. At such times when innovative problem-solving is needed, people nevertheless persist with once successful strategies that are now outdated.

### What to Look For

Strategic therapists are most interested in the here-and-now context of the problem, rather than in its history. They seek to learn what each involved person believes about the problem and how these beliefs are acted upon in efforts to generate a solution. Questions are asked about who, what, when, where and how people are involved, in order to ascertain how moves are sequenced in the family game.

### What to Do

The central aim of a strategic therapist is to motivate family members to try novel solutions, rather than repeating what has been tried in the past. Psychoeducation, direct behavioral assignments, and paradoxical or defiance-based directives are the cornerstones of strategic therapy. In-session interventions and out-of-session homework are used. Strategic therapists have become best known for their paradoxical directives. Paradoxical directives include:

- **Reframing or Relabeling the Symptom** By changing the context of actions constituting the symptom, the meaning of the event is reframed. For example, a husband's emotional distancing could be reframed as "his way of getting his wife to notice him".
- **Prescribing the Symptom or Behavioral Sequence** By using a rationale that is plausible in its logic, a therapist can encourage family members to engage in the very behavior that needs to be eliminated. For example, a wife whose husband is emotionally distancing might be told to continue to pursue her husband because "this lets him know that he is the center of her life and that there is nothing else about her life that she finds valuable or interesting". She might be instructed to continue in her behavior for his sake, even though it may give her friends a distorted idea about her. When the reframe "fits", yet the new meaning feels distasteful, the rebound against the directive can paradoxically propel therapeutic change.
- **Restraining the System** The therapist can attempt to discourage or even deny the possibility of change. For example, a therapist may tell couple-partners to "go slow" or may emphasize dangers of improvement. Family members may then react against the therapist's conservative outlook by pressing forward to change.
- **Positioning** The therapist attempts to shift a problematic "position" (usually an assertion that the patient is making about self, the problem, or a partner) by accepting but exaggerating that position. This intervention is used when the partner's position is thought to be maintained by its complementary, reciprocal response from the other partner. For example, when one partner takes an optimistic stance and the other a pessimistic one, a therapist may suggest the pessimistic spouse to worry even more so that the optimistic spouse can feel more secure and even more happily optimistic. Here, too, if a new explanation has a plausible logic, but frames the behavior in a manner that renders it aversive, the behavior will change.

## Cognitive–Behavioral Family Therapy

Cognitive–behavioral family therapy applies principles of learning theory to help family members solve problems by modifying cognitive distortions and repetitive problem-inducing interactions, and by learning new knowledge and skills. Cognitive–behavioral family therapy relies heavily upon family psychoeducation and a teaching/coaching stance of the therapist.

Cognitive interventions engage family members as coinvestigators who study the ecology of family problems and symptoms and discern how thoughts, feelings and behaviors interplay. A therapist assists family members in identifying when such cognitive distortions as catastrophic thinking, overgeneralization, or misattributions lead to conflicts in relationships (Epstein *et al.*, 1988; Freeman *et al.*, 1989).

### What to Look For

Families presenting problems for therapy often have:

- difficulties in recognizing deviant behavior
- lack of clearly-defined family rules
- problems in emotional communication among family members, usually a paucity of expression of positive feelings coupled with an excess of negative expressions
- relational conflict associated with either a paucity of relational skills or interpretive errors based on faulty assumptions or cognitive distortions.

### What to Think About

A cognitive–behavioral family therapist considers each member of the family to be doing his or her best to cope with the behavioral contingencies perceived at that point in time, given the practical and emotional restraints experienced. Family members need to acquire knowledge about cognitive and behavioral principles, to gain skills needed to reinforce desired behaviors, to eliminate reinforcement of undesired behaviors, to modify faulty assumptions and interpretations of others' actions, and to learn skills for communicating clearly and effectively.

### What to Do

- **Psychoeducation** Educational modules about the presenting problem are taught when family members appear to lack a significant understanding of issues, ranging from such general topics as developmental milestones of children and principles of learning theory, to specific information about a particular psychiatric disorder (Falloon, 1991).
- **Communication training** Empathic listening, expressing positive feelings, and speaking negative communications more respectfully are taught as skills (Falloon, 1991).
- **Problem-solving training** Family members practice consistent, structured approaches for resolving conflicts (Falloon, 1991).
- **Operant-conditioning strategies** Behavior shaping and time-out procedures are taught to increase desirable behaviors among children (Falloon, 1991).
- **Contingency contracting** Coercive, blaming patterns of family behavior are replaced by contracts that specify what behaviors involved family members each to agree to perform (Falloon, 1991).
- **Thought diaries** Out-of-session, assignments are made to track habitual patterns of thoughts, feelings and behaviors in generating symptoms (Freeman *et al.*, 1989).

## Postmodern Family Therapies

Innovations introduced by postmodern therapies including narrative, solution-focused, collaborative language systems and feminist family therapies (Andersen, 1987; Anderson, 1997; de Shazer, 1985; Epston, 1989; Epston and White, 1992; Freedman and Combs, 1995; Griffith and Griffith, 1994; Madsen, 1999; O'Hanlon and Weiner-Davis, 1989; Penn, 2001; Tomm, 1987; Weiner-Davis, 1992; Weingarten, 1995; White, 1989, 1995, 2000) have opened new ways for families to solve problems by valuing and learning from their own experiences, histories, traditions, values and identities, instead of seeking answers from mental health experts. The postmodern therapies have sought to empower families by helping them to develop reflective processes for exercising choice, to build supportive communities with other families, and to clarify undesirable ways in which cultural influences have limited appreciation and utilization of the family's own practical wisdom. In these ways, the postmodern family therapies have rendered family therapy more usable for those whose lives vary from the stereotypic American two-parent, middle-class, nuclear families, traditionally the largest consumers of private-practice family therapy.

The postmodern therapies have made contributions that have broadly influenced the clinical practice of family therapy through:

- the art of crafting interview questions for fostering reflection and creative problem-solving;
- clinical methods that help patients and families to identify and use skills, competencies, and resources from their everyday lived-experiences;
- clinical methods that counter adverse influences of culture in generating and maintaining problems that families face.

## What to Think About

Each person makes sense out of his or her life experiences by attributing meaning to them. This meaning is shaped by a canon of personal narratives as they are told and retold to self and to others. Among the most important of these narratives are those of identity about who one is as a person and as a family. There are certain dominant narratives in a person's life that, more than others, organize one's perceptions, cognitions and actions. How a family member views oneself and the other family members is shaped by the limits of the language – the metaphors, stories and beliefs – he or she employs.

Impasses occur in family relationships, and problems emerge when:

- one or more family members lack either the needed emotional vocabulary or the needed narrative skills to make one's personal experience understandable to others;
- the available narratives preclude ways of relating other than conflictual ones;
- specific words hold very different meanings for different family members due to different personal narratives connected to the language (e.g., "loyalty," "trust," "safety");
- family members have become positioned relationally such that they cannot hear, tell and/or expand their stories in conversation, i.e., they have become confused by or habituated to the conflict such that they have stopped listening.

Therapy provides a context where narratives that limit and constrain relationships can be identified. The power of

constraining narratives can be attenuated through careful interviewing that renders visible the specific historical, cultural, or political contexts from which they emerged and the hidden interpretive assumptions upon which they rest. Alternatively, more useful narratives often lie unnoticed within forgotten experiences the partners have had with one another, but are now outside their recollection.

## What to Look For

- Listen for the exact words and precise manner in which people use language. The focus of therapy is the language itself and the limits of its possibilities, not what this language is interpreted to mean.
- Metaphors, phrases and prominent or repetitive words in the family members' specific uses of language are noted as "doors to be knocked upon" by asking specific questions about stories of lived-experience that have given them meaning.
- "Unique outcomes" or "exceptions" when problems might have been expected to occur, but did not.

## What to Do

Narrative approach to therapy consists of two phases:

- **First Phases:** A first priority is creation of a therapeutic relationship within which important first-person narratives can be safely told, heard and changed. In particular, the therapist carefully watches for nonverbal signs that the dialogue is opening up or closing down, such as family members' breathing, posture, and flow and tone of speech. Creating a relationship and a conversation favorable for the telling of important personal stories is the priority, not gathering data.
- **Second Phase:** As important first-person narratives relevant to the problem are told, the therapist asks carefully designed questions that facilitate:
  - a. retrieval of other forgotten, or unnoticed, narratives that might enhance solving the problem of the therapy, in contrast to the dominant narrative;
  - b. cocreation of an alternative narrative to a form that holds more possibilities for resolving the problem of the therapy;
- The therapist utilizes such questions as circular, reflexive, unique outcome, or relative influence questions (Tomm, 1987; White, 1989).
- A solution-focused therapist may assign couple-partners the task of studying segments of time when the problem is "not" occurring, looking for "exceptions..." Examples of solution-focused questions include:
  - a. "Between now and the next time we meet, I would like you to observe – so that you can describe to us next time – what happens between both of you that you do value, would NOT want to change, and would like to see continue to happen in the future".
  - b. The Miracle Question (de Shazer, 1985): "Suppose that one night, while you were asleep, there was a miracle and this problem was solved. How would you know? What would be different? How would your partner know without your even saying a word about it?" [The therapist then negotiates with the partner(s) what part of this new reality the partner(s)

would be willing to implement the next day, as if the miracle had occurred.]

- c. (Weiner-Davis, 1992) “If the problems between you and your partner got resolved all of a sudden, what would you do with the time and energy you have been spending on fixing or worrying about the marriage? Describe what you would do instead?”
- d. (Weiner-Davis, 1992) “What might be one or two small things that you can do this week that will take you one step closer to your goal?”
- e. (Weiner-Davis, 1992) “What, if anything, might present a challenge to your taking these steps this week, and how will you meet the challenge?”

### Family Psychoeducation Therapies

The earliest approaches to family therapy were built upon individual psychotherapy and simply extended to the family their ideas about diagnosing and treating psychopathology, referring to “family pathology” instead of psychopathology. Early versions of psychodynamic, structural, strategic and cognitive-behavioral family therapies each assessed underlying family pathology and engaged families in corrective treatments. By the 1990s, however, family therapies were shifting to more collaborative therapeutic relationships in which families were regarded as allies, rather than sources of pathology, with education, rather than treatment, as the central focus.

This shift brought a sea change in how family therapy began to be practiced. Instead of diagnostic scrutiny, clinicians became preoccupied with learning to convey respect to families, to protect them from stigma, and to learn from their real-life experiences coping with illness. A focus on “looking at” families diagnostically in order “to intervene” in the family system, was gradually eclipsed by a commitment to “looking with” families as they coped with illness in order “to collaborate” with them in countering effects of illness on the family.

By the 1980s, some family therapists working with schizophrenia were proposing that family therapy could be more effectively applied by engaging families as partners in treatment, instead as sources of psychopathology. These efforts were characterized by a fresh set of assumptions (Dixon and Lehman, 1995):

- Severe psychiatric disorders, such as schizophrenia and bipolar disorder, are regarded as illnesses.
- The family environment does not cause the disorder but can influence its course and severity.
- Support is provided to families who are enlisted as partners and collaborators in treatment.
- Family interventions are only one component in a treatment program that includes routine drug treatment and outpatient clinical management.

These new clinical approaches mixed psychoeducation, behavioral problem-solving training, family support and crisis management in interventions with either individual families or groups of families.

As a research contribution, the construct of expressed emotion (EE) played a significant role in the evolution of family psychoeducation (Leff and Vaughn, 1985). During a structured interview, families were given an EE rating based on observations of critical comments, hostility and overinvolvement. Over

two decades an enormous body of research suggested that patients living with families characterized by high levels of EE were more vulnerable to relapse (Anderson *et al.*, 1986). Interventions were then designed that relied heavily upon family psychoeducation in order to enable high EE families to change to a low EE status.

Elements that appeared to be tied to its outcome effectiveness include:

- Creation of social contacts and support;
- Problem-solving with others bearing the burden of the same disorder;
- Countering stigma;
- Cross-parenting of adolescents;
- Normalizing family communications;
- Intervening effectively during crises.

Family-focused psychoeducational interventions also have been developed for other psychiatric disorders. Family-focused treatment for bipolar disorder, for example, integrates family psychoeducation, communication training and problem-solving into a 20-session therapy extending over most of a year. This intervention in a controlled study has been shown to delay relapse of bipolar disorder (Miklowitz and Goldstein, 1997; Miklowitz *et al.*, 2000).

### Family Resilience Therapies

While family psychoeducation approaches have focused on roles that families can play in reducing frequency of illness relapse or buffering its severity, family resilience interventions extend this strategy to identify salutary family processes that not only buffer severity of illness, but prevent its onset for those at risk. Key processes can be identified that enable couples and families facing disruptive crises or persistent stresses to strengthen relationships, regain functioning and further the growth of its individual members (Walsh, 1998; Wolin and Wolin, 1993).

Family resilience refers to coping and adaptational processes in the family as a functional unit (Walsh, 1998; Wolin and Wolin, 1993). From this perspective, a stressor affects at-risk children only to the extent that they disrupt crucial family processes that otherwise would neutralize or buffer the stressor (Patterson, 1983). Family resilience rests upon several systemic principles (Walsh, 1998, p. 24):

- The hardiness of individuals is best understood and fostered in the context of the family and larger social world, as a mutual interaction of individual, family and environmental processes.
- Crisis events and persistent stresses affect the entire family, posing risks not only for individual dysfunction but for relational conflict and family breakdown.
- Family processes mediate the impact of stress on all members and their relationships, with protective processes fostering resilience by buffering stress and promoting recovery, and maladaptive responses heightening vulnerability and risks for individual and relationship distress.
- All families have the potential for resilience, which can be maximized by encouraging their best efforts and strengthening key processes.

With programs such as Beardslee’s (Beardslee *et al.*, 1999), family resilience programs have moved past treatment of acute illness and relapse prevention, to primary prevention of the

**Table 70.1 Resilience Factors That Protect Children At Risk for Depression Due to Living with a Depressed Parent**

- Becoming activists and doers
- Becoming heavily involved in school and extracurricular activities
- Developing deep commitments to and involvement in interpersonal relationships
- Seeking self-understanding as a way to deal with a parent's depression
- Expressing articulate understandings of the parent's illness and problems ensuing from it
- Refusing to feel blame or guilt for the parent's illness
- Learning to link life experiences in the family to factual information about depressive disorders
- Acquiring an active voice in family discussions about the illness

*Source:* Beardslee WR (1998) Prevention and the clinical encounter. *Am J Orthopsychiatr* 69(4), 521–533; Beardslee W, Versage EM, Salt P *et al.* (1999) The development and evaluation of two preventive intervention strategies for children of depressed parents, in *Rochester Symposium on Developmental Psychopathology, Vol. 9, Development Approaches to Prevention and Intervention* (eds Cicchetti D and Toth SL). University of Rochester Press, Rochester, New York.

disorder itself. Such programs identify risk factors and protective factors for onset of illness; relate these factors to family organization, communications, and knowledge of the disorder; and design family interventions that enhance family understanding, attenuate risk factors, and amplify protective factors (see Table 70.1).

## Summary

Family therapy has evolved from a treatment modality that searched family relationships for the causes of mental illness to a framework for engaging the strengths and competencies of families in solving clinical problems and treating psychiatric disorders. The various clinical traditions of family that matured during the 1960s and 1970s remain rich sources of ideas and interventions that can be integrated into multimodality programs alongside family psychoeducation, individual psychotherapy and psychopharmacology. Such family-centered approaches as multifamily psychoeducation groups are sufficiently supported by empirical research to be regarded as evidenced-based practices. Family-centered models for primary prevention of major psychiatric disorders and family-centered community mental health programs for immigrant, refugee and international populations represent the developing frontiers of family therapy.

## Appendix I

### Psychodynamic Family Therapy

#### What to Look For

- Projective identification
- Unresolved grief
- Clarity of ego boundaries and capacity for intimacy/separateness

### What to Think About

- Internal processes within individual family members shape family interactions.
- Family members' motivations, conflicts, defenses and relationships from the past, currently influence present relationships.
- Therapeutic change occurs through family members gaining conscious insight into previously unconscious processes generating problems in family relationships.

#### What to Do

- Opening emotional expression in family relationships
- Clarifying communications
- Encouraging family members to speak from the “I” position
- Interpretation of unconscious conflicts to resolve projective processes, cutoff relationships, and difficulties in modulating closeness and distance in family relationships
- Psychodramatic techniques, such as doubling and role reversal
- Therapeutic rituals to facilitate developmental transitions and grief over losses
- Family genograms

### Structural Family Therapy

#### What to Look For

Contrasting the particular family structure with that “normal” to the culture and developmental stage in terms of:

- Organization (structure)
- Rules (sequences of action)
- Roles that shape family members' actions
- Boundaries
- Hierarchy of power
- Alliances
- Coalitions
- Verbal and nonverbal behavioral sequences.

#### What to Think About

Presenting problem results from a family structure out of alignment with the culture and the developmental stage of the family.

#### What to Do

- Actively shift the family structure
- In-session enactments
- Out-of-session homework assignments

### Strategic Family Therapy

#### What to Look For

- Here-and-now context of the problem
- Who, what, when, where, and how people are involved in trying to solve the problem

#### What to Think About

- “The solution to the problem is the problem”.
- Difficult life-cycle transitions give birth to clinical problems when people persist in old coping strategies but relational and

communication processes need to change to meet new life contexts.

### What to Do

- Psychoeducation
- Direct behavioral assignments to adopt new problem-solving strategies
- Defiance-based, paradoxical interventions

## Cognitive–Behavioral Family Therapy

### What to Look For

- Family member difficulties in recognizing deviant behavior
- Lack of clearly-defined family rules
- Problems in emotional communication among family members, usually a paucity of expression of positive feelings coupled with an excess of negative expressions
- Relational conflict due to a paucity of relational skills
- Relational conflict due to interpretive errors based on faulty assumptions or cognitive distortions

### What to Think About

- Each member of the family is assumed to be doing his or her best to cope with the behavioral contingencies perceived at that point in time, given the practical and emotional restraints experienced.
- Family members need to learn cognitive and behavioral principles of learning.
- Family members need to gain skills needed:
  1. To reinforce desired behaviors;
  2. To eliminate reinforcement of undesired behaviors;
  3. To modify faulty assumptions and interpretations about other family member's actions;
  4. To learn skills for communicating clearly and effectively.

### What to Do

- Conduct psychoeducation about the presenting problem.
- Conduct skill training in empathic listening expressing positive feelings and speaking negative communications respectfully.
- Conduct training in problem-solving and conflict-resolution skills.
- Teach operant conditioning strategies for behavior shaping with children.
- Teach principles for contingency contracting to replace coercive and blaming behaviors with contracts specifying what each family members agrees to perform.
- Teach family members to utilize behavioral observation and thought diaries in out-of-session assignments to track patterns of thoughts, feelings and behaviors that generate symptoms.

## Postmodern Family Therapies

### What to Look For

- Listen for exact usage of language expressed as metaphors, stories and beliefs.

- Listen for first-person narratives from family members' lived-experiences that imbue with meaning such abstractions as "love," "trust" and other important language of relationships.
- Note exceptions, or unique outcomes, when problems might have occurred but surprisingly did not.
- Note what is happening at times when problems are absent.

### What to Think About

- The limits of a person's language constitutes the limits of his or her experiential world.
- Narratives, or stories, are the basic units of human experience.
- A canon of personal narratives shapes the meaning each family attributes to his or her experience.
- Narratives of identity, about who one is as a family member, and who we are as a family, strongly influence family interactions.
- Family conflicts emerge:
  1. When lack of narrative skills makes their experiences unintelligible to others;
  2. When the available narratives preclude ways of relating other than conflictual ones;
  3. When specific words or expressions hold very different meanings for different family members due to the personal narratives with which they are associated;
  4. When family members become positioned relationally such that they cannot hear, tell, and/or expand their stories in conversation.

### What to Do

- Focus on creating a dialogue in which important personal narratives can be safely expressed, heard, and reflected upon by family members.
- Ask questions that elicit forgotten, or unnoticed, narratives of family life that open better possibilities for solving problems than the current narratives that have dominated the family dialogue.
- Engage family members in an inquiry of:
  1. What is happening in family interactions when problems are being solved successfully and symptoms are not occurring.
  2. Skills, practical knowledge, competencies and resources of the family that can be brought to bear upon the problem.

### What Is “Couples Therapy?”

Marital or couples therapy can be defined as a format of intervention involving both members of a dyad in which the focus of intervention is the problematic interactional patterns of the couple. In this chapter, we will use marital and couples therapy interchangeably as the majority of the issues are the same. The focus of couples therapy is on the dyad and its intimate emotional and sexual aspects.

Couples therapy is distinguished by the peer relationship of the participants, the ever-present question of commitment, and a need carefully to attend to gender issues. In general, even behaviorally focused couples therapy must attend particularly to the feeling level with the goals being positive feeling between the partners and more reasonable behavior.

It is important to understand that when considering different types of psychotherapy – individual, group and family therapy – “couples therapy” is considered as a subtype of “family therapy”. Further, we should make explicit the obvious: a couple is an example of a “family” (broadly defined).

Currently, there are various models and strategies for treating couples. Each may emphasize different assumptions and types of interventions. Some therapists prefer to operate with one strategy in most cases, whereas others intermix these strategies, depending on the presenting problem and the phase of treatment. At times, the type of strategy used is made explicit by the therapist, whereas in other instances it remains covert; irrespective of whether a therapist specializes in one or another approach or is eclectic, some hypotheses will be formed about the nature of the couple’s difficulty and the preferable approach to adopt.

Therapists may choose one school or another based on their training or their personality. For example, a very organized and directive person would probably prefer cognitive-behavioral methods, while a person who prefers long-term emotional intensity over problem-solving might gravitate to experiential models. Individuals and families as well may prefer some ways of working over others. This chapter encourages the integration of a variety of techniques depending on the particular problem and personalities of the couple as well as the skill-set of the therapist. It also encourages the therapist to look beyond the problem at hand, that is, the presenting complaint, to issues of power, intimacy and personal growth. Our approach is to emphasize models that have (at least some) empirical data.

With the therapeutic focus on one person, the emphasis is often on the individual’s perceptions, reactions and feelings, and also on the equality of status between the individual and the therapist; when two people are the operative system, attention is directed to interactions and relationships. Therapists who think in terms of a unit of three people look at coalitions, structures, and hierarchies

of status and power. The number of people actually involved in the interviews may not be as important as how many people are involved in the therapist’s way of thinking about the problem.

### Couples Function and Dysfunction

#### Couples Development

Dym (1993) has described how couples relationships evolve over time. Members of couples are influenced by past and present relationships and tend to form ties that have a distinct character that emerges through regular cycles of conflict and resolution. Dym draws attention to broad, normative changes in couples, characterizing these developmental shifts as periods of expansion, contraction and resolution. For example, in the early expansive years of a committed romantic relationship, the lives of two are in a sense woven into one. Some refer to this period of optimism, promise and fusion as moving from “I” to “We”.

In the next years of the relationship, Dym describes a predictable stage of contraction and a feeling of betrayal, in which members of the couple reconnect with a need for an “I”. This desire can be marked by experiences of doubts, fears and insecurities, and many couples retreat from their established routines. Partners may find themselves feeling “out of synch” with their own personal ambitions, describe themselves as feeling trapped or lonely, and may believe they are progressing at different tempos from each other. Stormy times may ensue with bitter conflict and blame. During the resolution stage couples may resort to compromise, negotiation, or even a more radical restructuring of their relationship in an effort to make room for both the individual and the relationship. In considering this dialectical movement from expansion to contraction to resolution, this cycle repeats several times over the course of the relationship. Dym notes that many couples have what he calls a “home base” where they tend to reside, in terms of the sense of “We”, “I”, or “working on it”. A home base is the point of the cycle of expansion and contraction where the couples find themselves most often.

#### Sexual Functioning of Couples

It has been estimated that 50 percent of American marriages have some sexual problems. These can be divided into “difficulties” (such as inability to agree on frequency) which are clearly dyadic issues; and dysfunction which are specific problems with desire, arousal and orgasm, as listed in the DSM-IV (American Psychiatric Association, 1994). Dysfunctions may be organic or psychological at base, and may be lifelong or acquired, generalized or situational. They may be deeply embedded in relational power or

intimacy struggles, or may be the only problem in an otherwise well-functioning relationship. While most family therapists believe that there is no uninvolved partner when one member of a couple presents with sexual dysfunction, that is different from saying that the relationship itself is the cause of the dysfunction. The job of the therapist is to ascertain as best as possible the etiology of the problem and to choose the most effective therapy, whether medical, individual, or relational. It is also within the therapist's purview to inquire about whether the couple would like to improve a technically functional but not very satisfying sexual relationship, in the same way that the therapist can offer methods or directions to increase intimacy in a couple that wishes personal growth.

## Diagnosis/Systems Issues

Sexual dysfunction or dissatisfaction is, in a minority of times, caused by a psychiatric disorder (depression and anxiety may often decrease sexual desire). It is commonly caused by ignorance of sexual anatomy and physiology, negative attitudes and self-defeating behavior, anger, power or intimacy issues with the partners, or medical/physiological problems. Medication side effects are a particularly common cause of sexual dysfunction in patients who are receiving selective serotonin reuptake inhibitors (SSRIs). Male erection problems are proving increasingly amenable to medical forms of treatment. It is also important to remember that people vary enormously in the importance they place on sex or eroticism in their lives. For example, in *The Social Organization of Sexuality: Sexual Practices in the US* (Laumann and Michael, 1994), about a third of the people surveyed have sex at least twice a week, about a third a few times a month, and the rest, sex with a partner a few times a year or not at all. In general, when sex is not part of a marriage over a long period of time, the relationship has less vitality and life. However, even well-functioning marriages may have periods in which sexuality is much less part of their lives (such as after the birth of a first child, or during a family or health crisis). Different people have vastly different tolerance for such periods.

Because sex is a way of each person being vulnerable to the other, it is difficult to have sex when one is angry or not in a mood to be close (although some people can block out other feelings and keep the sexual area more separate). In addition, people who feel abused, mistreated, or ignored in a relationship are less likely to want to please the other. For some who feel that they have no voice in the relationship, lack of desire is sometimes the only way they feel able to manifest displeasure.

Couples who continue in marital or individual treatment for long periods of time can resolve some of their marital problems but can still suffer from specific sexual difficulties in their marriage. It is also true that specific sexual problems may be dramatically reversed after relatively brief periods of sex therapy, even though such problems may have proven intractable following long periods of more customary psychotherapy. However, sexual functioning which is suffering because the partners do not want to be close is not likely to respond to sex therapy unless other issues are also addressed.

Usually, when a marital couple has a generally satisfactory relationship, any minor sexual problems may be only temporary. Resolution of sexual problems, however, will not inevitably produce positive effects in other facets of a relationship as well.

Marital and sexual problems interact in various ways:

1. The sexual dysfunction produces or contributes to secondary marital discord. Specific strategies focused on the sexual dysfunctions would usually be considered the treatment of choice in these situations, especially if the same sexual dysfunction occurred in the person's other relationships.
2. The sexual dysfunction is secondary to marital discord. In such situations, general strategies of marital treatment might be considered the treatment of choice. If the marital relationship is not too severely disrupted, a trial of sex therapy might be attempted because a relatively rapid relief of symptoms could produce beneficial effects on the couple's interest in pursuing other marital issues.
3. Marital discord cooccurs with sexual problems. This situation would probably not be amenable to sex therapy because of the partners' hostility to each other. Marital therapy would usually be attempted first, with later attention given to sexual dysfunction.
4. Sexual dysfunction occurs without marital discord. This case might be found in instances where one partner's medical illness has affected his or her sexual functioning, forcing the couple to learn new ways to manage the change. Another example might be when one partner has a history of sexual abuse or a sexual assault that creates anxiety related to the sexual experience. While individual therapy can be helpful in both of these cases, couples therapy can be especially useful in creating a safe place to address painful feelings and anxious expectations, and to provide education and guidance for couples undergoing these transitions.

## Secrets and Confidentiality

Unless a therapist sees both parties together at all times, he/she will eventually face a situation in which family secrets are disclosed in individual sessions. Since secrets are a common source of dysfunction, discovering and dealing with them is a frequent occurrence.

The therapist needs to make a distinction between **secrecy** and **privacy**. Privacy is usually considered to mean information held by one person that they would prefer not to share but that does not directly affect their relationship with others. It usually implies a zone of comfort free from intrusion. Secrets are usually considered to be feelings or information that would directly affect a relationship. They are most often connected to fear, anxiety and shame, and are often shared, that is, some people in the system know, whereas some do not. There is also a gray area in which different people have different ideas about whether the information is important or not. (Does a spouse consider an extramarital affair that ended 10 years ago private or secret?)

In general, the best rule of thumb is that a secret should be disclosed if it is seriously affecting connections between people, posing danger to a family member (sexual abuse), or shaping family coalitions and alliances. In general, keeping secrets is such a serious barrier that it is better to disclose them, even if painful, because otherwise the sense of mystification and isolation in the unaware is very strong.

The therapist must carefully consider the timing and type of disclosure. Premature disclosure, before the therapist has an alliance with the family, can cause the family to leave therapy with no place to deal with potentially explosive material. This is particularly true when there has been a history of violence or abuse.

Although the following guidelines do not sufficiently cover all couples' problems and situations, they do represent a generic set of ideas that therapists may apply to the specifics of many marital issues.

## Evaluation of the Couple

The evaluation of a couple involves obtaining data on the current point in the marital and/or family life-cycle, why the couple approaches for assistance at a particular time, and each partner's view of the marital or relationship problem (Table 71.1). Often the couple's therapist will hold one individual session with each partner after the first or second conjoint session. This gives each partner an opportunity to divulge information that might otherwise not be obtainable. Issues of confidentiality need to be carefully addressed.

In formulating the marital difficulties, the evaluator will want to consider the couple's communication, problem-solving, roles, affective expression and involvement, and behavioral expression, especially in sexual and aggressive areas. The clinician will also want to evaluate gender roles, cultural and racial issues, and power inequities resulting from gender, class, age, or financial status. It is critical to ask about alcohol, health and reproductive issues, and violence (Table 71.2).

Even if the partners do not mention their children as a problem, it is wise to spend some time developing a sense of how the children are doing, is there a favored child or problem with any of them, and whether the children are being pulled into marital conflicts. At times children can be the source of a couple's conflict and at other times they may function as the glue that keeps the relationship together. If a large part of the couple's difficulty centers around issues with the children, family therapy may be the preferred treatment modality (see Chapter 70-Family Therapy).

Other areas deserving special attention include each spouse's commitment to the marital union and the couple's sexual life. Assessment is complicated when one spouse is keeping commitment doubts or extramarital sex a secret. Conjoint and individual sessions with each partner may be needed. When infidelity or serious commitment questions arise, the therapist and couple must address whether or not the couple should stay together.

**Table 71.1 Outline for Family Evaluation**

- I. Current phase of family life-cycle and identifying data
- II. Explicit interview data:
  - A. What is the current family problem?
  - B. Why does the family come for treatment at the present time?
  - C. What is the background of the family problem?
  - D. What is the history of past treatment attempts or other attempts at problem solving in the family?
  - E. What are the family's goals and expectations of the treatment? What are their motivations and resistances?
- III. Formulating the family problem areas:
  - A. Rating important dimensions of family functioning:
    1. Communication
    2. Problem-solving
    3. Roles and coalitions
    4. Affective responsiveness and involvement
    5. Behavior control
    6. Operative family beliefs
  - B. Family classification and "diagnosis"
- IV. Planning the therapeutic approach and establishing the treatment contract

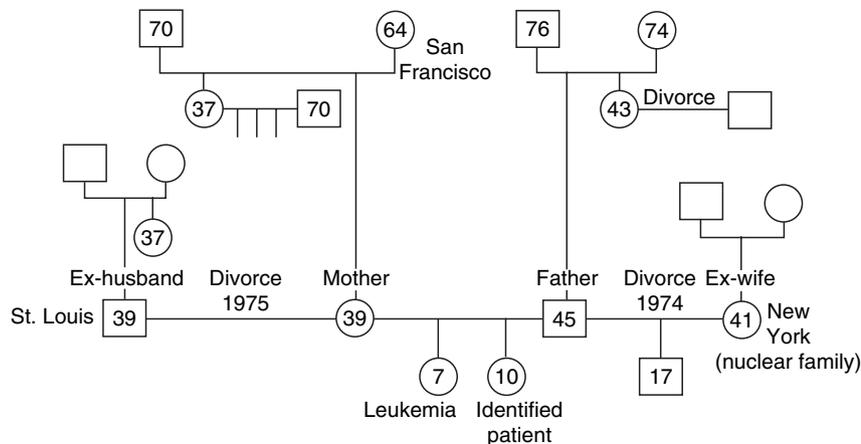

**Table 71.2 Guidelines for Interviewing Couples: The Process**

- Can you tell me about yourself? As individuals? As a couple?  
(Joining, forming an alliance with each member and the couple, creating a safe place)
- What brings you here? How do you understand the problem? What feelings does it elicit for each of you?  
(Developing an interactional problem focus)
- How does the problematic pattern actually work? Can you show me how it works?  
(Observing by staging an "enactment")
- How did this pattern originate? How did you create it?  
(Placing the problem in context of their relationship, family of origin, and their own individual development)
- How have you maintained this pattern? What have you done to keep it going?  
(Placing the pattern or problem under their joint control)
- Tell me about what you believe should be happening.  
(Myths, stories, ideas, expectations about love, sexuality, marriage, and closeness)
- In what other ways is the pattern currently reinforced? What do your family and friends believe is the problem?  
(How do jobs, extended family members, and friends contribute to the pattern's resilience?)
- Is this pattern always occurring or are there exceptions?  
(How pervasive is it, is it chronic, or related to a life transition?)
- What have you done to try to change the pattern?  
(Trying to avoid redundancy by inquiring about solution behavior)
- Have your efforts to change the pattern made things better or worse?  
(Looking at the problem as "attempted solutions")
- What has been the influence of this problem in your lives?  
(Again looking for the "influence" of the problem over their lives)
- How motivated are you to change the pattern now?  
(Assessing individual and couples motivation)
- What would happen if you succeeded in changing the pattern?  
(Anticipating possible consequences of change, both positive and negative)
- What patterns of relating have you created that you want to keep?  
(Identifying and honoring assets and resources)
- Are you ready to make a change? How about trying something different?  
(Preparing the couple for exploring new patterns of interaction)

The therapist is then free to track themes (always keeping an interactional focus), invent tasks and experiments designed to provide new experiences for the couple, and to evaluate the changes that occur or do not occur as a result of the couple's efforts to change their patterns of interaction.

## Genograms for Evaluation

A helpful device when evaluating a couple is the use of a genogram. The therapist can collect and organize historical data

**Figure 71.1** Example of a genogram.

through the use of a genogram, the three-generational family tree depicting the family's patterns regarding either specific problems or general family functioning. The genogram technique suggests possible connections between present family events and the prior experiences that family members have shared (e.g., regarding the management of serious illnesses, losses and other critical transitions), thereby placing the presenting problem in a historical context (Shorter, 1977; McGoldrick and Gerson, 1985). Constructing a genogram early on in treatment can provide a wealth of data that frequently offers clues about pressures, expectations and hopes regarding the marriage. This pictorial way of gathering a history allows each member of the couple to learn about beliefs or themes that characterize his/her family background. An example of a genogram can be seen in Figure 71.1.

### Assessment of Concomitant Psychiatric Illness

Having a spouse with a serious Axis I disorder, such as anxiety disorder, mood disorder, or substance abuse puts realistic strain on the marital relationship. The marital interaction prior to, during and following the onset of the symptoms in the spouse is influenced by numerous factors and is quite variant across dyads. It is incorrect to assume that in all cases the interaction between the spouses brought on, or caused, or even helped trigger the mental disorder and symptoms in the other. Whatever the symptoms in one spouse, the relationship of symptoms to the marital interaction is on a continuum and can take any one of the following forms:

1. The marital interaction neither causes the symptoms nor stresses the psychologically vulnerable spouse.
2. The marital interaction does not stress the vulnerable individual but following onset of symptoms the marital interaction declines and becomes dysfunctional, thus causing more distress.
3. The marital interaction acts as a stressor that contributes to the onset of symptoms in a vulnerable spouse.
4. The symptoms can be explained totally as under the control and function of the interactional patterns between the spouses.

The therapist meeting a new couple therefore can entertain a range of different ideas that may help illuminate and explain their distressing circumstances. The Axis I condition can be a useful focus and often is what brings the couple in for help.

### Evaluation of Sexual Disorders

A careful evaluation of the couple's total interactions needs to be done by the therapist as well as a physical assessment when dysfunction is present. When it appears that the basic marriage is a sound one, but that the couple suffers from specific sexual difficulties (which may also lead to various secondary marital consequences), the primary focus might be sex therapy per se. In many cases, however, specific sex therapy cannot be carried out until the relationship between the two partners has been improved in other respects; indeed, the sexual problems may clearly be an outgrowth of the marital difficulties. When marital problems are taken care of, the sexual problems may readily be resolved. It may be difficult to disentangle marital from sexual problems or to decide which came first. The priorities for therapy may not always be clear.

Specific techniques are available which have been devised for eliciting a sexual history and for evaluating sexual functioning. The marital therapist should become familiar with these ideas and obtain experience in their utilization. A systemic assessment of sexual difficulties includes, at the minimum, the following details as listed in Table 71.3.

In addition, in couples where there is any possibility that the problems may have an organic component, it is crucial to insist on a medical work-up. This is particularly key for men, for whom small physiological changes in potency may produce anxiety that exacerbates the problem.

The taking of an intimate sexual history of husband and wife should, of course, be conducted with the couple without children present. The process of taking a sexual history should be handled with care and regard for each person's level of comfort.

What type of language should be used when discussing sexual topics? Obviously, one should not use terms that would be offensive or uncomfortable for either the therapist or the couple. At the same time, care must be taken to avoid using bland generalities which fail to elicit specific sexual information. Frankness is encouraged, and when there is vagueness, the therapist needs to follow-up with more specific questions.

Taking a sexual history of lesbian and gay couples may be particularly difficult for a heterosexual therapist, either because of discomfort with homosexuality or lack of knowledge of homosexual norms and mores. In addition, the couple may have a wider or different set of sexual practices than the therapist is used to (of course, this may be true with heterosexual couples as well). Therapists have the options of educating themselves about homosexual sexuality, either by reading books available in mainstream

**Table 71.3 Assessment of Sexual Problems**

1. Definition of the problem
  - (a) How does the couple describe the problem? What are their theories about its etiology? How do they generally relate to their sexuality, as reflected in their language, attitudes toward sexuality, comfort level, and their permission system?
  - (b) How is the problem a problem for them? What is the function of the problem in their relationship system? Is the relationship problem the central problem? Why now?
2. Relationship history
  - (a) Current partner
  - (b) Previous relationship history
  - (c) Psychosexual history, including information about early childhood experiences, nature of sexual encounters prior to the relationship, sexual orientation, and feelings about masculinity and femininity.
  - (d) Description of current sexual functioning, focusing on conditions for satisfactory sex, positive behaviors, specific technique, etc. Who initiates sex, who leads, or do both? How does their sexual pattern of intimacy and control reflect on or compensate for other aspects of their relationship?
3. Developmental life-cycle issues (births, deaths, transitions)
4. Medical history, focusing on current physical status, medications and present medical care, especially endocrine, vascular, metabolic.
5. Goals (patients' and therapist's viewpoints): The task is to examine whether goals are realistic and what previous attempted solutions have yielded.

bookstores about gay and lesbian life, and/or asking the couple about their own and other common practices. If the therapist is very anxious in this situation, he/she must decide when the therapy is not proving effective and if he/she should refer to another therapist. Gay and lesbian couples may present with any of the dysfunctions or dissatisfactions of heterosexual couples.

### Indications for Couples Therapy

The process of choosing a type of therapy is complex and research is just beginning to develop guidelines for such decisions. The therapist must most often base his or her judgment on clinical intuition, general clinical opinion, and the wishes and judgments of the people involved.

### Marital Versus Individual Therapy

One of the most common questions for clinicians who are proficient in both therapies is regarding the decision about type and timing of therapy. The basic theoretical premise of couple/family therapy is that many problems are purely relational, that individual symptoms in one person can be viewed as interpersonal in terms of etiology or problem maintenance, and that they can be changed by altering the system. The basic principle of individual therapy is that problems or symptoms develop because of the biochemistry or dynamics of the individual, and that change occurs in the individual (either behaviorally or because of cognitive understanding of the problems) in the presence of an intense

and exclusive relationship with the therapist. In truth, for many people, both forms of therapy may be useful or necessary. Self-knowledge does not always help the person understand the complex family system and how one's behavior affects and is affected by family members. In addition, family therapy does not allow for intense exploration of psychodynamic issues. Individual therapy also does not allow the clinician to see how the problems of other family members may also be affecting the system.

Since people tend to pick partners at similar stages of differentiation, it is not unusual for people with psychological difficulties to have spouses with similar or complementary but equally severe problems. In addition to the need to evaluate the partner, it must be recognized that such couples create problems maintaining systems that need to be addressed directly. Children in such families often suffer either from genetically based similar illnesses (such as depression) or symptoms as a result of dealing with parental problems. These are often best treated with family therapy, but this does not rule out special time just for the child. For many people, both types of therapy are helpful, allowing for increased pleasure with the partner and also a context for personal and private growth.

The choice of timing of therapy is always of interest. If the person is highly symptomatic and has a problem which is usually amenable to medications, it is often helpful to begin medication and family therapy first, in order to reduce the symptoms and educate the family, as well as to eliminate family sources of stress.

In general, one tries to deal with the most acute problems first. If it is possible in terms of timing and finances, it is easily possible to do individual and couples therapy at the same time. It is often recommended that the therapies be conducted by different therapists, however, in this strategy it is imperative that the therapists remain in contact to avoid splitting or conflicting treatment. Others, including therapists on occasion, have treated both the couple and one member of the couple individually, although this can present some additional challenges to the therapist to remain neutral and unbiased. The therapist's criteria depend more on the characteristics of the couple and how they function than on the particular diagnosis or problem area. The bias of the couple or individual must also be taken into account.

### Individual, Couple, or Sex Therapy for Sexual Problems

This distinction was clearer 10 years ago when sex therapy was primarily focused on a specific and highly detailed behavioral protocol. Sex therapy in the last few years has moved in the direction of further understanding of the physiologic causes of sex dysfunction on one hand, and cognitive-behavioral issues on the other. It is clear at this point that, in general, sexual problems do not disappear with couple therapy unless specific attention is paid to the nature and quality of the sexual problems. Usually, it is most effective to deal with severe couple conflict before beginning to deal with sexual issues directly (Table 71.4). Sex therapy includes education, a focus on the intimacy and power aspects of sex, and often homework assignments that in some way deal with sexual anxiety and expansion of sexual options. Individual therapy is indicated if the problems are clearly related to the partner's history (sexual abuse, hatred of women), have occurred in multiple relationships, and are not amenable to being worked on in the couple. Individual therapy is the most inefficient way of dealing with most couple centered sexual problems. It is

**Table 71.4** Criteria for Sex and Marital Therapy

Sex Therapy	Marital Therapy
The marital problem is clearly focused on sexual dysfunction	Sexuality not an issue, or it is one of many issues in marital dysfunction.
<b>Enabling Factors</b>	
Willingness and ability to carry out the sexual functioning tasks that would be assigned by therapist.	Anger and resistance too intense to carry out extra-session tasks around sexual functioning.
Strong attachment to marital partner; both partners interested in reversing the sexual dysfunction.	Couple not committed to each other; there are covert and/or overt behaviors to dissolve the marriage.

also important to consider the possible role of organic problems in any dysfunction.

### Contraindications for Couples Therapy

Couples therapy is not indicated for every couple in distress. In fact, at times, it may even be contraindicated. If one member is keeping an important secret, an attempt to work with them as a pair may fail and the therapist often has to take a strong stand and refuse to treat the couple, as in the case of an HIV positive male who refused to share this information with his wife. At times, one member of a couple may be too ill to benefit from couples therapy. This may be the case when one partner has a bipolar disorder or schizophrenia and is acutely psychotic.

Other couples feel more comfortable when each partner has his or her own therapist. At times it can be more effective to have each member in individual therapy with good coordination between the two therapists. Finally, cases may arise where seeing a couple together may put one member of the couple in physical danger. When one member has a history of violence toward the partner, the therapist must often see each party alone to ensure the safety of a partner. Discussing areas of conflict together may risk increasing the violent behavior of one partner.

Sex therapy may be contraindicated in the same situations as above. In addition, many couples do not feel comfortable in a therapy exclusively focusing on sex. These couples may make more progress if the sex therapy is carefully included in the overall treatment of the couple. When referring to a sex therapist, it is particularly important to be familiar with the skill and credentials of the therapist.

### Treatment

We believe that for most people the strongest predictor of overall life satisfaction is the quality of the person's central relationship. In addition, "a good and stable relationship buffers against the genetic vulnerability to both medical and psychiatric disorder". Thus, helping a couple achieve a more satisfying relationship can have widespread and profound influence on their life and lives of those with whom they interact.

The treatment of each couple is unique and may require a combination of couples therapy, individual therapy, group therapy (particularly self-help groups such as Alcoholics Anonymous) family therapy and medication management. By using an integrative approach with each couple, the therapist maximizes the chances for success. Identifying goals of treatment will help determine which modalities will be most effective and in what order they need to be applied. Goals most likely attained by employing couples therapy include the following: specification of the interactional problem, recognition of mutual contributions to the problems, clarification of marital boundaries, clarification and specification of each spouse's needs and desires in the relationship, increased communication skills, decreased coercion and blame, and increased differentiation and resolution of marital transference distortions. Final goals of the marital intervention may involve resolution of presenting problems, reduction of symptoms, increased intimacy, increased role flexibility, balance of power, clear communication, resolution of conflictual interaction, and improved relations with children and families of origin.

The treatment of couples is often conceived of as a relatively brief therapy (though it need not be), usually meeting once weekly, with a focus on the marital interaction. The major indication for marital intervention is the presence of marital conflict but other indications include symptomatic behaviors that impact both parties such as depression, anxiety disorders, substance abuse and illness in a child, marital partner, or other family member.

### Strategies and Techniques of Intervention

Couples therapy utilizes strategies for imparting new information, opening up new and expanded individual and marital experiences, psychodynamic strategies for individual and interactional insight, communication and problem-solving strategies, and strategies for restructuring the repetitive interactions between the spouses or partners.

Sometimes, couples present with chronic histories of unresolved and unrelenting conflict. Other couples are in a state of transition, perhaps moving from the initial expansion stage of their marriage to the inevitable crisis related to the reevaluation of the contraction stage. In either case, clarifying the couples' process and their reoccurring patterns of behavior represents the starting place for couples therapy.

The focus should be primarily on the interpersonal distortions between husband and wife, and not on the couple-therapist transference. However, negative transference distortions toward the therapist must be addressed quickly and overtly.

There are three strategies in this focused, active treatment of marital discord:

1. The therapist interrupts collusive processes between the spouses. The interaction may involve either spouse failing to perceive positive or negative aspects of the other that are clear to an outsider (e.g., cruelty or alternately generosity) or when either spouse behaves in a way aimed at protecting the other from experiences that are inconsistent with the spouse's self-perception, (e.g., husband working part time views himself as breadwinner, whereas wife works full time and manages checkbook to shield husband from reality of their income and finances).
2. The therapist links individual experience, including past experience and inner thoughts, to the marital relationships.

3. The therapist creates and allocates tasks that are constructed to (a) encourage the spouses to differentiate between the impact of the other's behavior versus (the other's) intent, (b) to bring into awareness the concrete behavior of the partner that contradicts (anachronistic) past perceptions of that partner, and (c) to encourage each spouse to acknowledge his/her own behavior changes that are incompatible with the maladaptive ways each sees himself/herself and is seen by the marital partner. These tasks also help reconstruct the couple's narrative to make it more positive.

The last (c) is most important. In fact, in the initial stage of marital treatment the authors ask that each partner focus on what they want to change in themselves, not how they want the other spouse to be different.

In an integrative model of couples therapy, the focus is on three related domains: the functional relationships between the antecedents and consequences of discrete interactional sequences; the recurrent patterns of interaction including their implicit rules; and each spouse's individual schemata for intimate relationships. In the initial stage, alliances must be developed between the therapist and each marital partner, with the therapist offering empathy, warmth and understanding. The therapist must also ally with the couple as a whole and learn their shared language as well as their different problem-solving styles and attitudes.

Behavioral techniques, including giving between-session homework, in-session tasks, communication skills and problem-solving training, can facilitate the process of helping marital partners reintegrate denied aspects of themselves and of each other. However, the focus is not on behavioral change alone, as overt behavior is seen as reflecting the interlocking feelings and perceptions of each spouse. Ideally, the process of treatment should be one where each partner can consider what they want to change in themselves as opposed to how they want the other spouse to be different; safely explores new beliefs, feelings and behaviors; and experiments with new patterns of interaction that are unfamiliar and even anxiety-provoking.

### Treatment of Sexual Dysfunction

Treatment of psychosexual disorders, in the form developed by Masters and Johnson (1966), consisted of a thorough assessment of the partners and their relationship, education about sexual functioning, and a series of behavioral exercises. There are specific exercises for each of the sexual dysfunctions. Different authors developed different exercises and ways of approaching them. For a complete description of these exercises, we recommend Kaplan (1995), LoPiccolo and Stock (1996) and Zilbergeld (1992). This method works best when there is ignorance, shame, or specific dysfunction such as premature ejaculation. These exercises are difficult to complete if the couple feels angry or unloving toward each other.

Many of the patients who saw Masters and Johnson in the 1970s had issues related to sexual ignorance and inexperience. Two decades later, the increase in premarital sex and the proliferation of easily available articles and books on sexuality and information on the Internet have decreased the number of these couples, and allowed some couples with sexual dysfunction to work on their issues at home. Recent studies of couples requesting sex therapy have shown a higher proportion having concomitant, complicated marital problems. Recent writers in the field,

notably Schnarch (1997), have focused on cognitive/emotional issues in sexuality, and especially on the meanings attached to a particular act, and the level of intimacy involved. Having learned a great deal about the more mechanical and organic issues related to arousal and orgasm, it is important to rethink other aspects of sex, such as eroticism, passion, mystery and dominance/submission which make the act itself meaningful. This is particularly true in areas of sexual boredom or situational lack of desire. These therapists do not use rigidly staged exercises, but focus on the couple's relatedness during sex; they may, however, suggest specific homework to help a couple focus on a particular aspect of their sexuality.

### Effectiveness and Efficacy of Couples Therapy

There are two major sources for reviews of efficacy of couples therapy. Shadish and coworkers (1995) summarized 163 randomized studies, 62 marital and 101 family therapy. Pinsof and Wynne (1995) in a commentary have summarized the data. These studies point to the following general conclusions:

1. Family treatment is more effective than no treatment. This conclusion is manifest in studies that contrast family and marital treatment to no-treatment control groups. Roughly 67% of marital cases and 70% of family cases improve. The outcome may be slightly better if the identified patient is a child or an adolescent than if he or she is an adult. These findings were statistically significant. No one therapy method was demonstrated clearly to be better than another.
2. The deterioration rate (i.e., the percentage of patients who become worse or experience negative effects of therapy) is estimated at about 10% – lower than for individual therapy. Pinsof and Wynne (1995) believe the rate is lower than 5 to 10% and describe family therapy as not harmful.
3. In several areas evidence indicates that family treatment is the preferred intervention strategy. In other areas family therapy and individual therapy were tied – often in situations in which the identified patient had a significant Axis I problem (Shadish *et al.*, 1995). These treatments of choice are of great importance for practitioners and students.

### Dropouts

The dropout rate in the early stage of couple or family therapy is relatively high. In one study, about 30% of all the families or couples referred for family treatment failed to appear for the first session (defected) and another 30% terminated in the first three sessions, leaving about 40% who continued (Shapiro and Budman, 1973). The main reason families gave for termination was a lack of activity on the part of the therapist, whereas defectors in general had a "change of heart", and denied that a problem existed. The issue usually is that no matter how bad a situation was, it was preferable to what might happen if a couple changed their behaviors. The motivation of the husband appeared to play a crucial role: the more motivated he was, the more likely the family was to continue treatment. The idea that a dropout is "denying a problem" may or may not be true. Because the process of entering therapy is frightening for many people and because the therapist must meet the needs of several people, it is unsurprising that the process of engagement is rocky.

## Ethical Issues in Couples Therapy

The fundamental ethical dilemmas inherent in psychotherapy: confidentiality, limits of control, duty to warn/reporting of abuse and therapist–patient boundaries become more complex when the treatment involves more than one person. The couple’s therapist has an ethical responsibility to everyone in the family. In some cases, individual needs and system needs may be in conflict. For example, a husband may wish to conceal a brief episode of unprotected sex with another woman, while his wife is better protected, for health reasons as well as psychological reasons, if she knows about it. A wife’s wish to be divorced from a psychiatrically ill and demanding husband may conflict with his need for her care. Such clinical situations provide a set of ethical dilemmas for the therapist. The therapist must be clear that his/her job in most cases (such as impending divorce) is to help the partners sort out their values, obligations and options rather than making a decision for them. In some cases, however (such as the reporting of child abuse), the ethical decision must be the therapist’s. And in some cases the therapist faces difficult gray areas which must be decided on a case-by-case basis. The therapist also has certain unalterable ethical obligations such as not engaging in “dual relationships” (see later) with patients or exploiting them for their own benefit.

While the operative concept is “first do no harm”, the issues of how one defines harm, and who will or will not be harmed by a certain action, are complex and difficult questions, especially when treating a couple or family.

## The Conflicting Interests of Family Members

It is not unusual for the interests of each member of the couple to conflict at some point. Boszormenyi-Nagy and Spark (1973) years ago emphasized the contractual obligations and accountability between persons in the multigenerations of a family. Relational ethics are concerned with the balance of equitable fairness between people. To gauge the balance of fairness in the here-and-now, and across time and generations, each member must consider both his/her own interests and the interests of each of their partners. The basic issue is one of equitability, that is, everyone is entitled to have his or her welfare and interests considered in a way that is fair to the related interests of other family members.

There may be times when it is difficult to decide whether a therapeutic action or suggestion may be helpful for one individual, but not helpful or even temporarily harmful to the other individual. In their concern for the healthy functioning of the system as a whole, therapists may inadvertently ignore what is best for one individual. An ethical issue is how the decision is made. Should it be the therapist’s concern alone or should it be shared with the couple? How much information should they be given on the pros and cons of modalities? The authors’ bias is to negotiate and give the couple all the relevant information so that they can make the most informed decision possible (for further discussion, see also Hare-Mustin *et al.*, 1979; Hare-Mustin, 1980).

## Boundaries

The issue of boundaries and dual relationships is a critical one in all forms of psychotherapy. Because couples therapy involves more than one patient in the consulting room, there is less likelihood of inappropriate sexual contact between therapist and patient. However, there have been cases in which a therapist,

working with a couple, began an affair with one of the spouses, either during couple’s therapy or after the couple separated. The American Association of Marital and Family Therapy (AAMFT) Code of Ethics (1998) has a very sensible code of ethics making clear the inappropriateness of this kind of behavior.

Other confusing issues may arise because the issues that couples face are the same as issues therapists face in their own lives, making it very likely that at some point countertransference issues may become ethical ones. For example, seeing a couple going through a separation at the same time one is going through the early stages of one’s own divorce is an extremely difficult thing to do, and the likelihood of remaining neutral to both parties is not great. While it is obviously impossible for a therapist to stop treating patients while going through a divorce, he or she could certainly choose not to accept a new patient whose situation is very similar to their own or who reminds them of their departing spouse. Issues of “confidentiality” and “boundaries” are issues mentioned in the AAMFT Code of Ethics (1998). Three of these have special relevance to couples therapists:

1. Marriage and family therapists are aware of their influential position with respect to clients, and they avoid exploiting the trust and dependency of such persons. Therapists, therefore, make every effort to avoid dual relationships with clients that could impair professional judgment or increase the risk of exploitation. When a dual relationship cannot be avoided, therapists take appropriate professional precautions to ensure judgment is not impaired and no exploitation occurs. Examples of such dual relationships include, but are not limited to business or close personal relationships with clients. Sexual intimacy with clients is prohibited. Sexual intimacy with former clients for 2 years following the termination of therapy is prohibited.
2. Marriage and family therapists respect the right of clients to make decisions and help them understand the consequences of these decisions. Therapists clearly advise a client that a decision on marital status is the responsibility of the client.
3. Marriage and family therapists have unique confidentiality concerns because the client in a therapeutic relationship may be more than one person. Therapists respect and guard confidences of each individual client.

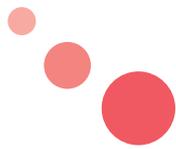

## Conclusion

Couples and sex therapy are important forms of psychotherapy. There is little question that developing the skills needed successfully to work with couples presenting with a wide range of difficulties requires an understanding of how normal couples’ relationships change over time, how problems emerge and are maintained, and how focused marital treatment can alleviate distress and dysfunction. The rewards, however, are great when therapists can assist couples in recognizing and shifting the patterns that inhibit their abilities to live rich, intimate lives together.

Long-term relationships that are mutually supportive with a high level of intimacy are rare. As societies around the world (including our own) continue to evolve, unexpected events create havoc even for very stable families. What couples ask of their psychiatrists is the basic knowledge and skills, artfully applied to their joint relationships, to improve the quality of their lives.

Hypnosis is a natural state of attentive, focused concentration. As such, most individuals are able to experience trance-like states at different times in their daily lives. An example is the alteration of awareness experienced by some persons as they concentrate intently on a movie or a play while disconnecting from awareness of the surrounding environment. Depending on the degree of natural ability to enter a trance state (hypnotic capacity or hypnotizability), a given subject will require more or less help to enter and use his or her hypnotic capacity. That is, highly hypnotizable individuals enter trance states with ease, on many occasions even without being fully aware of it. Individuals with low hypnotizability require more direction or help from the therapist who facilitates the trance experience. High hypnotic capacity may actually become a liability to patients who are unaware of their hypnotic capacity or of their unconscious use of this mechanism, as is the case of individuals suffering from a dissociative disorder. Even when we do not intend to use hypnosis formally, we must remember that the ability to enter a trance state is widely and naturally distributed throughout the normal population. Thus, some of our patients may be experiencing trance states even without our planning.

In 1960, the American Medical Association and the American Psychiatric Association (APA) officially recognized hypnosis as a legitimate therapeutic tool. At present, the uses of hypnosis in clinical and investigational areas continue to grow, as does research on the neuropsychological mechanisms involved in the hypnotic process.

### Definition

Hypnosis is a psychophysiological state of attentive, receptive concentration, with a relative suspension of peripheral awareness. Hypnotic phenomena occur spontaneously, and the alteration of consciousness that hypnotized individuals experience has a variety of therapeutic applications. The hypnotic experience may be understood as involving three main factors (Table 72.1).

### Hypnosis: What It is and What It is Not

Several principles provide guidance for the use of hypnosis in medicine and psychiatry. We attempt to clarify some of the myths and misconceptions about hypnosis by establishing what hypnosis is and what it is not (Table 72.2).

### Hypnotizability is a Stable and Measurable Trait

Not everyone is hypnotizable. Hypnotizability, or hypnotic capacity varies throughout the population. About 75% of the

**Table 72.1** Components of the Hypnotic Process

Component	Explanation
Absorption	Refers to the tendency to engage in self-altering and highly focused attention with complete immersion in a central experience at the expense of contextual orientation and more peripheral perceptions, thoughts, memories, or motor activities.
Dissociation	Permits keeping out of conscious awareness many routine experiences that ordinarily would be conscious. Dissociated material may be temporarily and reversibly unavailable to consciousness, but it continues to influence conscious and unconscious experiences and behavior.
Suggestibility	Involves heightened responsiveness to social cues. It allows subjects to suspend the usual conscious curiosity that makes us question the reason for our actions, making subjects more prone to accept suggestions given no matter how irrational.

**Table 72.2** What Is Hypnosis?

What It is
Hypnosis is a form of focused concentration. Hypnotizability is a stable and measurable trait. Hypnosis is something you do with, rather than to, a subject or patient. All hypnosis is self-hypnosis.
What It is Not
Hypnosis is not sleep. There are no apparent sex differences in hypnotizability. Hypnotizability is not a sign of weak-mindedness. Hypnosis is not intrinsically dangerous. Hypnosis is not therapy. There is nothing you can do with hypnosis that you cannot do without it.

population has some usable hypnotic capacity; of these, about 10% are highly hypnotizable. This means that about one of four adults has no usable hypnotic capacity (Spiegel and Spiegel, 1978). It is advantageous to determine this early and encourage those with the ability to use it; other treatment modalities are offered to those who are not hypnotizable.

### **Hypnosis is Something You Do *with*, Not Something You Do *to*, a Subject or Patient**

A therapist inducing hypnosis is in the position of the Socratic teacher, helping students discover what they already know. A useful metaphor to share with subjects is that of a coach. A correctly performed hypnotic induction allows the patient and physician to assess and explore the patient's hypnotic capacity or lack of it, just as a trainer assesses the athlete's natural capacities and then attempts to maximize them. This approach tends to minimize power struggles between the physician and the patient. For example, there is less chance of misinterpreting a patient's inability to experience a hypnotic trance as resistance.

### **All Hypnosis is Self-hypnosis**

The therapist helps the patient use his or her own hypnotic capacity to undergo a trance state. Helping patients to understand the degree of control they have over their mental processes is a good way to foster mastery and control. By doing this, patients may be able to comprehend the extent to which the unconscious use of their hypnotic abilities may create or contribute to their psychiatric symptoms, as in the case of dissociative disorders (Bliss, 1980, 1984; Spiegel, 1974; Spiegel and Fink, 1979). Similarly, hypnosis may help patients understand how certain physical symptoms may have unconscious etiological factors, as in the case of conversion phenomena (i.e., psychogenic blindness, pseudoseizures) or psychosomatic conditions (i.e., asthma, headache) (Maldonado and Spiegel, 2000).

### **There are no Apparent Sex Differences in Hypnotizability**

Men and women are equally hypnotizable (Hilgard, 1965; Stern *et al.*, 1979).

### **Hypnosis is Not Sleep**

The hypnotized individual is not asleep but rather awake and alert. To an outside observer, hypnotized individuals may appear asleep owing to their apparent lack of responsiveness to the environment. This is due to their intense absorption and concentration on their internal experience, rather than due to their lack of will.

### **Hypnotizability is Not a Sign of Weak-mindedness**

We know that a hypnotic trance requires an intact capacity for focused concentration. If anything, high hypnotizability is associated with the absence of serious psychotic and neurological disorders (Lavoie and Sabourin, 1980; Pettinati, 1982; Spiegel *et al.*, 1982).

### **Hypnosis is Not Intrinsically Dangerous**

For the most part, it is a benign process. The same cognitive flexibility that allows patients to enter the trance facilitates their exit from it with clear structure and support from the therapist. The dangers of hypnosis lay not in the process itself but

in how it is used. There are few contraindications for the use of hypnosis. A schizophrenic patient may incorporate an attempt at inducing hypnosis into a delusional system. A severely depressed individual may interpret a failure to benefit from hypnosis as further evidence of little self-worth. These problems can be avoided in part by use of hypnotizability testing at the beginning of the intervention. The most serious problem involves possible effects of hypnosis on memory. This is discussed under the section "Forensic Applications of Hypnosis" later in the chapter.

### **Hypnosis is Not Therapy**

Entry into a hypnotic state does not have any therapeutic effects of its own, although many find it pleasant and relaxing. Therapeutic change comes not from the state itself but from what happens during it. In this regard, hypnosis is not a treatment itself but rather a facilitator of a variety of treatment strategies. The state of intense concentration elicited in hypnosis can facilitate attention to a variety of strategies that enhance control over somatic function, reduce pain, allow the recovery and restructuring of memories, elicit the reproduction and control of conversion symptoms or fugue episodes, and provide control of dissociated states.

### **There is Nothing You can Do with Hypnosis that You cannot Do Without it**

As an adjuvant to therapy, hypnosis may help speed the process by which information can be accessed and processed because of its ability to heighten concentration and focus attention; however, it is not a treatment in and of itself.

### **Hypnotizability Scales**

Hypnotizability scales have been developed for clinical use (Hypnotic Induction Profile [Spiegel and Spiegel, 1978]; Stanford Hypnotic Clinical Scale [Hilgard and Hilgard, 1975]). These scales are designed for comfortable use even with patients who have severe psychiatric disturbances (Spiegel and Spiegel, 1978; Spiegel *et al.*, 1982, 1988). They are well accepted by patients and help to bypass anxiety by shifting the focus of the interaction from one in which the therapist tries to make the patient have a hypnotic experience to one in which the therapist assesses the patient's response to a set of instructions, like any other medical or psychological test (Spiegel and Spiegel, 1978). The therapist focuses on evaluating the patient's ability to enter the state rather than on getting the person into the state. They all involve a structured hypnotic induction and an assessment of the subject's response to a variety of instructions, such as alterations in the sense of control over body movements, physical sensations, orientation to time and space, and perception. Furthermore, such a standardized testing induction permits an important deduction regarding the hypnotic capacity of the subject. The restricted range of input from the therapist maximizes the information provided by variations in subjects' responses. After the results of the testing are discussed with the subject, both can proceed knowledgeably, choosing to use hypnosis or other techniques in the service of an agreed on treatment goal.

The use of this kind of objective measurement has several clinical advantages and therapeutic implications (Table 72.3).

### **Hypnosis Induction Profile**

The Hypnotic Induction Profile (Figure 72.1) is a useful clinical screening test for hypnotic capacity. It consists of a number

**Table 72.3 Benefits of the Use of Hypnotizability Measures**

- It objectively assesses the patient's natural ability to use his or her hypnotic capacity.
- It relieves performance pressure on both therapist and patient.
- It provides objective data about the patient's ability to respond to treatment employing hypnosis.
- It provides the therapist with scientific data to make rational treatment choices.
- It provides helpful information about the subject's interpersonal style and possible psychiatric illness.
- It helps predict the patient's likely response to psychotherapeutic treatment.

of the simple instructions that allow the measurement of patients' natural ability to tap into and use their hypnotic capacity. It begins with a simple and quick induction, counting from 1 to 3, accompanied by the eye roll. This involves instructed upward gaze and lowering of the eyelids (Figure 72.2). The dissociation between upward gaze and lowering of the eyelid can be scored (Figure 72.3), providing the therapist with an initial prediction of the subject's hypnotic capacity. The eye roll is then followed by a series of instructions briefly to influence the subject's behavior during and shortly after the test (posthypnotic suggestions). The Hypnotic Induction Profile allows the therapist to rate the subject on five items (Table 72.4) assessing cognitive and behavioral aspects of the single continuous but brief hypnotic experience elicited during the test. These

### Hypnotizability in Psychiatric Disorders

Charcot described a relationship between conversion phenomena and hypnotizability. He later incorrectly attributed both phenomena to a pathological process afflicting the central nervous system. Charcot believed that only sick or hysterical people could be hypnotized. Others, including Bernheim, Janet and Breuer, refuted the idea. They attributed the symptoms of conversion to unconscious mechanisms and viewing hypnosis as a tool useful in both the elicitation and removal of such states. Research in hypnosis has lately been directed at understanding the relationship between hypnotizability and psychiatric illness.

Some psychiatric disorders are associated with high hypnotizability scores (Table 72.5).

Several psychiatric syndromes (schizophrenia, generalized anxiety disorder, and to a lesser extent major affective disorder) (DSM-IV-TR) have been associated with generally lower hypnotic responsiveness. It may be that the primary illness process impairs the use of a patient's natural capacity for hypnotic concentration. Because of this, hypnotizability testing can sometimes be used to clarify diagnoses. As always, the presence or absence of hypnotic capacity should be interpreted within the context of the presentation, medical and psychiatric histories, and genetic background. In the case of an acute psychosis in which there is no familial background, the presentation is later in life than normal, there is a past history of physical or sexual abuse, and the patient has a high hypnotizability score, a diagnosis of hysterical psychosis or a dissociative disorder should be strongly considered when the possibility of schizophrenia is evaluated (Spiegel and Fink, 1979; Steingard and Frankel, 1985).

## Applications of Hypnosis

### General Considerations

Because of the intrinsic qualities of the hypnotic state, it can be an effective adjunct to the treatment of a variety of symptoms and problems, both in psychiatry and in medicine in general. The first criterion to consider is the patient's level of hypnotizability. Once it has been determined that the patient has usable hypnotic capacity (defined by high scores in hypnotizability scales), a discussion about the nature of the hypnotic process follows. It is important at this point to dispel any myths and correct misconceptions the patient may have about the process. This includes the cooperative nature of the hypnotic process, rather than the "tell me what to do" most patients expect. Finally, the therapist must decide whether the problem presented by the patient is amenable to hypnotic intervention or whether other steps should be taken instead.

We have divided the discussion of the applications of hypnosis into five areas: general psychiatry, general medicine, psychosomatic disorders, habit control and forensic psychiatry (Table 72.6).

### Application in Psychiatric Disorders

The use of hypnosis in the context of conventional psychotherapy can facilitate the therapeutic process in a number of ways. For example, hypnotherapeutic techniques may be used to enhance the patient's sense of self, restructure traumatic and phobic experiences, or access to repressed memories that have

not emerged with use of other techniques. This is true not only of painfully repressed memories but also of situations in which both the patient and the therapist have worked on resistance issues and feel that some additional leverage is necessary. In conventional psychotherapy, the transference is observed and analyzed; in hypnosis, the transference is used as part of the therapeutic process.

Conventional psychoanalytic psychotherapy involves observation and analysis of the meaning of the transference reaction that arises during therapeutic interactions. On the other hand, when hypnosis is used, transference is not avoided or bypassed but may be amplified. All the usual therapeutic rules and processes of psychotherapy apply when hypnosis is used in the psychotherapy context, which may intensify or accelerate the therapeutic process.

Because of the intense emotions that are characteristic of the hypnotic retrieval (which facilitates expression of inner fantasies), intense feelings and deep personal experiences may be elicited. Some patients may find that the hypnotic state facilitates a sense of infantile dependency in which the therapist becomes the transference object. The quality of this transference reaction will be based on the patient's early object relations, just as in any other therapeutic relationship. Indeed, the transference reaction may develop so fast that the inexperienced therapist may not have the opportunity to recognize it or may do so too late. The difference here is the intensity of the feelings developed as a result of the strong emotions that arise during trance. As in the case of victims of abuse, the therapist may use the transference relationship under hypnosis to foster the patient's ability to help herself or himself.

The difficult aspect of doing hypnosis is not the induction of the hypnosis trance, but what happens once the patient is under trance. Remember that all hypnosis is self-hypnosis. Thus, there are two factors which will predict the success of the hypnosis intervention: the patients' hypnotizability and the therapeutic skills of the therapist.

### Anxiety Disorders

Anxiety disorders are among the most widely prevalent psychiatric disturbances. They afflict as much as 15% of the population (Myers *et al.*, 1984). Anxiety can be seen as a state of hyperarousal experienced by both emotional and somatic discomfort. Patients describe their experience in physical terms, such as palpitations, gastrointestinal discomfort, chest pain, sweating and motor restlessness. Among anxiety disorders most responsive to hypnotic intervention are generalized anxiety disorder, panic disorder, phobias and post traumatic anxiety disorders (these will be discussed in the section that follows).

Most of the strategies in the treatment of anxiety disorders employing hypnosis combine instructed physical relaxation with a restructuring of cognition, using imagery coupled with physical relaxation. As in the treatment of anxiety disorders by systematic desensitization (Marks *et al.*, 1968) or progressive relaxation, patients are instructed to maintain a physical sense of relaxation (e.g., floating) while picturing the feared situation or stimulus. It is important that the relaxation instruction use an image that connotes reduced somatic tension, such as floating or lightness, rather than being a direct instruction to relax. The more cognitive term "relax" may actually induce more anxiety, whereas affiliation with a somatic metaphor usually produces

some reduction in tension. Unlike systematic desensitization, hypnosis produces a physically relaxed state that can be rapidly achieved with a quick induction. Also different from systematic desensitization, the coupling of relaxation to a fearful stimulus does not require the development or working through of a hierarchy.

A typical self-hypnosis induction can be rapid. For example, a patient can be told:

Now just get as comfortable as you can. There are many ways to enter a state of self-hypnosis. One simple but useful method is to count to yourself from 1 to 3. On 1, do one thing: look up. On 2, do two things: slowly close your eyes and take a deep breath. On 3, do three things: let your eyes relax but keep them closed, let your breath out, and let your body float. Then let one hand or the other float up into the air like a buoyant balloon. This is your signal to yourself and to me that you are ready to concentrate.

Initially, the use of hypnosis in the session can help in demonstrating to patients that they have a greater degree of control over somatic responsiveness than they had imagined. It is often useful to begin by teaching patients to create a place in their mind's eye where they feel safe and secure. On occasion, it helps the subjects to learn how to project their image onto an imaginary screen. Later, they can learn to manipulate the screen by making it either bigger or smaller, having the screen nearer or farther away, as needed:

Just allow your body to float, as if you were floating in a bath, a lake, or a hot tub. Enjoy this sense of floating lightness. Now, picture in your mind's eye an imaginary screen. It might be a movie screen, a television screen, or a piece of clear blue sky. First picture a pleasant scene, somewhere you enjoy being.

Allow the patient to experience this state for a minute or two, then inquire about the experience:

With your eyes closed and remaining in this state of concentration, describe how your body is feeling right now. What image are you picturing?

After receiving the answers, add:

Notice how you can use your store of memories and fantasies to help yourself and your body feel better.

After they have learned to manipulate the screen and their physical sensations, patients may be ready to do therapy work. They may, for example, learn to re-create the physical state of relaxation while projecting the fearful situation onto the screen. This, then, becomes a useful procedure by which to control and obtain mastery over anxiety-producing situations by dissociating the somatic reaction from the psychological response to the feared stimulus. Initially, the patient is asked to re-create the physical feeling of relaxation. Then, the patient projects onto the screen images associated with the feared situation, only this time the somatic reactions associated with anxiety do not develop. On occasion, it helps for patients to foresee likely physical sensations or situations associated with a fearful experience to master them. For example, in the case of plane phobia, the patient can learn to couple the real sensation of floating in the air with the hypnotic experience: "Learn to float with the plane".

Patients may also use the trance state as a means of facing their concerns more directly. As in the preceding cases, they may

make use of the screen technique. They can achieve this by placing an image of an upcoming performance or fearful situation on one side of the screen, testing out various strategies for mastering the situation on the other side.

Other approaches using hypnosis have included instructing patients in a trance to imagine that they are literally somewhere else, away from the fearful stimulus, thus separating themselves from the anxiety-producing experience (Erickson and Haley, 1967). Positive reinforcement or "ego-strengthening" techniques have also been used; for example, hypnotic instructions are given to patients suggesting that their capacity to master the situation and their response to it will improve (Crasilneck and Hall, 1985). There is little reason to use uncovering techniques seeking to link anxiety to some early traumatic experience in cases of phobia or generalized anxiety disorders. This is different in cases of PTSD (DSM-IV-TR), however, in which more work may be needed to confront and place into context the traumatic experience.

Certainly, in some cases, understanding the cause of the feared situation may help resolve the conflict. One of the techniques used to facilitate the recovery of traumatic memories associated with fearful situations is the affect bridge technique (Watkins, 1987).

## Post Traumatic Stress Disorder

Trauma constitutes a sudden discontinuity in both physical and mental experiences. The effect of the traumatic experience forces the victim to reorganize mental and psychophysiological processes to buffer the immediate impact of the trauma. This process is meant to be an adaptive mechanism to maintain psychological control during a time of enormous stress. Unfortunately, a number of trauma victims go on to suffer acute or chronic symptoms, such as dissociation, intrusive thoughts, anxiety, withdrawal and hyperarousal, leading to a diagnosis of acute stress disorder or PTSD.

There may be a relationship during childhood between stress, such as early trauma, and high hypnotizability. In support of this idea are reports of high hypnotizability in children who were victims of severe punishment during childhood (Nash and Lynn, 1986; Spiegel and Cardena, 1991). It is possible that the impact of the stress suffered encouraged them to use their self-hypnotic abilities more effectively (Kluft, 1984, 1992; Spiegel *et al.*, 1982).

The major categories of symptoms in PTSD are similar to the components of the hypnotic process (American Psychiatric Association, 1994; Maldonado and Spiegel, 2002a). Hypnotic absorption is similar to the intrusive reliving of traumatic events experienced by these patients. When in a flashback, trauma victims become so absorbed in the memories of the traumatic event, they lose touch with their present surroundings and even forget that the events took place in the past. Likewise, highly hypnotizable individuals may become so intensely absorbed in the trance experience that they can reenact a previous life event (during hypnotic age regression) as if they were reliving it. A hypnotized patient may dissociate a body part to the extent of not recognizing it as part of his or her body. Similarly, PTSD patients may dissociate feelings to the extent of experiencing the so-called psychic numbing. This allows them to disconnect current affects from their everyday experience in an attempt to avoid emotions triggering memories associated with the trauma. Finally, suggestibility is comparable to hyperarousal. The

heightened sensitivity to environmental cues observed in those patients suffering from PTSD is similar to that experienced by a hypnotized individual who responds to suggestions of coldness by shivering.

Because many patients suffering from PTSD are highly hypnotizable, and because of the resemblance between the symptoms of PTSD and the hypnotic phenomena, it makes sense to use hypnosis in its treatment. If patients suffering from PTSD are unknowingly using their own hypnotic capacities (Kluft, 1991, 1992; Maldonado and Spiegel, 2002a; Spiegel 1986, 1989; Spiegel *et al.*, 1988), it is therapeutically useful to teach them how to enter, access and control their trance potential. Hypnosis may be invaluable as a tool to access previously dissociated traumatic material.

We do not refer here to uncontrolled abreaction. The purpose is not simply to help the patient remember the trauma, because in a way, every time a patient goes through a flashback, an uncontrolled abreaction is experienced. An abreaction that is not conducted within the context of cognitive restructuring and before new defenses are in place can lead to the further retraumatization of the patient (Kluft, 1992; Spiegel, 1981). At the end of the following section (Dissociative Disorders), we summarize a comprehensive approach to the use of hypnosis in the treatment of psychiatric syndromes associated with severe trauma.

### Dissociative Disorders

Hypnosis is one of the most helpful tools in the treatment of patients suffering from dissociative disorders (Maldonado and Spiegel, 2002a; Maldonado *et al.*, 2000). As a rule, these patients experience their symptoms (i.e., fugue states, dissociated identities and blackouts) as occurring unexpectedly and beyond their control. Because these patients are unknowingly using their hypnotic capacities, it makes sense to teach them how to turn their weakness into a strength (Maldonado and Spiegel, 1995). Hypnosis can be used formally both as a diagnostic tool and for therapeutic purposes. The hypnotic state can be seen as a controlled form of dissociation (Nemiah, 1985). Hypnosis is useful in the treatment of these patients, first in determining whether they have a dissociative disorder, and second in providing rapid access to these dissociated states. When used by the therapist in the context of treatment, it can demonstrate to patients the amount of control they have over this state, which they normally experience as “automatic and unpredictable”. This not only serves to teach patients how to control dissociation but also allows them to establish a process of communication that will eventually lead to a reduction in spontaneous dissociative symptoms. Therapists must remember that many of these patients have suffered physical, emotional, or sexual abuse. It is imperative that we recognize and take account of the impact of whatever trauma occurred and help patients work through their reactions to it, as in the case of PTSD. Recognizing and teaching patients with dissociative disorders how to master their capacity to dissociate are among the most important psychotherapeutic tasks in the course of their treatment (Maldonado and Spiegel, 2002a; Maldonado *et al.*, 2000).

We can make use of hypnotic techniques as a way to help patients access repressed and dissociated memories. Teaching patients to use self-hypnosis allows them to obtain a sense of control over their symptoms and eventually their lives. The repression or dissociation of traumatic events and

the realities that surround them may serve a defensive purpose of avoiding painful affect associated with the memories. The memories are there, either transformed or interspersed with fantasy. Our approach to the treatment of these victims is directed at helping them acknowledge the extent of the emotional pain caused by the trauma. Then, through therapy, we can assist in the development of mature and adequate coping mechanisms that will allow the patient to place the experience into proper perspective. The goal is to allow the patient to come to terms with the trauma and to redefine herself or himself in view of the past, but with a firm hold on the realities of the present.

Dissociation as a defense serves a dual purpose. It represents an effort to preserve some form of control, safety and identity when faced with overwhelming stress. At the same time, victims use it in an attempt to separate themselves from the full impact of the trauma. Unfortunately, these individuals may ward off memories of the trauma so well that they may act as if it is not happening and later as if it never happened. Some individuals can so effectively repress traumatic memories that they become unable consciously to work through them. As a consequence, they are unable to put the facts surrounding the events associated with the trauma into perspective, but slowly, the dissociated feelings and memories leak into consciousness. This creates some of the classic symptoms associated with PTSD and DID, such as flashbacks or intrusive thoughts.

The advantage of using hypnosis comes from the facilitation of the recovery of affect or memories, the ability to dissociate memories from cognition, and the speed with which the process is achieved. Finally, because of the relationship between a history of childhood abuse and trance, these patients are usually highly hypnotizable (Chu and Dill, 1990; Hilgard, 1984; Nash and Lynn, 1986; Putman, 1993; Spiegel, 1988, 1990; Spiegel *et al.*, 1988).

Many former victims of childhood abuse may unknowingly use their hypnotic capacities to keep out of awareness the content of traumatic memories and in effect create different degrees of psychiatric illness (Sanders and Giola, 1991; Spiegel, 1984, 1986, 1989; Spiegel *et al.*, 1988; Terr, 1991). Teaching these patients self-hypnosis is a way of turning a weakness into a strong tool for self-mastery and control. The controlled use of hypnosis, then, becomes a way systematically to access previously dissociated material.

### The Condensed Hypnotic Approach

The use of hypnosis in the treatment of PTSD and dissociative disorders can be conceptualized as having two major goals, which can be achieved by the use of six different techniques (Maldonado and Spiegel, 1994, 1995, 2002b; Spiegel, 1992) (Table 72.7). The goals are to bring into **consciousness** previously repressed memories and to develop a sense of **congruence** between memories associated with the traumatic experience and current self-images. By making conscious previously repressed memories, the patient has the opportunity to understand, accept and restructure them. These goals are achieved by working through six treatment stages: confrontation, condensation, confession, consolation, concentration and control.

First the patient must **confront** the trauma. The therapist helps the patient recognize and understand the factors involved in the development of the symptoms for which help is now being

**Table 72.7 Condensed Hypnotic Approach**

Goals
To bring into consciousness previously repressed memories
To develop a sense of congruence between the traumatic memories and the self
Treatment Stages
Confrontation
Condensation
Confession
Consolation
Concentration
Control

sought. Hypnosis is then used to help the patient **condense** the traumatic memories. The hypnotic experience can be used to define a particularly frightening memory during the revision of the patient's history, which summarizes or condenses the main conflicts. The focused concentration achieved during the hypnotic state not only can facilitate recall of traumatic material but also helps place boundaries around it. After memories are recovered, we can help patients restructure them and even "become aware of things you did at the moment of trauma to survive". Once memories are recovered, patients usually need to **confess** feelings and experiences of which they are profoundly ashamed. These are usually things that they may have told no one else before; in fact, they have been running from them all their lives. At this time, the therapist must convey a sense of "being present" for the patient while remaining as neutral as possible. This is followed by the stage of **consolation**. Here, the therapist needs to be emotionally available to the patient. This stage must be carried on with caution and in a most professional manner. Therapists should be aware that the body and emotional boundaries of these patients may have been violated in the past. Then comes the stage of **concentration**. This component of the trance experience allows patients to have access or "turn on" the traumatic memories during the psychotherapeutic session and then "shut them off" once the work has been done. During the final stage, the patient comes to define herself or himself as being in **control** again.

The underlying principle to remember is that the most damaging effect of overwhelming trauma is that it renders its victims defenseless. Because of the lack of physical and emotional control, patients activate dissociative defenses in an attempt to master their experiences. By using self-hypnosis, the therapist can model and teach the patient to regain control over her or his memories. Patients must be encouraged to remember as much as they feel is safe to remember at a given time. The goal is that patients learn how to think about traumatic experiences, rather than negating their existence. The use of self-hypnosis teaches patients that they are in control of their experiences. Patients must dispel the magical beliefs that therapists "can take away the memories". Rather, by modeling this sense of trust in their therapists, patients learn to trust themselves. They relearn trust in their own feelings and perceptions.

The challenge in treating victims of abuse is to achieve a new sense of unity within the patient after the initial fragmentation

**Table 72.8 Therapeutic Precautions**

caused by the traumatic experience. Overwhelming trauma tends to cause sudden and radical discontinuities in consciousness, which leaves the victims with a polarized view of themselves involving, on one hand the old self (before the trauma) and, on the other, the helpless, defenseless and traumatized victim. Our goal is to find ways to integrate these two aspects of the self. Here, the patient's task is to acknowledge and place into perspective painful life events, thereby making them acceptable to conscious awareness.

One of the advantages of the use of hypnosis is that the affect elicited can be so powerful that most patients do not need to remember every single event of abuse or trauma. In fact, through the use of hypnosis, the therapist may help the patient consolidate the memories in a constructive way, thus facilitating recovery. After a condensation of the traumatic experiences, patients become ready to accept the victimized self. Instead of continuing the self-blame and shame because of what happened to them, they can learn to acknowledge and even thank themselves for what they did to survive. This restructuring allows them to shift their perception of self, changing their self-image from that of a victim to that of a survivor.

**Therapeutic Precautions** Therapeutic precautions are shown in Table 72.8. The strength of transference during the psychotherapy of trauma victims is enormous. The use of hypnosis does not prevent development of a transference reaction; it may actually facilitate its emergence earlier than in regular therapy owing to the intensity with which the material is expressed and memories are recovered (Maldonado and Spiegel, 1994, 1995, 2002b).

Reliving the traumatic experience along with the patient may allow a special feeling of "being there with them" at the moment of trauma. This allows the therapist to provide guidance, support, protection and comfort as the patient goes through the difficult path of reprocessing traumatic memories. On the other hand, this kind of **traumatic transference** between the therapist and the victim of sexual assault is different in the sense that the feelings transferred are related not so much to early object relationships but to the abuser or circumstances that are associated with the trauma (Spiegel, 1992). Instead of seeing this expressed anger at the therapist as a form of negative transference reaction, we should explore the possibility that this may be a healthy attempt for the patient to experience anger toward the perpetrator. As therapists, we should not minimize or shut off these feelings. This will only confirm the patient's former perception that there was something wrong with him or her for having these feelings, which will probably activate further use of primitive defenses, including dissociation or acting out.

A more serious complication of the use of hypnosis with trauma victims is the possible creation of **false memories**. Hypnosis, with its heightened sense of concentration, allows the patient to focus intensely on a given time or place, enhancing memory recall. The principle of state-dependent memory also makes it plausible that the mere entrance into this trance state can facilitate retrieval of memories associated with a similar state of mind that may have occurred during the trauma and subsequent flashbacks. However, not every memory recovered with the use of hypnosis is necessarily true. Hypnosis can facilitate improved recall of true as well as confabulated material (Dywan and Bowers, 1983). Suggestibility is increased in hypnosis, and information can be implanted or imagined and reported as verdict (Laurence and Perry, 1983; McConkey, 1992). Because of this, therapists are warned about “believing” everything a patient is able to recall. Just as we use therapeutic judgment to analyze and interpret our patients’ (nontraumatic) childhood memories, fantasies and dreams, so should we treat hypnotically recovered material with caution.

To this date, no evidence proves that the patient’s confrontation with alleged perpetrators of childhood abuse or pursuit of legal retribution toward the perpetrator provides any therapeutic benefit. As therapists, we cannot be certain of which memories are real, which are completely confabulated, and which are a combination of both. Because of this, we should not encourage our patients to take legal actions. If, on the other hand, our patients insist in pursuing this avenue, it is our duty to warn them of our concerns but to be supportive of whatever final decision they make. Certainly we will do a service to our patients if we inform them of all the legal ramifications that the use of hypnosis, or any other form of memory enhancement, may have for their defense, including their ability to testify in court or to use the material recovered by such techniques.

## Applications in General Medicine

### Medical Procedures

Because hypnosis can be used to produce a state of relaxation and to reduce anxiety, it has proved to be valuable as an adjuvant to medical procedures. Once patients have been trained in the use of self-hypnosis, they can use it both in preparation for a hospital visit and while in the clinic or hospital. Once in that state, they can imagine themselves being somewhere they enjoy and feel safe, thereby dissociating their mental experience from the physical (and possibly painful or unpleasant) aspects of the procedure. It can also be used as a way of mastering the anxiety associated with potentially threatening procedures, such as computed tomography, bone marrow aspirations, phlebotomy, needle biopsy, lumbar punctures, or therapeutic interventions, such as chemotherapy, external beam radiation therapy and dental procedures.

### Pain Control

Pain is always a psychosomatic phenomenon, combining somatic with subjective distress. It never exists in a vacuum and always represents a combination of tissue injury and the emotional reaction to it.

Despite the organic factors causing pain, it is clear that psychological factors are major variables in the intensity of the pain experience. Beecher (1956) demonstrated that the intensity of pain was directly associated with its meaning. For example, to the extent that pain represented threat and the possibility of future disability, it was more intense than it was among a group of combat soldiers to whom the pain of injury meant that they were likely to get out of combat alive.

Hypnosis can facilitate an alteration in the subjective experience of pain (Brose and Spiegel, 1992). Several techniques can be used to achieve this goal. Most techniques involve the production of physical relaxation coupled with visual or somatic imagery that provides a substitute focus of attention for the painful sensation.

Even though the precise mechanism for hypnotic analgesia is not known, it is suspected to have components of two complementary mechanisms: physical relaxation and attention control. Patients in pain tend to splint the painful area instinctively, which in turn increases muscle tension around the painful area, often resulting in increased pain. Therefore, creating a state of hypnotically induced relaxation may easily decrease their experience or perception of pain.

Studies have also shown the superiority of hypnotic analgesia to the level of analgesia provided by either placebo (McGlashan *et al.*, 1969) or acupuncture (Knox and Shum, 1977). Katz and colleagues (1974) have shown a correlation between hypnotizability and responsiveness to acupuncture, proving that hypnotic mechanisms of pain control may be mobilized by other treatment techniques. Nevertheless, the explicit use of hypnosis with hypnotizable patients has proved to be the most powerful means of controlling pain. Hilgard and Hilgard (1975) estimated a 0.5 correlation between hypnotizability and treatment responsiveness for pain control.

## Psychosomatic Disorders

Hypnosis is useful in both the diagnosis and the treatment of psychosomatic illness. By using hypnosis with these patients, the therapist may assist in diagnosing the symptoms as psychosomatic. Under hypnosis, many of the symptoms may improve or be completely reversed. It is important not to “force a cure” in any patient, but rather to allow patients to improve at a pace that feels comfortable, or to give up the symptom when ready. This allows patients not only to feel in control of the treatment and recovery process but also slowly to get back their sense of control over their body. Some patients obtain insight into what is happening to their bodies owing to the ability to explore the meaning and cause of the symptoms hypnotically.

In most instances, it is better if hypnosis is used as an adjuvant to any other medical treatment, including physical rehabilitation or any other treatment modality typically used in the treatment of the “real illness”. Most such problems involve a combination of somatic and psychological symptoms. Using a rehabilitation model avoids the trap of humiliating the patient who improves with the inference that the problem was “all in the mind”.

Hypnosis can be invaluable in the treatment of a number of psychosomatic conditions. In particular, disorders affecting the gastrointestinal system are among those conditions in which studies demonstrated a dramatic response. In cases of ulcerative colitis and regional enteritis, peptic ulcer disease and side effects of chemotherapy, hypnosis can produce a sense of control over

a symptom that causes the patient to feel especially helpless, thereby diminishing the cycle of reactive anxiety.

## Applications of Hypnosis in Habit Control

### Smoking Cessation

A number of studies demonstrate the efficacy of hypnosis as a tool to facilitate control of smoking, with success rates in cigarette abstinence after treatment with hypnosis ranging from 13 to 64%.

There are several mechanisms by which hypnosis may contribute to success in smoking cessation. The ritualistic process of the hypnotic exercise may provide a kind of substitute physical relaxation for the “breathing exercise” that accompanies the act of smoking; the positive affirmations in self-hypnosis provide positive reinforcement for behavior change and promote positive self-image; its use enhances self-observation and self-monitoring; and finally it can facilitate cognitive restructuring of the smoking habit.

The single-session method developed by Spiegel (1970) emphasizes teaching patients self-hypnosis rather than having multiple sessions with a therapist. It uses a strategy that is intrinsically self-reinforcing and meaningful to the patient. It can be practiced whenever the urge to smoke comes on the patient. This method of cognitive restructuring involves emphasizing that the act of smoking is destructive specifically to the patient’s body and thereby limits what the patient can do with his or her life by shortening the life span and deteriorating the quality of life. Hypnosis is used to emphasize the patient’s commitment to protect the body from the poison in cigarettes. This approach gives the patient the ability to examine priorities and to balance the urge to smoke against the urge to protect his or her body from damage. Smokers are instructed to focus on what they are **for** – protecting their bodies – rather than what they are **against** – smoking. This reduces the amount of attention they pay to smoking or its absence and provides immediate internal reinforcement for attending to care of the body (Spiegel and Spiegel, 1978).

There is no evidence that treatments employing hypnosis are more effective than other interventions for smoking. Nevertheless, they may be more efficient because they enable patients to employ a self-administered treatment strategy (self-hypnosis) to reinforce a more adaptive cognitive restructuring while providing patients with an exercise in physical relaxation.

### Weight Control

Seldom will the use of hypnosis alone be sufficient for the treatment of weight problems. It is usually employed as an adjunct to a comprehensive dietary and exercise control program for weight reduction and management. Similar to the use of self-hypnosis in the control of smoking, the purpose in dietary control is to restructure the patient’s experience with overeating. Patients are asked to examine their excess food intake and to pay attention to the damaging effects to their body. This then translates into an exercise about learning to eat with respect for one’s body. Once again, the emphasis is on what the patient is **for**, rather than being **against** food.

Unfortunately, long-term outcome studies on the usefulness of hypnosis for weight control are lacking. Clinical experience

suggests that those within 20% of their ideal body weight may obtain some benefit from such restructuring techniques with self-hypnosis, combined with a regimen of a balanced diet and exercise.

### Applications in Forensic Psychiatry

The most serious problem involves possible effects of hypnosis on memory. There is evidence that hypnosis can distort memory in two ways: through **confabulation**, the creation of pseudomemories that are reported as real, or through **concretizing**, an unwarranted increase in the confidence with which hypnotized individuals report their memories, either true or false (McConkey, 1992; Orne *et al.*, 1985; Spiegel and Spiegel, 1986; Spiegel and Vermuten, 1994). Hypnosis can facilitate the recall of dissociated memories, especially when recall is hampered by the strong affect associated with trauma (Kardiner and Spiegel, 1947; Spiegel, 1984, 1992). However, the research literature indicates that the most clearly reproducible problem is the production of confident errors, exaggerating the true value of memories unearthed in hypnosis.

This is especially a problem when the memories involve witnessing a crime and civil or criminal action in court is a possibility. Most states prohibit the use of hypnotically induced testimony, but some prescribe witnesses who have been hypnotized regarding the content of their potential testimony (Spiegel and Schefflin, 1994). If the possibility exists that a patient may be required to testify, it is wise to discuss the use of hypnosis with the patient and (with the patient’s permission) the patient’s attorney or the district attorney and obtain written agreement regarding its use. If the patient is likely to be called to testify, the therapist should obtain electronic recording of all contact with the patient (preferably on videotape) so the court can examine for possible suggestive influences. Full guidelines for use of hypnosis in the forensic setting include careful debriefing of the subject before hypnosis is employed, the use of nonleading questions, complete videotaping of all contact with the patient, and careful debriefing afterward (Spiegel and Spiegel, 1986).

The controversies surrounding so-called false memory syndrome have reignited questions regarding the validity of the material recovered by the use of hypnosis. One of the most common applications of hypnosis in the court and legal settings had been refreshing recollection of witnesses and victims of crimes. Even though the current controversy focuses on the dangers of hypnotically induced confabulation or excessive confidence in memories (Diamond, 1980), there have been some positive results. A well-known example is the case involving the driver of a hijacked school bus in Chowchilla, California (*People v. Schoenfeld*, 1980). Under hypnosis, the bus driver was able to recall the license plate number of the car driven by the kidnapers. This information, not consciously available to him before hypnotic intervention, led to the arrest and conviction of the criminals.

Because hypnosis involves a suspension of critical judgment, and therefore a state of heightened suggestibility or responsiveness to social cues, it is important that the interview be conducted with a minimum of inserted information. To minimize the risk of contaminating subjects’ memories, it is important to use open-ended questions, such as, “What happens next?” rather than, “How did he sexually abuse you?”

Information retrieved with the aide of hypnosis may simply be the result of an additional recall trial (Erdelyi and

Kleinbard, 1978), it may be new and true (Dywan and Bowers, 1983), or it may be a confabulation (Laurence and Perry, 1983). It may indeed be a combination of all three (Orne *et al.*, 1985). As a result, courts have long been unwilling to admit the testimony of a person hypnotized while testifying and have also begun to exclude testimony of witnesses who have previously been hypnotized about the event in question. Even when a subject is acting in good faith, hypnosis can amplify both truth and falsehood. A good guideline is that hypnosis increases the recovery of memories, both true and confabulated.

On the other hand, people do dissociate during trauma, often failing to recall events despite being conscious at the time (Cardeña and Spiegel, 1993; Spiegel and Cardeña, 1991). There is evidence that such memory gaps may persist for years or even decades after such traumatic events as physical or sexual abuse (Williams, 1994).

Therapists treating victims of sexual abuse must be aware that the use of hypnosis may compromise the ability of a witness to testify in court. After much legal battling, some courts now allow witnesses to testify after the use of hypnosis provided that certain guidelines are followed (California Legislature, 1985). These relate primarily to the training and independence of the professional doing the hypnotic interrogation and the electronic recording of the entire process (Spiegel and Spiegel, 1986).

To address this controversial issue, the Council on Scientific Affairs of the American Medical Association convened a panel of experts to examine the research evidence relevant to this problem. The report issued by the panel concluded that the existing evidence indicates that the use of hypnosis tends to increase the productivity of witnesses, resulting in new memories, some of which are true and some of which are incorrect (Orne *et al.*, 1985). The panel recommended that careful guidelines similar to the ones adopted by the state of California be followed when hypnosis is used in the forensic setting (Table 72.9).

As a rule, it is advisable to caution attorneys and witnesses that the use of hypnosis might open the possibility of challenge to the credibility or even the admissibility of a witness. The kind of situation in which hypnosis is most likely to be

worth the risk is one in which there is a traumatic amnesia for the events of a crime or in which all other avenues of exploration have been exhausted. Hypnosis is by no means a truth serum, and the courts must weigh the effects of any hypnotic procedure on a witness.

The medico-legal aspects of the use of hypnosis in psychiatric practice have been discussed at length elsewhere (Maldonado and Spiegel, 2002a, 2002b).

### Treatment Outcome Studies in Hypnosis

Most outcome studies, of which there have been a number, have resulted in two main conclusions related to the therapeutic uses of hypnosis. First, there is no doubt that hypnosis is effective. Secondly, the degree of hypnotizability is predictive of treatment response (Spiegel *et al.*, 1981b). It also has been observed that hypnosis is particularly useful and yields better results when it is specifically requested by the patient (Glick, 1970; Lazarus, 1973).

### Conclusion

Hypnosis is a natural state of mind. As a trait, it can be measured and mastered. Even though it occurs naturally, not everybody has the same hypnotic capacity. It involves the ability to concentrate intensely, the capacity to receive new information, and the flexibility to change behavior. The capacity to experience hypnosis constitutes a therapeutic resource in the patient that can be mobilized by formal hypnosis during the therapy session and self-hypnosis exercises afterward. Strategies such as cognitive restructuring under hypnosis can help patients alter their perspective on their symptoms by experiencing symptom resolution as an occasion to enhance their sense of mastery. Many therapeutic approaches using hypnosis involve changing the patient's perspective on the relationship between the psychological and the physical state, dissociating mental from physical stress and suffering (i.e., pain), adopting a stance of protectiveness toward the body rather than fighting destructive urges (i.e., quality of life versus smoking), or learning to see sudden discontinuities in consciousness (i.e., flashbacks and episodes of dissociation) as understandable and controllable hypnotic phenomena.

Training patients in the use of self-hypnosis can facilitate the therapeutic process. This use of hypnosis can communicate the therapist's desire to enhance the patient's mastery and independence. Thus, patients can learn to use their hypnotic capacity rather than be used by it. This newly developed ability can be understood as an exercise in self-control rather than submission to the will of the therapist. It can be used to enhance control of somatic processes, reactions to anxiety-provoking stimuli and impulsive behavior.

If you consider the use of hypnosis in a trial case, certain guidelines need to be observed:

- Caution attorneys and witnesses that the use of hypnosis might open the possibility of challenge to the credibility or even the admissibility of a witness.
- Carefully document memory before hypnosis of the witness.
- Use an expert psychiatrist or psychologist as a hypnosis consultant.
- Electronically record all interaction preceding, during and after hypnosis sessions. Document and record all contact with the victim.
- Conduct the interview in a neutral tone. Guide the victim through the experience but avoid using leading or suggestive questions. Avoid introducing information during the interrogation.

The developmental consequences of schizophrenia are substantial with typical onset of the first psychotic episode in late adolescence or young adulthood. People with schizophrenia become progressively more removed from their peer group, fail to achieve (or sustain) adult milestones such as marriage, higher education and employment, and often become socially isolated. These functional, psychosocial consequences become more severe and entrenched as illness duration increases, and result in multiple treatment needs that are superimposed on the neurobiological aspects of illness. While innovative new medications could potentially ameliorate (or compensate for) some of the consequences of anomalous neural development, it is unlikely that any pharmacological approach could restore normal brain function. Furthermore, no medication could undo the lifelong consequences of impaired learning, failure to master adult developmental tasks, and social withdrawal. These impairments mandate a multifaceted approach to treatment that includes an array of psychosocial strategies, of which rehabilitation plays a key role (Bellack, 1989).

The term **rehabilitation** is generally used to imply a subcategory of psychosocial treatment in which there is an emphasis on teaching/training, rather than discussion, and the focus is primarily on behaviors and functioning, rather than on intrapsychic processes (thinking and feeling). Reference is made to **psychosocial intervention** when the issues have generality to the broader domain of psychological treatment.

### Issues in the Design of Psychosocial Interventions

The potential benefits of psychosocial treatment are often not achieved in the community due to poor understanding of the special needs and liabilities of schizophrenia patients. Five factors need to be taken into account when implementing psychosocial interventions and evaluating the results: 1) timing and duration of treatment; 2) individual differences in treatment needs; 3) the role of the patient in treatment; 4) the limitations imposed by impairments in information processing; and 5) the need to base interventions on a compensatory model.

### Timing and Duration of Treatment

The *APA Practice Guidelines for the Treatment of Patients with Schizophrenia* (American Psychiatric Association, 1997, p. 1) makes a number of important points that are germane to rehabilitation programming, not the least of which pertains to the need for multimodal, long-term care: "Schizophrenia is a chronic condition that frequently has devastating effects on many aspects of the patient's life and carries a high risk of suicide

and other life-threatening conditions. The care of most patients involves multiple efforts to reduce the frequency and severity of episodes and to reduce the overall morbidity and mortality of the disorder. Many patients require comprehensive and continuous care over the course of their lives with no limits as to duration of treatment". This guideline is widely reflected in case management and pharmacotherapy but has not been adequately addressed in rehabilitation programs.

The role for psychosocial treatment and rehabilitation increases as the patient becomes more stable and shifts from support and stress reduction to specific rehabilitation strategies such as social skills training and cognitive rehabilitation. This three stage model and associated treatment emphasis has good face validity.

Treatment planning must be individualized. While this might seem like a given, many outpatient treatment systems are designed with a **one-size-fits-all** model, in which most patients are assigned to a standard set of group treatments paired with case management. This is a strategy that maximizes dropouts and minimizes effectiveness. This is a population that is difficult to treat effectively under the best of circumstances. Positive outcomes are likely only if both the content of treatment and the format of treatment are tailored to the individual patient's needs and learning capacities.

The combination of psychosis, thought disorganization and negative symptoms (especially anergia, apathy and anhedonia) often lead to the false assumption that patients are not capable of being active participants in their own treatment. Indeed, many patients seem unmotivated and are noncompliant, but such seeming disinterest and passivity should not be interpreted as accurate reflections of the person's goals and desires or as immutable traits. Negative symptoms are not always stable, and they may be secondary to demoralization, psychotic symptoms, medication side effects and other factors that vary over time (Carpenter *et al.*, 1988; McGlashan and Fenton, 1992). Paul and Lentz (1977) have shown that even extremely withdrawn, chronic schizophrenia patients can be motivated by a systematic incentive program. Similarly, desire to change and inclination to do the work required for treatment also vary over time in the same way that motivation to lose weight or quit smoking varies in nonpatient populations.

As cogently argued by Strauss (1989), schizophrenia patients have an active "will". Much of their behavior is goal directed and reflects an attempt to cope with the illness as best they can. Consequently, it is essential to view the patient as a potentially active partner and involve him or her in goal setting and treatment planning. Too often, treatments are imposed on patients by the treatment team and family members, with little consideration of the patient's own desires or capacities. It should not be surprising in such circumstances if the patient fails to

adhere to treatment recommendations, increasing the risk of relapse and creating tensions in relationships with family members and treatment providers. To be sure, engaging the patient to establish treatment goals can be a long, arduous process, but failure to do so courts the larger risk of undermining the very purpose of the intervention.

### Impairments in Information Processing

It is now well established that impaired information processing represents one of the most significant areas of dysfunction in schizophrenia. The illness is marked by neuropsychological deficits in multiple domains, including verbal memory, working memory, attention, speed of processing, abstract reasoning and sensorimotor integration (Braff, 1991; Green and Nuechterlein, 1999). These deficits are highly related to social functioning and role performance in the community, as well as to performance in skills training programs (Green, 1996; Green *et al.*, 2000).

A related issue concerns the impact of neurocognitive deficits on the generalization of treatment effects. A basic assumption of all psychotherapies is that skills acquired in treatment sessions must be transferred or generalized to the patient's natural environment. Yet, such generalization is contingent upon cognitive processes that are often disrupted in schizophrenia, especially "executive functions" mediated by the dorsolateral prefrontal cortex (Weinberger, 1987).

Unfortunately, clinical rehabilitation programs have lagged behind the experimental literature in this arena and neurocognitive deficits generally are not well addressed in a systematic manner.

### Adoption of a Compensatory Model

A rehabilitation model is more appropriate for treatment of most patients with schizophrenia than the standard treatment model as: 1) it implies a narrower focus on specific skills and behaviors, and 2) it aims to improve functioning in specific areas, rather than eliminating or curing an entire condition. As indicated above, cognitive impairment is a central feature of the disorder, evident in childhood and progressing sharply with the onset of psychotic illness. It is reasonable to speculate that the impairments observed in ill adult patients are at least of two types: 1) those present from early in development; and 2) those that are related to clinical psychotic illness. The existence of such early, developmentally based impairments suggest that the concept of "premorbid" functioning in schizophrenia may no longer be tenable; rather, there is a prepsychotic period during which there is subtle evidence of the "morbid" process. Thus, the challenge confronting attempts at cognitive enhancement may not be restoration of function, but instead may be the development of critical competencies and strategies for coping with deficits.

Consistent with this hypothesis, a compensatory approach to treatment may be more appropriate than the restorative or reparative approach characteristic of most treatment programs. Cognitive adaptation training (CAT) is a creative compensatory approach developed by Velligan and colleagues (2000). Case managers provide patients with home-based, compensatory environmental strategies to help structure the patient's living environment which maximizes the likelihood that she/he can complete requisite activities of daily living. Examples include posting reminders about appointments on the exit door from the apartment, listing items of clothing to be worn on the closet door, and

### Clinical Vignette 1

Susan R was a single white woman first diagnosed with schizophrenia when she was 24. She had been working as a clerk in a small store and living with her parents when she first became ill. She had had few friends and dated infrequently. She was 32 when she began to participate in our rehabilitation program. She was living in a group home and had been unable to work since her first psychotic episode. She was described by her case manager as a passive, shy woman who was frequently taken advantage of by other residents in the group home and the day treatment program she attended. She was referred to us because of concerns that: 1) she needed to be more assertive with other patients who were borrowing her money and personal items, and 2) that she had expressed an interest in getting a job but was so quiet that she was unable to get past interviews.

Susan was well-maintained on medication, she did not have significant negative symptoms and she did not manifest behavioral problems that would prevent her from working. Based on the case manager's report and a review of Susan's medical record we focused our attention on social skills. She was appropriately groomed and did not present herself as a "patient" (e.g., no inappropriate mannerisms, no intrusions of psychotic or tangential thoughts, able to track conversation and provide appropriate responses to questions). However, she had a **deer in the headlights** quality. She seemed quite ill at ease; she scarcely made eye contact, looking mostly at the floor; her arms were wrapped round herself and she seemed to be physically tense; her shoulders were hunched and her head tilted toward the floor; she spoke haltingly in a very soft voice, such that the interviewer frequently had to ask her to repeat what she had said and to speak more loudly. When asked about her case manager's concerns about lending things to peers she indicated she didn't always want to give away her money and things, but that she was afraid people would get angry with her if she refused. She expressed the desire to return to work as a clerk, especially if the job did not involve much pressure. She reported that she always felt nervous during job interviews even when she thought she could do the work.

In response to our evaluation and Susan's expressed desire to be more assertive and to be able to get a job, we contracted with her to participate in a social skills training group for 3 months. The group included six other patients and met twice per week for 60 to 90 minutes. Susan's program consisted of three interrelated curriculum units: 1) assertiveness training to teach her how to be more effective in refusing unreasonable requests from peers; 2) job interview skills; and 3) sexual assertion skills. The unit on sex was based on our concern that Susan was vulnerable to unwanted sexual advances, and addressed refusal skills (how to say "no") and safe sex skills (how to get a partner to use a condom). Skills training for all three units consisted primarily of role-play rehearsals. A theme was defined for each sessions (e.g., telling a friend you cannot lend them money) and each patient was prompted to identify a specific situation which had recently occurred or might occur in the near future. Patients then took turns

### Clinical Vignette 1 (continued)

engaging in repeated role plays in which the therapist portrayed someone in the patient's environment. In Susan's case, she identified other patients who frequently asked her for things and she rehearsed saying no to typical requests. Training Susan in job interview skills was coordinated with efforts by her case manager to arrange for interviews, as training is invariably more effective when it has near-term relevance and the new skills can be practiced in the real world. Training in safe sex skills proved to be very relevant as Susan admitted that she was being pressured to have sex by other patients.

Susan responded well to treatment. She was able to secure a part time job as a clerk within a few months of training, and had maintained the job when we followed up some 6 months later. Her case manager reported that she was better able to refuse requests for money, although it was arranged for staff to bank her paychecks and keep a minimal amount of cash on hand just to be safe. The case manager also reported that Susan had a boyfriend, another patient attending the day treatment center. While there is no assurance that Susan was practicing safe sex skills, she had not become pregnant, there was no evidence of an STD, and the boyfriend was known to be taking condoms from the bowl at the reception desk.

placing medications in a location that makes it maximally likely that the patient will see it and be reminded to take it. Prompts and other environmental aides are individually tailored to the patients' level of apathy, disinhibition and executive dysfunction. CAT can be administered in a time limited fashion, but may be a lifelong service for severely impaired patients. Velligan and colleagues found 9-months of CAT to be superior to an attention placebo and standard outpatient care on positive symptoms, negative symptoms, motivation, community functioning, global functioning and incidence of rehospitalization. This is an excellent model for compensatory interventions, and warrants further study (Table 73.1).

## Rehabilitation Strategies

The following sections will briefly describe and evaluate the two types of rehabilitation programs that have had the greatest impact on the field in the 1990s, social skills training and cognitive rehabilitation, and promising directions in vocational rehabilitation.

### Social Skills Training

The most useful perspective for understanding social functioning and social dysfunction in the illness has been the "social skills model" (Meier and Hope, 1998; Morrison and Bellack, 1984). Social skills are specific response capabilities necessary for effective performance. They include verbal response skills (e.g., the ability to start a conversation or to say "No" when needed), paralinguistic skills (e.g., use of appropriate voice volume and intonation) and nonverbal skills (e.g., appropriate use of gaze, hand gestures and facial expressions). These skills tend to be stable over time and make a unique contribution to the performance of social roles and quality of life (Bellack *et al.*, 1990; Mueser *et al.*, 1991). Increasing social competence and improving social role

functioning has been a major focus of rehabilitation efforts for the past 25 years, and a well-developed technology for teaching social skills has been developed and empirically tested: social skills training (SST) (Bellack *et al.*, 1997; Liberman, 1995).

Social skills training is a highly structured educational procedure that is generally conducted in small groups. Complex social repertoires such as making friends and dating are broken down into steps or component elements such as maintaining eye contact and asking questions. Patients are first taught to perform the elements and then gradually learn smoothly to combine them. Each session has a specific focus such as how to initiate conversations with strangers and how to refuse an unreasonable request. Trainers are more like teachers than traditional therapists. They first give patients simple instructions about how the behavior is to be performed, then they model appropriate behavior in a simulated conversation, and then they engage patients in role playing of simulated social encounters as a vehicle for practicing new skills. The therapists provide social reinforcement after each role played response and shape improved performance.

SST is clearly effective in increasing the use of specific behaviors (e.g., gaze, asking questions, voice volume) and improving functioning in the specific domains that are the primary focus of the treatment (e.g., conversational skill, ability to perform on a job interview). However, it is unclear whether other more diffuse dimensions of social functioning are affected, or the extent to which learning in the clinic translates into improved role functioning in the community. The effects of SST on relapse rate and symptoms appear to be negligible, although this is not surprising given the narrow focus of the intervention. SST is clearly an effective teaching technology that is well-received by both patients and clinicians. Nevertheless, it may well be that no time-limited, compartmentalized, office-based treatment can have broad-based effects. As discussed earlier in this chapter, it may be necessary to employ longer-term treatments that extend into the community and that are integrated with an array of intervention strategies.

Liberman and colleagues (2001) have approached the problem of generalization with an innovative approach referred to as *in vivo* amplified skills training (IVAST). It combines standard skills training with intensive case management, based on the assertive community treatment (ACT) model (Stein and Test, 1985). Office-based SST is supplemented and extended by a case manager who helps guide and reinforce appropriate behaviors in the community such as by helping a patient make a doctor's appointment or learn how to use public transportation. IVAST requires careful assessment of individual skills and needs and the extent to which the living environment is concordant with the patient's capacity to succeed. The case manager/trainer helps develop skills and/or shape the environment as needed, rather than putting the onus for success on the patient. IVAST has not yet been evaluated empirically but it is a creative approach that warrants careful study.

### Cognitive Rehabilitation

Recognition of the importance of neurocognitive deficits has stimulated increasing interest in the prospects for cognitive remediation. Results have not been particularly robust but the work has had tremendous heuristic value.

Wykes and colleagues (1999) developed an intervention called **cognitive remediation therapy** that focuses on executive functioning (e.g., cognitive flexibility, working memory and

**Table 73.1** Examples of Promising Rehabilitation Strategies

Strategy	Representative Source	Brief Description
Social skills training	Bellack <i>et al.</i> (1997)	A small group intervention for teaching patients social skills. Social behaviors are broken down into component units (e.g., making eye contact). Patients receive instruction on how to perform the units, and then rehearse effective social behaviors in simulated social encounters, analogous to learning motor skills.
	In Vivo Amplified Social Skills Training (Lieberman <i>et al.</i> 2001)	A program designed to foster generalization to the community by combining social skills training with intensive case management.
Cognitive rehabilitation	Integrated Psychological Therapy (Brenner <i>et al.</i> 1990)	A small group approach that attempts to reduce cognitive impairment that interferes with social functioning. Program involves a series of stages beginning with basic cognitive processing and ending with social skills training.
	Neuropsychological Educational Approach to Remediation (Medalia and Revheim, 1999)	A training program that employs commercially produced educational software that is selected to be of high <b>intrinsic</b> interest to patients. Patients select from a variety of software programs that involve diverse neurocognitive capacities and work at their own pace.
	Cognitive Remediation Therapy (Wykes <i>et al.</i> , 1999)	A one-on-one training program that focuses on executive functioning and higher level cognitive capacities using paper and pencil tasks and neurocognitive tests. Emphasis is placed on teaching response strategies (e.g., problem-solving) in a graduated fashion that minimizes errors and frustration.
Vocational rehabilitation	Integrated Placement and Support Model (Drake <i>et al.</i> , 1999)	An innovative approach that employs a <b>train</b> and <b>place</b> model, rather than the traditional <b>train</b> and <b>place</b> approach. Patients work with a case manager who helps them find a real job in the community, and then provides ongoing support at the workplace to help the person succeed.
Cognitive adaptation training	Velligan <i>et al.</i> (2000)	Based on the assumption that many patients cannot monitor and manage their own behavior in the community, a clinician goes to the person's home to help structure the environment in ways that minimize demands on limited cognitive capacity. Techniques include: 1) organizing drawers and closets so person automatically selects appropriate clothing items; 2) placing signs and other prompts in highly visible places in the apartment (e.g., bathroom mirror) to remind patient to perform ADLs (activities of daily life); 3) to take medicine, etc.

planning). The approach employs a sophisticated training model that is based on principles of errorless learning, targeted reinforcement and guided practice on cognitive tasks. Training media consist of a variety of paper and pencil games and neurocognitive tests. A preliminary trial yielded improvement on several neuropsychological measures and modest retention of training effects over a 6-month follow-up interval. A limitation of this program is that it employs a highly tailored individual treatment model and demands high levels of therapist skill slowly to shape patient behavior. However, the focus on executive functioning seems much more likely to lead to transferable effects than narrowly focused programs designed to strengthen working memory or attention.

An alternative approach to cognitive rehabilitation capitalizes on the ease of standardization and flexibility provided by computer software. Wexler and colleagues (1997) and Bell and colleagues (2001) reported positive results for similar programs that provide self-directed practice on basic attention, memory and reasoning tasks (e.g., visual tracking, pyramids). These programs are limited in that patients find the

tasks repetitive and boring, and they do not receive training *per se*. Patients may become more skilled on the specific tasks but they do not necessarily learn effective strategies that normalize dysfunctional neural circuitry or foster generalization to other situations.

### Vocational Rehabilitation

The ability to perform productive work, earn money and achieve a degree of independence is generally regarded as a major factor in self-esteem, quality of life and relationships with significant others. Yet it is a domain that is particularly difficult for schizophrenia patients. Rates of competitive employment for persons with schizophrenia are generally less than 25%, and participation in sheltered employment is not much better (Lehman, 1995). There have been numerous hypotheses to explain the poor employment performance of schizophrenia patients, many of which place the onus on symptomatology, especially the sequelae of negative symptoms. Conversely, evidence suggests that employment history, work adjustment and ability to get along or function socially with others are better predictors of employment (Anthony and

Jansen, 1984). Social skill and ability to get along with others appear to be critical factors in both securing work (Charisiou *et al.*, 1989) and maintaining employment (Chadsey-Rusch, 1992; Cook *et al.*, 1994; Lehman, 1995).

There are many forms of vocational programs available in the community, including sheltered workshops, job clubs, transitional employment, the Boston University model and programs of job support. With the exception of programs involving job support, there is little evidence that these types of vocational interventions often result in sustained competitive employment among patients with severe mental illness (Lehman, 1995). Such programs, however, appear to provide many patients with structured opportunities for socialization and meaningful daily activity. Such limited goals may be appropriate for certain patients. However, for patients who are interested in competitive employment, it is clear that traditional approaches to psychiatric rehabilitation have proven to be disappointingly ineffective.

Recent evidence from several well-controlled studies suggests that the integrated placement and support (IPS) model of vocational rehabilitation may provide a distinct advantage in increasing rates of competitive employment among patients with severe mental illness (Drake *et al.*, 1999; Lehman *et al.*, 2002). The IPS model emphasizes the integration of vocational and mental health services by having an employment specialist becoming a member of the multidisciplinary clinical management team. The employment specialist helps patients search for real jobs in the community, rather than for placement in sheltered workshops or training programs. After employment is secured, the specialist provides follow-along support in a time-unlimited manner, including intervening with the employer if necessary. A manual has been developed to ensure fidelity of implementation of the approach. However, job retention is a major problem, that requires different strategies than job finding. Given the high priority placed on employment by patients, family members, and the community, improved employment services should be a major focus of research efforts in the future.

## Conclusion

As evidenced by the approaches discussed here, the scientific literature is moving away from long-term, unfocused day treatment approaches to targeted intervention strategies designed to deal with specific problems. This approach, which is much more likely to produce useful outcomes, has not yet had adequate penetration of community services. Further research is required to match interventions with patients to determine when specific interventions should be provided, and to build in sufficient booster or follow-up procedures to maximize the chances for enduring change in the community. It is by now very apparent that neither a **one-size-fits-all** nor a time-limited, up-and-out approach works with the population of major concern, those with schizophrenia.

# Electroconvulsive Therapy, Transcranial Magnetic Stimulation, and Vagal Nerve Stimulation

Following six decades of uneven use, modern ECT has found a narrow but important niche among contemporary treatments in psychiatry. A large body of controlled data supports the efficacy and safety of ECT in the treatment of major depression and other severe psychiatric disorders (American Psychiatric Association, 2001).

## Indications for ECT

### General Considerations

In contrast to its origins as a treatment of schizophrenia, ECT today is generally utilized more frequently in patients with depression, especially psychotic depression and in the elderly. Mania and schizophrenia account for most of the remainder of convulsive therapy use. The indications have been most clearly spelled out by the American Psychiatric Association on ECT (American Psychiatric Association, 1990, 2001), which identified “primary” and “secondary” use of convulsive therapy. Primary indications are those for which ECT may appropriately be used as a first-line treatment. These include situations where the patient’s medical or psychiatric condition requires rapid clinical response, where the risk of alternative treatments is excessive, or where, based on past history, response to ECT or nonresponse to medications is anticipated. If these conditions are not met, medication or other alternative treatment is recommended first, with ECT reserved for cases of nonresponse to adequate trial(s), unacceptable adverse effects of the alternative treatment, or deterioration of the patient’s condition, increasing the urgency of the need for response (American Psychiatric Association, 2001). These general principles in turn require individualized interpretation in the presence of specific psychiatric and medical disorders. Even where ECT is not used as treatment of first choice, its introduction sooner in the decision tree rather than being reserved as a “last resort” may spare the patient multiple unsuccessful medication trials, thereby avoiding months of suffering and possibly reducing the likelihood of treatment resistance (American Psychiatric Association, 2001). Modern diagnostic and clinical considerations in the recommendation of ECT are summarized in Table 74.1.

### ECT in Depression

It is well established that major depression is a heterogeneous disorder, encompassing mildly ill, functioning outpatients, as well as profoundly disturbed, dysfunctional, or often psychotic inpatients. Along this spectrum, ECT appears higher in the treatment hierarchy for the more severe presenting depression, usually defined by the presence of neurovegetative signs, psychosis, or suicidality (Abrams, 1982; American Psychiatric Association, 2000, 2001).

While there are no absolute rules, severely melancholic or psychotically depressed patients are often appropriate candidates for ECT as treatment of first choice, whereas more moderately ill individuals might not be considered for ECT until adequate medication trials have failed.

### Predictors of Response

The literature describes an overall response rate to ECT of 75 to 85% in depression (Crowe, 1984; O’Connor *et al.*, 2001). Efforts to delineate subtypes of depression particularly responsive to ECT have yielded inconsistent results. ECT is most likely to be helpful in an acute episode of severe depression of relatively brief duration (Rich *et al.*, 1984). Combined data from two simulated-ECT-controlled trials (Brandon *et al.*, 1984; Buchan *et al.*, 1992) identified the presence of delusions and psychomotor retardation as predictive of preferential response.

Psychotic depression, increasingly recognized as a distinct subtype of mood disorder that responds poorly to antidepressants alone, has emerged as a powerful indication for ECT (Potter *et al.*, 1991; Petrides *et al.*, 2001). In this subgroup, ECT is at least as effective as a combination trial of antidepressant and antipsychotic medications. On balance, the evidence supports the early use of ECT in psychotic depression, particularly in lieu of prolonged, complicated medication trials that may be poorly tolerated, especially in the elderly (Khan *et al.*, 1987; Potter *et al.*, 1991; Sackeim, 1993).

While bipolar (discussed below) and unipolar depressions are equally responsive to ECT (American Psychiatric Association, 2002), response may be less likely with secondary than primary depression, in both adults (Kramer, 1982; Zorumski *et al.*, 1986; Zimmerman *et al.*, 1986a), including the elderly

**Table 74.1 Indications for Electroconvulsive Therapy**

I. Diagnostic Considerations	
A.	Major depression: unipolar, especially primary <b>psychotic</b> (but other subtypes may respond); bipolar
B.	Mania
C.	Schizophrenia: acute
D.	Schizoaffective disorder
E.	Neurologic disorders: Parkinson's disease catatonia neuroleptic malignant syndrome
II. Clinical Considerations	
A.	Need for rapid response on medical or psychiatric grounds (e.g. suicidality, inanition)
B.	History of treatment-resistance or excessive risk of alternative treatments
C.	Severity of illness
D.	History of previous positive response to ECT
E.	Patient preference
F.	Informed consent required

(Zorumski *et al.*, 1988) and adolescents (Schneekloth *et al.*, 1993). This may be especially true when depression is secondary to another psychiatric disorder, rather than to a medical illness.

### Bipolar Disorder

ECT is an extremely effective and rapidly acting treatment for both acute mania and bipolar depression (American Psychiatric Association, 2002). However, it is infrequently used for mania, because of the availability of pharmacological strategies. Nonetheless, ECT has been repeatedly endorsed as an accepted second- or third-line treatment for acute manic episodes, particularly in cases of medication resistance, in patients of all ages (NIH/NIMH, 1985; Goodwin and Jamison, 1990; Mukherjee *et al.*, 1994; Van Gerpen *et al.*, 1999; American Psychiatric Association, 2002). In medical emergencies associated with mania, ECT can be regarded as a treatment of first choice (American Psychiatric Association, 2002). The same is true for medical conditions accompanying acute mania (including pregnancy, discussed later) that contraindicate or render intolerable the use of psychotropic medications.

There is little information on which manic patients benefit most from ECT or on optimal ECT treatment in mania. Bipolar depression responds as well as unipolar depression to ECT, in both adult and geriatric patients (American Psychiatric Association, 2002). Hypomania or mania is a risk of using ECT for depression in bipolar patients, but this is not different from the experience with any antidepressant treatment in this disorder (Gormley *et al.*, 1998; American Psychiatric Association, 2001, 2002).

### Schizophrenia

Among the changes undergone by convulsive therapy over its 60-year history, few are as striking as those associated with its use in chronic psychotic illness. ECT has evolved from a treatment of

first choice to often a treatment of last resort for DSM-IV schizophrenia. However, the efficacy of ECT for depressive symptoms associated with psychotic illness is reflected in recent nationwide data showing the use of convulsive therapy in almost 12% of patients with recurrent major depression comorbid with schizophrenia (Olfson *et al.*, 1998), a utilization rate higher than that seen in uncomplicated recurrent depressive disorder.

The American Psychiatric Association Task Force on ECT (American Psychiatric Association, 2001) and the Canadian Psychiatric Association (Enns and Reiss, 1992) identified a role for ECT as a second-line treatment for selected patients with schizophrenia, particularly when associated with a brief duration of illness and/or affective symptoms.

It has been consistently found that the schizophrenic patients most likely to respond to ECT are those with good prognosis signs: mood disturbances, short duration of illness, predominance of positive rather than negative symptoms, and overexcitement (Fink and Sackeim, 1996). The potential responsiveness of acute psychotic symptoms in schizophrenia to ECT is more emphatically stated in the 2001 revision of the American Psychiatric Association Task Force Report compared with the previous edition, based on research conducted and compiled in the intervening decade (Fink and Sackeim, 1996).

### Other Axis I Disorders

As reiterated in the Surgeon General's report on mental health (US Department of Health and Human Services, 1999), ECT has no demonstrated efficacy in dysthymia, substance abuse, or anxiety disorder. Nonetheless, ECT may play a role when the severity of a secondary major depression is severe and/or treatment refractory (American Psychiatric Association, 2001). In such circumstances, ECT can be expected to improve the comorbid mood component, leaving the underlying primary disorder untreated; in some circumstances, removal of the burden of overlying depression may indirectly benefit the underlying disorder. In the face of a potentially ECT-responsive major depressive episode, the presence of a nonmood Axis I disorder, even substance abuse, should not constitute a contraindication to the use of convulsive therapy (Olfson *et al.*, 1998; American Psychiatric Association, 2001).

### Axis II Disorders

There are no evidence-based biological treatments for DSM-IV Axis II personality disorders, including ECT. Given the high incidence of comorbid, often treatment-refractory depression that accompanies Axis II pathology, ECT has been used in personality disordered patients, with inconsistent – but generally negative – reports of success, for many years.

### Neurologic Disorders

Only 1% of patients admitted with a primary diagnosis other than a mood disorder or schizophrenia are treated with ECT in this country (Thompson *et al.*, 1994). Nonetheless, individuals with neurologic or other medical problems often suffer from primary or secondary mood or motor disorders that are ECT-responsive.

### Catatonia

Over the past decade, benzodiazepines have emerged as the pharmacological treatment of choice for catatonia (Rosebush *et al.*,

1992; Ungavari *et al.*, 1994). However, in medication-unresponsive patients, prolonged drug trials with continuing clinical deterioration can be avoided in favor of a course of ECT (Ungavari *et al.*, 1994). Reflecting current understanding of the syndrome and its treatment, Fricchione (1989) recommended that “given the significant morbidity and mortality associated with catatonia, ECT should be considered if an expeditious 48- to 72-hour benzodiazepine trial is unsuccessful”. As a practical point, given the now-common initial use of benzodiazepines in this condition, the catatonic patient may come to ECT with an initially elevated seizure threshold, and treatment parameters should be adjusted accordingly (Fink, 2002).

### Other Neurologic Illness

The remaining neurological indications for ECT can be considered to fall into two major categories: 1) those for which, as with any medical illness, ECT is considered for treatment of a secondary depression when benefit–risk analysis favors ECT over antidepressant medications and 2) those for which ECT may play a special role by virtue of its unique actions compared with alternative treatment options.

In the first category are such conditions as poststroke depression (Murray *et al.*, 1986; Currier *et al.*, 1992) and mood disturbance in the context of brain trauma, tumor, or dementia (Hsiao *et al.*, 1987; Liang *et al.*, 1988; Kohler and Burock, 2001). Medication may be difficult to tolerate by these neurologically ill patients, tilting the potential benefit–risk ratio in favor of ECT (Price and McAllister, 1989).

Potential contraindications to ECT are very few and rarely are absolute (American Psychiatric Association, 2001). Although ECT generally should not be performed in the presence of raised intracranial pressure, it has been given safely even in the face of brain tumors and other mass lesions (Hsiao *et al.*, 1987; Fried and Mann, 1988; Abrams, 1991; Kohler and Burock, 2001) with special steps taken to protect against the ECT-associated hemodynamic changes; intracranial pressure may be reduced with the use of oral or parenteral steroids (Beale *et al.*, 1997).

### Other Considerations in the Use of ECT

It can be appreciated that while accurate psychiatric diagnosis is essential to prioritize treatment options, it is far from the only consideration for the clinician weighing the advantages and potential problems of prescribing ECT (American Psychiatric Association, 2001). Two often-related variables are the patient’s state of physical health and age. A large number of individuals receiving ECT in this country are elderly, many of whom are physically compromised.

Two general points should be made about the use of ECT in the elderly: 1) the physiological changes associated with ECT – cardiovascular (elevated blood pressure, arrhythmias), cognitive (confusion, memory loss), risk of traumatic injury to bones and teeth – that are benign and easily tolerated in young and middle-aged patients are prominent sources of potential ECT-associated morbidity in geriatric patients, and 2) the safety of ECT is appreciably enhanced if the foregoing effects on the older body, whether healthy or diseased, are anticipated and controlled. For example, Casey and Davis (1996) noted that a “rigorous falls prevention protocol” helped protect their elderly ECT patients from a potentially dangerous complication seen in earlier studies.

The very limited use of modern ECT in young people is generally reserved for cases of depression or mania complicated by medication resistance or the need for an urgent clinical response. Nonetheless, where ECT is utilized in younger patients, its efficacy and safety appear comparable to those in adults (Rey and Walter, 1997; Cohen *et al.*, 2000).

A special physical health challenge to the treatment of mental disorders is presented by pregnancy. Guidelines for the administration of ECT in the pregnant patient, incorporating measures such as intravenous hydration, avoidance of hyperventilation and nonessential anticholinergic medication, measures against gastric reflux, proper positioning of the patient during treatment, and uterine and fetal cardiac monitoring, have been developed and incorporated into modern practice (American Psychiatric Association, 2001).

### Pretreatment Evaluation

Once the decision has been made to proceed with a course of ECT, specific steps are taken by the treatment team to maximize the benefits and minimize the risks. In some instances these procedures are part of the initial work-up, and the results may influence treatment decisions, as when certain psychiatric or physical disorders are ruled in or out.

The psychiatrist will want to make use of appropriate consultants, especially representing the fields of anesthesiology and, when indicated, internal medicine (often cardiology) or obstetrics. Given the current regulatory climate, the physician needs to be aware of local requirements regarding the need for second opinions or other pretreatment procedures in certain circumstances, or to arrange for guardianship or court proceedings where the patient’s capacity to consent to ECT is in question, to assure that the initiation of treatment is not unduly delayed.

### Psychiatric Considerations

The pre-ECT evaluation is a good time to confirm psychiatric diagnosis, including Axis II and III. In many settings, a specific ECT consultation may be helpful in evaluating the patient for a potentially ECT-responsive disorder and weighing the various treatment options (Klapheke, 1997). Input from nursing and other professional staff that have been working with the patient should be factored in. Should the indications for ECT remain present, baseline assessments of mental status including evaluation of suicidality, orientation and memory will help monitor changes in both therapeutic and adverse effects over the course of treatment. The history and effects of previous treatment with ECT should be obtained. Also, this time, decisions must be made regarding ongoing psychotropic medications particularly those increasing the risk of toxicity in combination with ECT, for example lithium and those affecting seizure threshold, such as benzodiazepines and anticonvulsants – and steps instituted to adjust, taper, or discontinue these medications, when appropriate.

### Other Medical Considerations

History and physical examination should focus on the cardiovascular and neurological systems, the areas of greatest risk. The consulting internist, anesthesiologist, or other physician should advise the treatment team regarding cardiovascular risk of ECT and the need for any modifications in treatment technique, such as medications to moderate hemodynamic changes (Dolinski and

Zvara, 1997). Appropriate pretreatment optimization and monitoring of medical conditions that may be affected by ECT, such as diabetes, should be arranged at this time.

In the uncomplicated situation, the routine laboratory work-up for ECT is that indicated for any procedure involving general anesthesia: complete blood count, serum electrolyte levels and electrocardiogram (ECG) (American Psychiatric Association, 2001; Chaturvedi *et al.*, 2001). Chest X-ray is often obtained as well. The need for further pretreatment work-up, such as serum chemistries, urinalysis, HIV antibody titers and medication blood concentrations, is determined on an individual basis (Lafferty *et al.*, 2001). Given a normal neurologic and fundoscopic examination, computerized tomography (CT) or magnetic resonance imaging (MRI) of the brain is not indicated. Lumbosacral spine films, historically routine prior to institution of muscle relaxation in the ECT premedication protocol, have become optional for many patients. This remains appropriate for older patients with a history of or at risk for osteoporosis, and for any patient with a history of bone trauma. A formal anesthesiology consultation should result in an assignment of the degree of anesthesia risk and recommendations for any necessary modification in the ECT protocol (Folk *et al.*, 2000). A personal or family history of anesthesia complications may call for special assessment. The condition of dentition should be routinely assessed to avoid the treatment-associated risk of aspiration or fracture of loose teeth or bridgework.

### Informed Consent

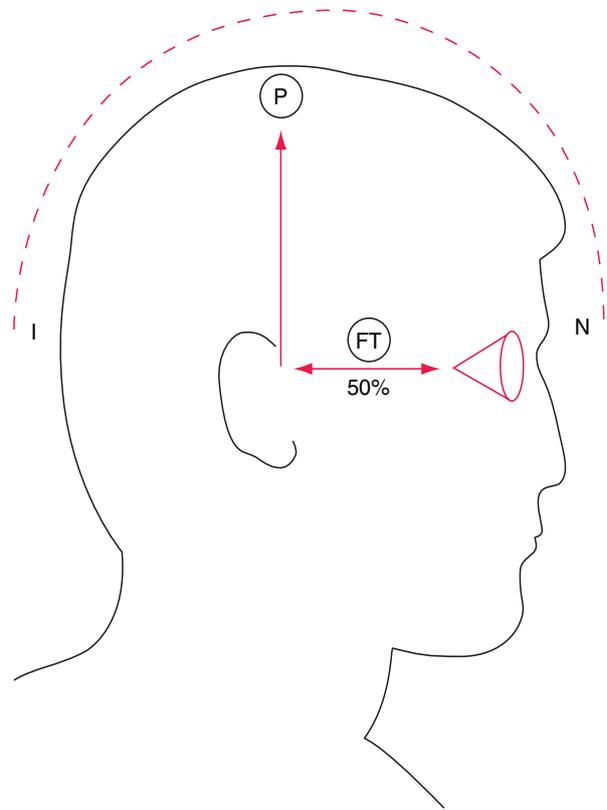

Among the unique features of ECT compared with other standard psychiatric treatments is the requirement for written informed consent by the patient or legal guardian or other substitute. Guidelines regarding the content of a standard informed consent form for ECT have been published (American Psychiatric Association, 2001). Supplemental information regarding ECT for patients and their families in a variety of media is also available and its distribution is encouraged (Fink, 1999; American Psychiatric Association, 2001).

The NIH/NIMH Consensus Development Conference on ECT (1985) emphasized that informed consent is a process that continues throughout the treatment course. Given the transient cognitive impairments common in depression and during an ECT course, it is particularly necessary to maintain a dialogue with the patient as treatment progresses to assure that all of the patient's questions and concerns are addressed, even if repetitive discourse ensues. With appropriate modification of the presentation of information, including use of nonverbal demonstration of the procedure, even patients with mental retardation often can make informed decisions about consent for ECT (Van Waarde *et al.*, 2001).

### Initiation of Treatment

Once informed consent has been obtained, the initiation of treatment involves several decisions. These include selection of ECT device, electrode placement, dose of electricity, choice of premedications and frequency of treatment.

In choosing electrode placement there are two important factors to consider: antidepressant efficacy and cognitive side effects. The choices of electrode placement can be divided into unilateral placement over the nondominant (generally right) hemisphere and bilateral electrode placement (Figure 74.1),

**Figure 74.1** Positioning of stimulus electrodes with bilateral and right unilateral ECT. For the standard bifrontotemporal (bilateral) placement, the electrodes are placed in position FT (frontotemporal). The midpoint of the line connecting the external canthus and the tragus is determined on both sides of the head. The center of the electrode is positioned 1 inch above this point. In the USA, stimulus electrodes are typically 2 inches in diameter, so the bottom of the electrode is adjacent to this point. For the commonly used d'Elia placement with right unilateral ECT, one electrode is in the FT position on the right side. The other electrode (P) is over parietal cortex and is positioned by determining the intersection between the line connecting the left and right tragus and the inion (I) and nasion (N). The center of this electrode is 1 inch below this intersection. (Source: American Psychiatric Association, [2001] *The Practice of Electroconvulsive Therapy: Recommendations for Treatment, Training and Privileging – A Task Force Report*, 2nd edn. American Psychiatric Press, Washington DC.)

*As potential but still experimental alternatives to traditional bifrontotemporal electrode placement, novel bifrontal and asymmetric placements are undergoing investigation as to whether they confer cognitive advantages by reducing electrical stimulation in left temporal areas while retaining therapeutic efficacy (Bailine *et al.* 2000). The bifrontal placement of Lawson and coworkers (1990) positions the center of each electrode approximately 5 cm above the lateral angle (external canthus) of each orbit, about 14 to 16 cm apart. The asymmetric (anterior bilateral) placement of Swartz (1994) positions the left-sided electrode above the left eye, with the lateral edge bordering the bony ridge between the forehead and the temple. The right-sided electrode is placed in an identical position to that used for the right-sided electrode in the traditional bifrontotemporal placement.*

traditionally bifrontotemporal. The advantage of unilateral placement is that there is less memory loss and confusion than with bilateral electrode placement (Horne *et al.*, 1985; Weiner *et al.*, 1986; Abrams, 1982). The disadvantage of unilateral ECT is that it appears to be less effective when the dose of electricity given is close to seizure threshold (Sackeim *et al.*, 1993), and the seizure threshold can vary more than 40-fold from individual to individual (Sackeim *et al.*, 1987, 1991). With bilateral placement, seizure threshold is less of a concern, and the degree and speed of response appears greater with (high dose) bilateral than unilateral ECT (Nobler *et al.*, 1997; Sackeim *et al.*, 2000). Although bifrontotemporal placement has been more widely used, a limited number of studies suggest that bifrontal electrode placement may offer comparable treatment efficacy with fewer cognitive side effects (Weiner, 1994). Individuals who are unresponsive to several adequately dosed unilateral treatments may benefit from a switch to bilateral electrode placement.

From the start of the treatment procedure (see Table 74.1) EKG, heart rate and blood pressure are monitored and oxygen saturation is measured via pulse oximetry. Oxygen by mask is typically administered after the induction of anesthesia and until the return of spontaneous respiration. Depending upon the preference of the treatment team, patients may or may not be premedicated with an anticholinergic agent. Atropine and glycopyrrolate are the agents most commonly used (Abrams, 1997). The rationale for using these premedications is twofold. First, they reduce the bradycardia observed immediately after the delivery of the stimulus, and secondly, they dry secretions during anesthesia (Sommer *et al.*, 1989). The decrease in heart rate initially observed during seizure induction is the result of increased vagal tone which occurs immediately after the stimulus (Elliot *et al.*, 1982).

The patient is rendered unconscious with a short-acting general anesthetic. Methohexital 0.75 to 1.0 mg/kg given intravenously is the agent most commonly used (Folk *et al.*, 2000). Once the patient is unconscious, a muscle relaxant is administered. Intravenous succinylcholine 0.5 to 1.0 mg/kg is almost always used for this purpose. The goal of the muscle relaxant is to dampen the tonic-clonic movements from the seizure and reduce the risk of musculoskeletal injury (Elliot *et al.*, 1982; Lippmann *et al.*, 1993; Weiner, 1994). The **cuff technique** (Fink and Johnson, 1982) may be applied to an ankle or forearm, preventing localized circulation of the muscle relaxant, thereby facilitating monitoring of the motor seizure duration. The degree of relaxation is somewhat dependent upon the preference of the practitioner; however, when there is a history of skeletal disease the paralysis should be nearly complete. The fasciculations induced by succinylcholine can cause myalgias which can be prevented by administration of a small dose of the nondepolarizing agent, curare, prior to dosing with the succinylcholine. When curare is used in this manner it is necessary to increase the succinylcholine dosage by approximately 25% to achieve the same level of muscle relaxation as previously.

When the patient is unconscious and relaxed, the stimulus is delivered, using the desired electrode placement. Initially, the jaw will clench as a result of direct electrical stimulation. The heart rate will slow and the patient will generally have tonic contraction of the extremities (Elliot *et al.*, 1982). This initial period, which lasts anywhere from 2 to 5 seconds, is usually followed by a marked increase in blood pressure and heart rate (McCall, 1993). This is secondary to a centrally mediated catecholamine surge (Elliot *et al.*, 1982; Swartz, 1993). The

extremities change to tonic-clonic contractions, the intensity of which depends on the degree to which they have been modified by the muscle relaxant.

During the treatment, seizure duration should be monitored, if possible, via a one- or two-channel electroencephalogram (EEG), an integral component of most modern ECT devices (Stephens *et al.*, 1991). Combining motor movement timing with EEG monitoring yields the most reliable seizure duration determinations in the clinical setting (Lippmann *et al.*, 1993). Although dose of electricity relative to seizure threshold is the important variable, in general, an adequate seizure is usually between 20 seconds and 2 minutes in duration.

Once the seizure terminates, the patient is continuously supported and monitored until breathing spontaneously and responsive to voice commands, with return of muscle strength. The patient's vital signs are monitored every 15 minutes until stable.

This process is repeated for an average of 6 to 12 sessions in the treatment of depression. In the USA, ECT is usually performed three times per week, while in the UK and Europe twice-a-week schedule is more common. The available data suggest that the twice-a-week schedule produces an equivalent therapeutic response with fewer treatments, but the speed of clinical improvement is slower than the three times per week schedule (Lerer *et al.*, 1995; Shapira *et al.*, 2000). On the other hand, the more rapid therapeutic response to thrice weekly ECT is accompanied by greater cognitive adverse effects than those associated with the slower rate of treatments (Lerer *et al.*, 1995; Shapira *et al.*, 2000).

Regardless of the treatment schedule, the rate of response will vary for each patient. Often, the patient's vegetative symptoms will respond before the patient feels subjectively improved.

## Adverse Effects

The potential adverse effects from ECT range from mild complications such as myalgias, to serious events such as fractured bones, to catastrophes such as death. At present, the risk of serious complication is about 1 in 1000 patients. The risk of death is about 1 in 10 000 patients, which approximates the risk of general anesthesia for a minor surgical procedure (NIH/NIMH, 1985) and is actually lower than the spontaneous death rate in the community (Abrams, 1997).

Cardiac complications are the most frequent medical side effects associated with ECT. The arrhythmias range in severity from the common and benign sinus tachycardia to rare life-threatening or fatal ventricular arrhythmias.

Confusion and memory loss are also commonly occurring side effects. These adverse effects are the major factor limiting the use of ECT. Transient confusion occurs universally as a post-ictal event. Memory disturbance also occurs quite frequently (Calev, 1994). In general, during the acute course of ECT, both retrograde and anterograde memory are impaired to some degree (NIH/NIMH, 1985; Calev, 1994). Retrograde amnesia is generally felt to be more problematic. After the treatments end, the memory difficulties gradually resolve over the ensuing weeks to months (Lisanby *et al.*, 2000). Some patients may have permanent spottiness in memory for events that occurred in the weeks to months before, during and following the ECT course. Rarely, patients have complained of persistent memory difficulties severe enough to interfere with social and/or occupational functioning (NIH/NIMH, 1985). However, the infrequency with which this occurs, and certain technical factors such as the lack

of nondepressed pretreatment memory and other neuropsychiatric measures (Coffey, 1994) has made it difficult to study these individuals systematically. Subjective impressions of post-ECT memory deficits appear to correlate more closely with clinical outcome and mood state than with objective cognitive measures (Prudic *et al.*, 2000). Although evidence to date points to only a transient and tolerable degree of cognitive impairment with continuation and maintenance ECT (Datto *et al.*, 2001) as these treatment strategies continue to play an increasing role in the long-term treatment of mood disorders, more definitive research on their effects on memory will help guide clinicians.

Few formal studies of ECT effects on cognitive functioning in children and adolescents have been conducted in the past 50 years.

### ECT–Drug Combinations and Interactions

As most patients referred for ECT already are taking psychotropic medications, many ECT–drug interactions result from the inadvertent or intentional continuation of preexisting medication regimens with the initiation of convulsive therapy. Community surveys indicate that fewer than half of patients have discontinued all previous psychotropic medications at the time of ECT (Prudic *et al.*, 2000). While more definitive research is underway, the American Psychiatric Association Task Force recommends that, particularly for patients with a history of treatment resistance, “concurrent treatment with an antidepressant medication and ECT should be considered” (American Psychiatric Association, 2001).

### Continuation and Maintenance Treatment

Among the unique features of ECT is the time-limited nature of its use in the treatment of acute episodes of illness. Following completion of an acute treatment course, ECT is generally terminated abruptly, coincident both with clinical response and, in many cases, impending inpatient discharge. It is now clearly established that left untreated after completion of ECT, at least half of patients will relapse, most within 6 months (American Psychiatric Association, 2001; Sackeim *et al.*, 2001a). Antidepressant treatment is now used routinely following a course of ECT to help prevent such relapse. Most contemporary authors adhere to the distinction between **continuation** treatment, over 6 months or so, to prevent relapse into the index episode, and **maintenance** treatment beyond that point, with the goal of avoiding recurrence, that is a new episode of illness. Nearly all published data on continuation and maintenance treatment have dealt with ECT administered for the treatment of depression.

Additional research is necessary to develop even more effective strategies to prevent relapse after completion of ECT.

Although the optimal methodology for an extension of the traditional ECT course – including electrode placement, frequency and duration of treatment – is yet to be determined (Scott *et al.*, 1991) it has become the subject of the ongoing NIMH-supported four-site CORE trial (O’Connor *et al.* 2001). Following an acute course of generally successful bilateral ECT (see earlier), patients in the CORE trial were randomized for the next 6 months to either a weekly to monthly maintenance ECT trial or to an active control pharmacotherapy condition, consisting of the most effective post-ECT medication regimen (combined nortriptyline plus lithium) identified by Sackeim *et al.*, (2001a). Moreover, additional data are required on the

**Table 74.2** Typical Electroconvulsive Therapy Schedule of Events

12:00 AM	Patient begins NPO.
7:45 AM	Patient is escorted to the ECT suite.
7:50 AM	Nurse ascertains that patient has voided, has remained NPO, has dentures and jewelry removed, has clean and dry hair, and orders for ECT are completed properly.
7:55 AM	Psychiatrist and anesthesiologist review medical chart and determine any change in medical or mental status or medications.
8:00 AM	An intravenous line is placed; EKG, EEG, blood pressure and oximetry monitoring are instituted; stimulus parameters are selected on the ECT device.
8:02 AM	Sites of the ECT electrodes are prepared to reduce impedance.
8:05 AM	Anticholinergic premedication with glycopyrrolate or atropine is given; other adjunctive medications are administered as needed.
8:07 AM	Short-acting barbiturate anesthetic (e.g., methohexital or thiopental) is administered through IV; positive pressure respiratory support is instituted.
8:08 AM	Loss of consciousness is ascertained (eyelash reflex); blood pressure cuff is inflated over a lower or upper extremity to block distribution of the muscle relaxant (succinylcholine), which is then administered through IV.
8:09 AM	Fasciculations are noted in the cuffed extremity; a nerve stimulator may be used to ensure adequate muscle relaxation.
8:10 AM	Electrodes are positioned and integrity of the electrical circuit is checked; bite block or mouth guard is put in place; electrical stimulus is applied.
8:11 AM	Seizure activity is monitored and duration timed for both motor and EEG manifestations; cardiac status is closely monitored; respiratory support is provided until patient is breathing spontaneously.
8:12 AM	Vital signs are monitored frequently until return to baseline level.
8:20 AM	When the patient is breathing spontaneously, is responsive to commands, and vital signs are stable, the patient is transferred by stretcher to a recovery room.
8:25 AM	Patient is assessed for recovery of orientation; with continued stability of vital signs, the patient is discharged from recovery when reoriented and able to ambulate without assistance, usually 30–60 min following the treatment.

risk of cognitive and other adverse effects of continuation and maintenance ECT, and the best means of minimizing untoward effects of this potentially valuable intervention (Fox, 2001). There is general agreement that new written informed consent, beyond that obtained for the acute series of treatments, must be secured for continuation/maintenance ECT. In the event of prolonged maintenance ECT, the American Psychiatric Association (2001) Task Force recommends that the informed consent process be repeated every 6 months.

### Treatment Failure

The total population of patients who are considered ECT treatment failures can be divided into three categories: true nonresponders; relative nonresponders for whom ECT can yet be made to work; and individuals for whom, upon closer inspection and examination, ECT was not the right treatment choice. Thus, the first approach to the ECT-resistant patient is to assure that an appropriately intensive trial of convulsive therapy has been attempted. Then reassessment, removal of any obstacles to treatment responsiveness and, in most cases, entry into a treatment-resistant depression algorithm are indicated.

### Adequacy of ECT Trial

A course of eight to 12 bilateral ECT treatments should be completed before any patient is declared ECT resistant. Patients who fail to respond to several treatments with unilateral electrode placement should be switched to bilateral ECT and offered an opportunity to respond to a full trial of that modality (Delva *et al.*, 2001). The treatment history of the ECT-refractory patient should be reviewed to ensure that seizures were generalized and of adequate duration, and that in the case of unilateral electrode placement, stimulus intensity was sufficiently above seizure threshold. Some resistant patients may require additional ECT sessions in order to respond (Sackeim *et al.*, 1990).

### Re-evaluation

Even in carefully selected patients, lack of response to a course of ECT may occur in 10 to 30% of individuals (NIH/NIMH, 1985). Nonetheless, this degree of refractoriness should trigger a reassessment of the patient, with confirmation of the original diagnosis. The additional information learned during a hospitalization may enable a more accurate assessment of the chronicity of illness, presence of medical disease, degree of mood congruence of symptoms, vegetative functioning, mood reactivity, Axis II pathology, alcohol or other substance abuse, and outstanding psychosocial issues than was available on admission. Such data may both help explain the lack of response to ECT and open avenues to further evaluation or treatment efforts.

### New Somatic Treatments

#### Transcranial Magnetic Stimulation

Coincident with the considerable advances in clinical research aimed at optimizing the use of ECT, the past decade has also witnessed renewed interest in the development of new somatic, nonpharmacologic interventions for mental disorders, particularly depression. Ongoing research supports the antidepressant efficacy of repetitive transcranial magnetic stimulation (rTMS)

(Holtzheimer *et al.*, 2001). These and other related interventions stimulate the brain in manners less direct but more focused than does ECT. In contrast to the application of an electrical stimulus to the scalp, as in ECT, a more precisely localized electrical current can be produced within the brain by pulsing a magnetic wave (generated through a coil on the head), which passes undistorted through the skull. A train of TMS pulses, delivered to the left prefrontal cortex repeatedly but at a subconvulsive rate up to 20 minutes/day to an awake and alert patient, has demonstrated antidepressant efficacy in several small open and sham-controlled trials. To date, antidepressant effects have been relatively modest, and few patients have been medication free or followed systematically beyond a 1- or 2-week rTMS treatment trial.

#### Vagus Nerve Stimulation

Vagus nerve stimulation (VNS) has been used as an effective treatment of refractory seizure disorders, and now is showing promise as an antidepressant intervention. VNS is now approved by the US Food and Drug Administration for selected cases of depression. The afferent connections of the left vagus nerve with locus coeruleus, dorsal raphe and limbic structures have been implicated in the putative antidepressant effect of this intervention.

An initial surgical procedure is required for implantation of a small pacemaker-like stimulus generator beneath the clavicle, with an attached lead wrapped around the left vagus nerve in the neck. The generator can be programmed automatically to deliver a fixed duration of vagus nerve stimulation, for example 30 seconds of stimulation every 5 minutes. Many patients notice physical concomitants of vagal stimulation, such as coughing or hoarseness (Sackeim *et al.*, 2001b). While this may defeat the masking of no-stimulation programming as a control condition in research studies, the intervention otherwise appears well tolerated. In the event of disturbing adverse effects, a magnet held over the stimulus generator will abort a stimulation. Safety experience thus far with seizure disorder patients has been satisfactory; stimulation of the left vagus nerve has no cardiac effects.

### Conclusion

ECT retains a limited but important role in the treatment of selected patients with severe mood and other mental disorders. While efforts to continue to minimize the adverse effects, particularly cognitive, of ECT while retaining its effectiveness, other research is underway at developing additional or alternative nonpharmacologic somatic interventions for depression and other mental illnesses (Rasmussen *et al.*, 2002). Optimal treatment for a given individual continues to require the determination of the benefit–risk ratio for each particular person and situation.

# Neurosurgery for Treatment-Refractory Psychiatric Disorders: Obsessive–Compulsive Disorder and Major Depressive Disorder

## Characteristics of Patients Undergoing Neurosurgery for Treatment-refractory OCD and MDD

Though selection criteria have not been standardized across centers, a review of most reported studies from several countries suggests that only a small number of OCD or MDD patients who have not responded to a variety of exhaustive treatments are considered for palliative neurosurgery. Treatments include multiple adequate medication trials, an adequate trial of behavioral treatment/psychotherapy and electroconvulsive therapy (ECT) for MDD – encompassing patients who remain severely disabled for several years despite these efforts (Table 75.1). In addition to the essential informed consent of the patient, a panel of specialists, usually constituted at the institutional level, carefully reviews all aspects of the patient's condition before making a consensus decision on surgery.

Severe, chronic OCD and MDD referrals commonly present with comorbidities including depression, obsessive–compulsive “psychosis”, substance abuse, history of harmful behavior and personality disorders. The decision to offer surgery must be evaluated on a case-by-case basis, carefully considering the benefits and risks of intervention, alongside those of nonintervention. Tables 75.2 and 75.3 contain guidelines for indications and relative contraindications for these procedures evolved in the context of 25 years of experience with the stereotactic cingulotomy procedure for intractable psychiatric disorder at one center. (Massachusetts General Hospital (MGH): OCD Clinic and Cingulotomy Program, Boston, MA, USA).

## Interventions

Currently, only a few specialized centers in the world conduct neurosurgical procedures for treatment-refractory OCD and treatment-refractory MDD. These procedures have evolved at particular centers more by convention and experience than by controlled research studies and direct comparison of the various procedures. The modern neurosurgical procedures include 1) cingulotomy, 2) anterior capsulotomy, 3) subcaudate tractotomy

**Table 75.1** Suggested Guidelines: Indications for Neurosurgical Intervention for IOCD (Intractable Obsessive–Compulsive Disorder)

1. Patient fulfills the diagnostic criteria for OCD/MDD (SCID derived DSM-IV OR comparable such as ICD-10).
2. The duration of illness exceeds 5 yr.
3. The disorder is severe (while not necessarily reflective of overall disability, OCD patients usually have YBOCS scores of  $\geq 20$ ) and is causing substantial distress.
4. The disorder is causing substantial reduction in the patient's psychosocial functioning (e.g., Global Assessment of Functioning (GAF) of 40 and below).
5. Current treatment options\* tried systematically for at least 5 yr either have been without appreciable effect on the symptoms or must be discontinued owing to intolerable side effects.
6. The prognosis, without neurosurgical intervention, is considered poor.
7. The patient gives informed consent.
8. The patient agrees to participate in the preoperative evaluation and postoperative rehabilitation programs respectively.
9. The patients' local referring physician is willing to acknowledge responsibility for the postoperative long-term management of the patient.

\*OCD: Adequate trials (at least 12 weeks at the maximally tolerated dose) of all serotonergic agents (clomipramine, paroxetine, fluoxetine, fluvoxamine, sertraline), and possibly a serotonergic–noradrenergic agent (venlafaxine) and MAO-I as well; as augmentation of at least one of these drugs for 1 month: lithium, clonazepam, buspirone or other experimental agents; all patients must have had an adequate trial of behavioral therapy (at least 20 hours of “real” exposure and response prevention therapy).

and 4) limbic leukotomy. All four procedures involve magnetic resonance (MR) imaging guided stereotactic lesions placed bilaterally in the various target regions, after which they are named.

**Table 75.2 Suggested Guidelines: Relative Contraindications to Neurosurgical Intervention**

1. Age younger than 18 yr or older than 65 yr.
2. The patient has another current or lifetime Axis I diagnosis (e.g., organic brain syndrome, delusional disorder, somatization or current or recent substance abuse) that substantially complicates diagnosis, treatment, or the patient's ability to comply with treatment or a chronically unstable clinical course (e.g., history of multiple impulsive suicidal attempts).
3. A complicating current DSM-IV Axis II diagnosis from cluster A (e.g., paranoid personality disorder) or B (e.g., borderline, antisocial, or histrionic personality disorder). A current cluster C personality disorder (e.g., avoidant or obsessive-compulsive personality disorder) is generally not a contraindication.
4. The patient has a current Axis III diagnosis with brain pathology, such as moderate or marked cerebral atrophy, stroke, or tumor or has undergone previous neurosurgical procedures that have a high likelihood of producing unacceptable complications.

### Results of Comparative Reviews of Outcome

Chiocca and Martuza (1990) reviewed 10 studies ( $n = 210$ ) involving all four current procedures to investigate comparative efficacy. After acknowledging the inherent limitations of such a comparison, the authors concluded that the percentages of patients who improved with each of these four procedures were roughly the same. This latter conclusion may be disputed, however, because the number of outcome categories was not identical (e.g., A, B and C for limbic leukotomy; A and B only for capsulotomy).

Waziri (1990) reviewed 12 studies ( $n = 253$ ) of patients undergoing stereotactic interventions for treatment-refractory OCD and noted that 38% of patients were reported to be symptom free, 29% markedly improved, 10% unchanged and 3% worse or dead on follow-up (including one suicide). An overall figure for satisfactory response to surgery of 67% was found in these 253 OCD patients.

Hodgkiss and colleagues (1995) reported on a 12-month follow-up study of 286 patients who underwent SST between 1979 and 1991 (249 were completely evaluated including 74 who were evaluated by an independent rater); 63/183 (34%) MDD patients and 5/15 (33%) of OCD patients were classified as good outcome. There were six deaths during this period though none was attributed to neurosurgery or suicide. The authors noted that most deaths involved patients over 70 and cautioned the use of this procedure for the elderly.

The methodological issues discussed earlier and the lack of rigorous, controlled and/or head to head comparison studies prevent comment on which of these procedures is superior. This is further complicated by the heterogeneous profile of OCD patients. At present, there is little evidence to suggest the clear superiority of one procedure over another. More research addressing these issues is desirable.

### Predictors of Outcome

Most investigators reporting outcome studies concerning various procedures have naturally attempted to identify predictors

of outcome, though these have been elusive. Bridges and colleagues (1973) reported that OCD subjects who were considered responders in their study had an older age of onset (mean 28.5 years) versus nonresponders (mean 22 years). In a prospective cingulotomy study, using comprehensive assessment strategies, Baer and colleagues (1995) reported that the presence of symmetry obsessions, ordering and hoarding compulsions were predictive of lower YBOCS score at final follow-up (partial correlations). More recently, Rauch and colleagues (2001) utilizing a retrospective design, reported that higher preoperative metabolic rates in a single right posterior cingulate locus (determined by FDG-PET) was associated with better postcingulotomy outcome in II OCD patients. The advantages of predicting response in such invasive palliative procedures are obvious and need further study.

## Risks of Neurosurgical Intervention

### Surgical Risks

Surgical risks include acute and subacute complications like hemorrhage, postoperative infections and seizures, as well as more serious enduring side effects such as focal neurological deficits, cognitive or personality change and weight gain.

### Neuropsychiatric Risks

#### Cognitive/Intellectual Domain

With regard to cingulotomy, an independent study of a cohort of patients was performed for the US government by the Department of Psychology at the Massachusetts Institute of Technology. The authors reported that they found no evidence of lasting neurological, intellectual, personality, or behavioral deficits after surgery (Corkin *et al.*, 1979; Corkin, 1980). In fact, a comparison of preoperative and postoperative scores revealed modest gains in the Wechsler IQ ratings. The only apparent irreversible decrement identified by these investigators was a decrease in performance on the Taylor Complex Figure Test in patients older than age 40 years. Several authors, using varying assessment strategies and batteries pre and postoperatively, have reported the relative lack of serious adverse cognitive effects following cingulotomy (Corkin *et al.*, 1979; Corkin, 1980), subcaudate tractotomy (Bartlett and Bridges, 1977; Göktepe *et al.*, 1975), limbic leukotomy (Mitchell-Heggs *et al.*, 1976; Kelly, 1980) and capsulotomy (Herner, 1961; Bingley *et al.*, 1977; Vasko and Kullberg, 1979) (Figures 75.1 and 75.2). Nevertheless, the need to include carefully thought out (based on the procedure involved) neurocognitive assessments before and at regular intervals after the surgery/surgeries cannot be overstated. Long-term studies are desirable for the existing procedures better to inform patients and clinicians of the risks as well to help rehabilitative efforts.

#### Affective/Social and Personality Domains

As these neurosurgical procedures may be expected to influence, directly or indirectly, frontal lobe and other functions comprising one's "personality", it is important that this is an integral part of the pre and postoperative assessment. Important domains that need to be addressed are executive functions, impulsivity/aggressiveness, social propriety and mood changes. Ideally this would involve input from both the patient as well as the family and treating clinician. In general, anecdotal evidence from most reported

**Table 75.3 Suggested Guidelines for Neurosurgical Intervention in Neurosurgery for Intractable Psychiatric Illness****1. Center and expertise**

Center/s with stereotactic neurosurgical expertise and integrated multidisciplinary expertise in the evaluation, neurosurgical treatment and management of patients with intractable psychiatric disorders.

**2. Patient selection**

Suggested guidelines for patient selection presented in Tables 75.2 and 75.3. A clinical psychiatrist with OCD expertise evaluates patients and orders a presurgical work-up (below).

**3. Profiles**

Work-up should be carefully thought out and relevant to the specific procedures as well as to enhance comparability. Information should be collected from multiple sources (patient, family, psychiatrist, etc.).

## Psychiatric:

Preferably a structured clinical interview (e.g., SCID-CV\* for DSM-IV). Reliable and valid scales (inventories and clinician administered) of mood, obsessions and compulsions, and anxiety (e.g., BDI†, HDRS‡; YBOCS§).

## Neuropsychological

Batteries of both general cognition as well as specific to lesion: (e.g., general intellectual functioning, executive functions, memory, personality assessment)

## Neuromedical

General surgical risk work-up.

Specific neurological issues: neurological examination, prelesion MRI (for lesion demarcation), documentation of past neurological problems, especially seizures.

**4. Raters and schedule**

Assessors and raters should be blinded to the extent possible.

**5. Documentation of neurosurgical effects**

Documentation of lesion site, size, and extent. Pre and poststructural and functional scans would be highly desirable.

**6. Postsurgical follow-up**

Should involve administration of selected profiles mentioned above at various intervals (e.g., 1 wk postsurgery, 3, 6, 9, and 12 mo and longer when possible).

## Enhancing comparability of data

- Centers should attempt to use universally accepted/equivalent patient selection criteria, psychiatric instruments, neuropsychological batteries and objective quantification and monitoring of lesions.
- Establishment of a database to remove inherent bias of only publishing positive studies.
- Consortium of centers investigating different procedures.

studies concerning the different procedures suggest a remarkable freedom from significant adverse personality changes. On the contrary, the few studies that have directly addressed this issue report an improvement in negative personality traits at follow-up.

One of the better researched instruments is the Karolinska Scales of Personality (KSP), developed by Schalling and coworkers (1987). The KSP contains subscales measuring traits related to frontal lobe function as well as those reflecting anxiety proneness. In capsulotomy studies reported from Sweden, the KSP was administered to 24 consecutive patients 1 year and 8 years after radiofrequency capsulotomy. Small changes in mean scores towards normalization were apparent on all 15 KSP subscales at the 1-year follow-up and significant improvement was reported in anxiety proneness at the 8-year follow-up (Mindus *et al.*, 1999).

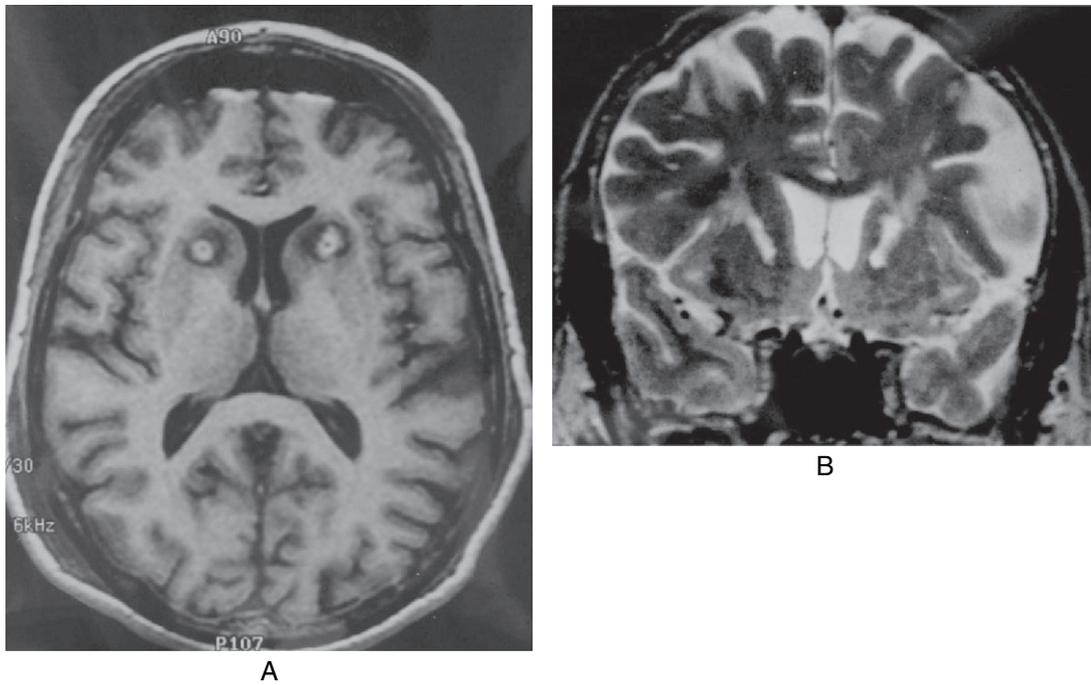

One would expect that the more precise modern surgical procedures should further reduce this risk. In fact most recent studies report a low incidence of adverse behaviors postsurgery. However, this remains a potential risk and conclusions based on

observations made on groups of patients may not preclude negative adverse effects in an individual patient.

## Suicide

While suicide is not considered a known complication of neurosurgical procedures in nonpsychiatric patients undergoing these procedures, the possibility of contributing directly or indirectly to this process in psychiatric patients is theoretically present. However, it is important to note that severe major depression is associated with high lifetime suicide rates (approximately 3–8%) (Nierenberg *et al.*, 2001). Thus, of the suicides reported in psychiatric neurosurgical cohorts, it is difficult to ascertain whether these are a result of existing psychopathology or whether the surgery contributed in some way to this process.

For example, Jenike and colleagues (1991) found that four of 33 patients who had undergone cingulotomy for OCD had died by suicide at follow-up that averaged 13 years. Chart reviews revealed that each of these suicide completers had been noted to suffer from extensive comorbid disease (especially

**Figure 75.1** Anterior capsulotomy (A) Acute axial view; (B) Chronic coronal view.

severe depression) with prominent suicidal ruminations at initial evaluation for cingulotomy. On the contrary, none of the OCD patients without baseline suicidality became suicidal after the operation. In the large ( $n = 44$ ) prospective long-term follow-up study following one or more cingulotomies, Dougherty and colleagues (2002) reported one suicide (2%) in a patient having severe depression with chronic suicidal ideation and a past history of a suicide attempt. Thus, in most published studies, the suicide rate has been low and these patients have been noted to have had significant presurgical suicidality. This highlights the need

carefully to assess for and monitor suicidality in this severely ill population.

Patients with a poor response to surgery may be at increased risk for suicide (Jenike *et al.*, 1991). Preventative strategies therefore include careful assessment of suicidality at baseline and follow-ups, assessment of family and clinician support networks, clear explanations of the scope of the procedure as well as the long response latency (usually a year for cingulotomy), education that presurgical nonresponders sometimes respond to treatment postsurgery, and the need for secondary or tertiary lesions in case of cingulotomy in some patients to achieve response.

**Figure 75.2** Subcaudate tractotomy. Acute axial view.

## Recent Advances

### Neurosurgical Advances and Imaging Strategies

The routine use of MR guided stereotactically placed neurosurgical lesions and the increasing availability of the gamma knife offer more precise procedures with objectively quantifiable lesions. High resolution structural MRI studies are being used to track volumetric changes local and distal to the lesions (Rauch *et al.*, 2000) and PET studies are providing information about blood flow and regional metabolism that may serve as predictors of response (Rauch *et al.*, 2001). Recordings in implicated brain structures such as the cingulum (similar to intracortical recordings and microdialysis in the temporal lobe in surgical epilepsy patients) may provide useful additional information. Strategies such as magnetic resonance spectroscopy (MRS) and newer methods such as diffusion tensor imaging (DT-MRI) can provide information about regional neurochemistry and white matter tract integrity, respectively. They offer the exciting possibility of collecting valuable neurobiological data, which may aid in monitoring changes as well as predicting response.

## Newer Strategies

Recently, several new experimental strategies have emerged and are being investigated in refractory OCD and MDD. These are invasive modalities currently being offered only in the context of research studies and thus have not been proven or approved for treatment. They are included in this discussion for the sake of completion.

## Deep Brain Stimulation

Deep brain stimulation (DBS) involves stimulation of target regions via stereotactically placed electrodes that can be programmed to deliver low voltage electrical stimulation to modulate transmission of specific brain pathways. While DBS of different regions has been experimentally investigated for treatment-refractory pain syndromes, movement disorders and seizure disorders, only DBS for treatment-refractory Parkinson's disease or essential tremor is currently FDA approved in the USA. Recently following a preliminary report of deep brain stimulation in the anterior limb of the internal capsule in four patients with treatment-refractory OCD (Nuttin *et al.*, 1999), a few specialized centers in the world (including the USA) are conducting ongoing controlled studies of DBS in treatment-refractory OCD patients. Nuttin and colleagues described four patients with treatment-refractory OCD who underwent DBS with bilateral stereotactically implanted quadripolar electrodes in the anterior limb of the internal capsule (instead of anterior capsulotomy) and reported "beneficial effects" in three of the four patients. It is important to note that this remains an experimental procedure at this stage for treatment-refractory OCD. Nevertheless these developments offer the exciting possibility of reversible "lesions" as well as ethically justifiable sham procedures (controls can be implanted but the stimulation not turned on or at lower voltage undetectable by the patient who can subsequently receive the benefit of the treatment) (Greenberg, personal communication).

## Vagal Nerve Stimulation

Vagal nerve stimulation, used formerly only as an FDA approved treatment strategy for some patients with drug-resistant, partial-onset epilepsy due to its seizure attenuating effects, has been approved for use in treatment of depression. See the section on new approaches in the chapter on ECT for further discussion of this modality.

## Conclusion

A small but significant number of psychiatric patients remain refractory to state-of-the-art treatments and are severely disabled. Based on the existing data, palliative neurosurgery continues to be an option for these patients. The impressive advances in psychiatry as well as stereotactic and radioneurosurgery and neuroimaging have resulted in promising outcomes with a better benefit/risk ratio, suggesting that these options should be further pursued. Improvement of study design as well as improved communication between interested specialized centers is desirable to further advance the field. See Table 75.4 for suggested guidelines. Meanwhile newer, less invasive strategies, such as the gamma knife as well as potentially reversible manipulation of the CNS such as DBS and VNS, have emerged and could potentially change the nature of this field. Until we have data from more sophisticated controlled studies, it is highly recommended that these procedures be carried out only in centers that have the necessary expertise, personnel, and resources to undertake and follow through with such procedures.

## Clinical Vignette 1

JS, a 44-year-old, single, Caucasian male, living on a disability income in a semi-independent living facility, was referred for neurosurgical evaluation by his treating psychiatrist. He was first diagnosed to have OCD when he was a 20-year-old sophomore in college and has suffered a progressively deteriorating course despite treatment, leading to his being unable to work as well as care for himself adequately, over the past 10 years. He had failed adequate trials of treatments including fluoxetine, sertraline and clomipramine as well as multiple courses of exposure and response prevention, including long-term intensive residential treatments. His most disabling symptoms have been his fear of contamination and related washing and checking compulsions. He spends most of his day locked in his room engaged in repeatedly washing and showering and often has to be supervised by his family (who live close by) to feed and groom himself. This has taken a significant toll on his family who have constantly to monitor his progress. John has also suffered from several depressive episodes, is chronically dysthymic, and has attempted suicide in the past due to feeling hopeless about his situation.

At the specialized center, a psychiatrist with experience in presurgical evaluations evaluated John. He also underwent neuropsychological and psychosocial evaluations and a medical fitness examination. His case was then discussed by a panel of experts at the institutional level to review his eligibility for anterior cingulotomy. After informed consent from John and his family, he underwent a magnetic resonance guided, stereotactic, bilateral anterior cingulotomy. The immediate postsurgical period was notable for some transient confusion and urinary incontinence. After recovery, John was referred back to his psychiatrist and his medications were continued. At the 3-month follow-up, John did not report any change in his symptoms. At the 6-month and 1-year follow-ups, however, John and his family reported that the frequency of "getting stuck" in his washroom had observably reduced. He still reported contamination obsessions but with less frequency and severity. When they did occur, he was able to "unstick" himself with less difficulty. His mood and self-care was better and he had begun to socialize more. He was considering participating in a day program at the facility. His psychiatrist corroborated these reports.

# Ethnic and Cultural Perspectives in Psychopharmacology

---

## Dispelling the “Color Blind” Approach

Substantial individual variation in drug responses, at times up to 100-fold in terms of optimal dosing, is the rule rather than the exception. Although the current understanding of such remarkable variability remains incomplete, it is clear that the interplay between genetics and environmental factors plays a pivotal role in pharmacotherapeutic responses, particularly in the context of an individual's ethnic origin, lifestyle and other socio-demographic variables.

As shown in Figure 76.1, virtually all factors affecting pharmacological responses are significantly influenced by culture and ethnicity. Furthermore, patterns of genetic polymorphism, often with substantial ethnic variation, exist in a large number of genes encoding drug metabolizing enzymes as well as receptors and transporters believed to be targets of pharmaceutical agents. The expression of these genes is often significantly modified by a large number of environmental factors, including diet and exposure to various substances (e.g., tobacco). Of even greater importance, the success of any therapy, including pharmacotherapy, depends on the participation of the patient and, as such, depends significantly on the quality of interaction between the clinician and the patient. The importance of culture in this regard is paramount.

## Clinicians' Attitudes

A large body of literature indicates that patients' cultural/ethnic backgrounds significantly determine the way clinicians conceptualize and label their problems, which in turn dictate the choices for therapeutic intervention (Mezzich *et al.*, 1995). Using case vignettes that are identical except for ethnic group identification, a number of studies demonstrated that cases identical in every other aspect were nevertheless given significantly more severe diagnoses if the patients were identified as being of ethnic minority origin (Gaw, 1993; Lopez, 1989). Paralleling such a tendency, African-American psychiatric patients are more likely to have been given a diagnosis of schizophrenia as compared with their Caucasian counterparts (Littlewood, 1992; Lopez, 1989). Interestingly, in studies where patients were reassessed with the use of structured interviews, such differences largely disappeared, suggesting that such a differential diagnostic pattern is possibly determined by variables related to clinicians' biases rather than to the patients' clinical conditions (Adebimpe, 1981; Marquez *et al.*, 1985; Mukherjee *et al.*, 1983; Roukema *et al.*, 1984).

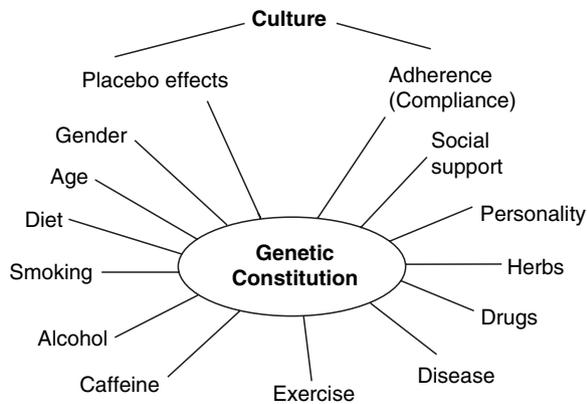

## Adherence

Most studies exploring correlates of nonadherence have focused on patient and treatment variables, and have shown that a large number of factors significantly predict problems with adherence. These include the sociodemographics of the patient, the financial burden of the treatment, and the side effect profile of the medications (Manne, 1998; Fenton *et al.*, 1997). The health belief model has served as the theoretical framework for a large number of seminal research endeavors, which in aggregate demonstrate that the beliefs held by patients and those significant in their lives to a large extent determine their participation in and response to treatment decisions (Hughes *et al.*, 1997).

Following the logic of the health belief model, one would expect adherence to be an even larger problem in cross-cultural clinical situations. This has been substantiated by a number of clinical observations and reports of the service utilization of particular ethnic minority groups (Sue *et al.*, 1991). Compared with Caucasians, ethnic minority patients are often found to enter treatment at a significantly delayed stage, and they also are more likely to drop out of psychiatric treatment prematurely. Programs aiming at bridging cultural gaps have been shown significantly to improve treatment retention and outcome (Acosta *et al.*, 1982).

Adverse effects of psychotropics are often substantial. Depending on beliefs and expectations, many positive drug effects could be interpreted either as negative or positive. For example, in a study of Hong Kong Chinese bipolar patients treated with lithium, Lee and colleagues (1992) found that, unlike Western patients, the Chinese rarely complained of “missing the highs”, and “loss of creativity” and actually regarded polydipsia, polyuria and weight gain as part of the therapeutic effect of the medicine. In contrast, lethargy, drowsiness and poor memory represented serious concerns for many of these patients, and were prominent in their complaints, even though objectively they were not likely to be due to the medications they were taking, since they occurred at similar rates among matched controls. Such findings highlight the importance of culturally based beliefs and expectations in determining how physical and psychological experiences associated with drug treatment and recovery are attributed.

The Explanatory Model (EM) approach, as originally proposed by Kleinman (1988), may be a particularly effective way for the systematic assessment of such beliefs and expectations. By

**Figure 76.1** Factors affecting drug response.

methodically eliciting the patient's perspectives on the symptoms that are most salient and worrisome to them (patterns of distress), their attributions (perceived causes), their help-seeking experiences and preference, as well as their perception on stigma, discrepancy between the patients' and the professionals' EMs could be systematically identified and bridged (Weiss, 1997). Elements of the EM are included in Appendix I of the DSM-IV manual as part of the Outline for Cultural Formulation (American Psychiatric Association, 1994).

### Expectation (“Placebo”) Effects

The term “expectations effect” reflects the importance and power of expectation and beliefs on treatment effects in determining patients' response to any therapy, whether psychosocial or pharmacological. Expectations regarding the safety and effectiveness of any therapeutic interventions, in turn, are shaped by patients' sociocultural backgrounds as well as individual “idiosyncratic” experiences (e.g., past experiences of side effects). Since patients' beliefs regarding medical treatments are often shaped by their cultural backgrounds, it stands to reason that patients' expectation regarding the therapeutic effect of the offered treatment would be largely affected by their cultural construct of the illness.

Despite rapid modernization, traditional medical theories and practices remain deeply rooted and influential in determining individuals' health beliefs and behaviors in many societies (Wolffers, 1989; Okpaku, 1998; Wig, 1989; Rappaport, 1977). For example, most traditional medical systems emphasize the importance of maintaining a dynamic balance between “coldness” and “hotness” (Castro *et al.*, 1994) or between “Yin” and “Yang” in the case of the Chinese system (Lin, 1981). These principles provide guidance for assessment as well as for formulating treatment approaches. For patients who subscribe to such beliefs, a perceived mismatch between the therapeutic agents and the afflictions may significantly lower the expectation effect. For example, red-colored pills might be regarded as capable of enhancing the “hot” element, and might be regarded as less effective in the treatment of conditions perceived as a result of excessive “hotness” (e.g., fever, anxiety state, or mania). Interestingly, Buckalew and Coffield (1982) reported findings from a well-controlled study showing significant ethnic differences in response to placebo pills with different colors.

### The Concomitant Use of Alternative/Indigenous Treatment and Healing Methods

“Alternative” health care traditions (e.g., Chinese medicine and Ayurvedic medicine) seemed to have responded well to challenges of modern medicines and have continued to evolve and thrive (Landy, 1977; Leslie, 1976). Multiple medical and healing traditions and treatment modalities coexist in all societies, and patients often utilize these services simultaneously or sequentially, frequently without informing their physicians. Problems with drug–drug interactions from such behavior that could potentially arise from such a practice are not limited to particular ethnic groups, and constitute an important consideration for clinicians prescribing medications.

Various herbs utilized by traditional practitioners and healers are biologically active (it has been estimated that approximately 40% of our “modern” pharmacotherapeutic agents originated from natural sources [Balick and Cox, 1996]). Although much remains unclear, herbal preparations do exert significant impact on various biological systems, including those crucial for the functioning of the central nervous system (Cott, 1997; Duke, 1995). Since most patients do not regard herbs as medicines and typically fail to inform their physicians of such uses unless specifically inquired, toxicities or treatment failures due to “herb–drug interactions” are likely widespread and unsuspected. Herbal preparations may modulate the effect of modern therapeutic agents, including psychotropics, both at the pharmacodynamic level (the effect of the drugs on the organism), and at the pharmacokinetic level.

### Biological Diversity and Its Consequence in Psychotropic Responses

Emerging data now convincingly demonstrate that for the majority of the genes, polymorphism is the rule rather than the exception. Furthermore, the frequency and distribution of alleles responsible for such polymorphisms often vary substantially across ethnic groups, effectively requiring that ethnicity always be considered in genetic studies (National Institute of Mental Health, 1997). These phenomena have long been known in blood and human lymphocyte antigen (HLA) typing (Polednak, 1989). In recent years, it has become increasingly clear that equally extensive polymorphisms exist in genes governing key aspects of how drugs are metabolized (see Table 76.1) as well as how they affect the target organs. These processes, commonly called pharmacokinetics and pharmacodynamics, are depicted in Figure 76.2 (Greenblatt, 1993). Together, these genetic factors may explain to a large extent the often extensive inter-individual cross-ethnic variations in drug responses (Kalow, 1992; Lin *et al.*, 1993).

### Genetic Polymorphism of Genes Encoding “Drug-metabolizing Enzymes”: The Cytochrome P-450 System

As shown in Figure 76.2, of the four factors (absorption, distribution, metabolism and excretion) that together determine the fate and disposition of most drugs, variability in the process of metabolism is most substantial and usually is the reason for inter-individual and cross-ethnic variation in drug responses (Lin and Poland, 1995). Most drugs are metabolized via two phases: Phase I, commonly mediated by one or more of the cytochrome

**Table 76.1** Genetically Variable Enzymes of Drug Metabolism

Adapted from Kalow W (1992) *Pharmacogenetics of Drug Metabolism*. Pergamon Press, New York; Lin KM and Poland RE (1995) *Ethnicity, Culture, and Psychopharmacology in Psychopharmacology: The Fourth Generation of Progress* (eds Bloom FE and Kupfer DI). Raven Press, New York.

P-450 enzymes (CYPs), leads to the oxidation of the substrate; Phase II involves conjugation and is usually mediated by one of the transferases. There is clear evidence of inter-individual and cross-ethnic variations in the activity of enzymes in both phases, the genetic basis of which has been increasingly elucidated in recent years (Kalow, 1992; Weber, 1997).

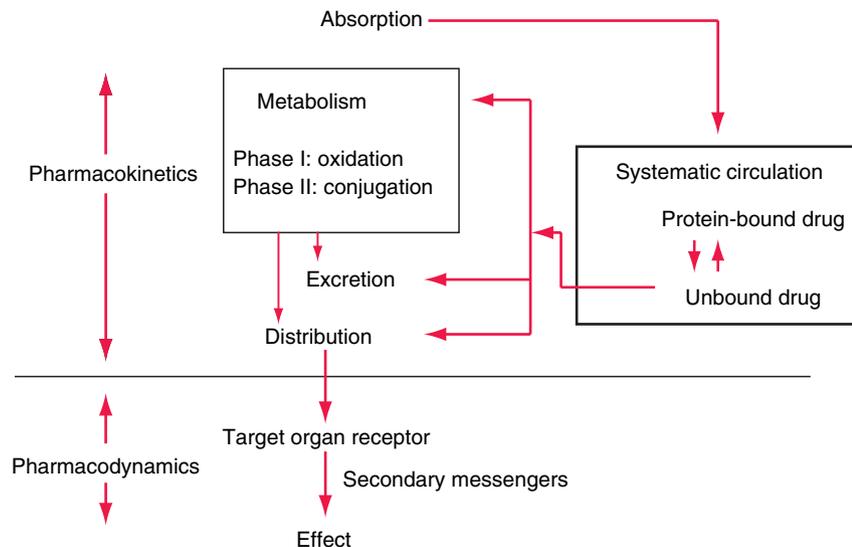

Table 76.2 includes a list of major CYPs that are responsible for the Phase I metabolism of commonly used psychotropics

as well as selected substances that are psychoactive and are commonly used by psychiatric patients.

Functionally significant genetic polymorphisms exist in most of the CYPs (Lin and Poland, 1995), leading to extremely large variations in the activity of these enzymes in any given population (Table 76.2). CYP2D6 represents the most dramatic example, with more than 20 mutations that inactivate, impair, or accelerate its function (Daly *et al.*, 1996). Significantly, most of these mutant alleles are to a large extent ethnically specific. For example, CYP2D6\*4, which leads to the production of defective proteins, is found in approximately 25% of Caucasians, but is rarely identified in other ethnic groups. This mutation is mainly responsible for the poor metabolizers (PM) in Caucasians (5–9%), who are extremely sensitive to drugs metabolized by CYP2D6. Instead of CYP2D6\*4, extremely high frequencies of CYP2D6\*17 (Leathart *et al.*, 1998, Masimirembwa and Hasler, 1997) and CYP2D6\*10 (Wang *et al.*, 1993; Dahl *et al.*, 1995; Roh *et al.*, 1996) were found among those of African and Asian origins, respectively. Both of these alleles are associated with lower enzyme activities and slower metabolism of CYP2D6 substrates (Figure 76.3), and may be in part responsible for previous findings of slower pharmacokinetic profiles and lower therapeutic dose ranges observed in Asians in regard to both classes of psychotropics, and in African-Americans in regard to tricyclic antidepressants (Lin and Poland, 1995).

Genetic polymorphism also exists in CYP2C19, CYP2C9, CYP2E1, CYP3A4 as well as the majority of other drug metabolizing enzymes. It is interesting to note that, almost without exception, wherever genetic polymorphism is identified, the allele frequency of the mutations typically show substantial ethnic variations (Stephens *et al.*, 1994; Gill *et al.*, 1999; Kidd *et al.*, 1999).

Patients from different ethnic/cultural backgrounds live divergent lifestyles, and are likely to be exposed to unique substances that may have strong effects on the expression and activity of drug metabolizing enzymes. Thus, what we currently know about environmental influences on drug metabolism may represent only the tip of the iceberg. This may be especially true in regard to ethnic minority and other nonWestern populations.

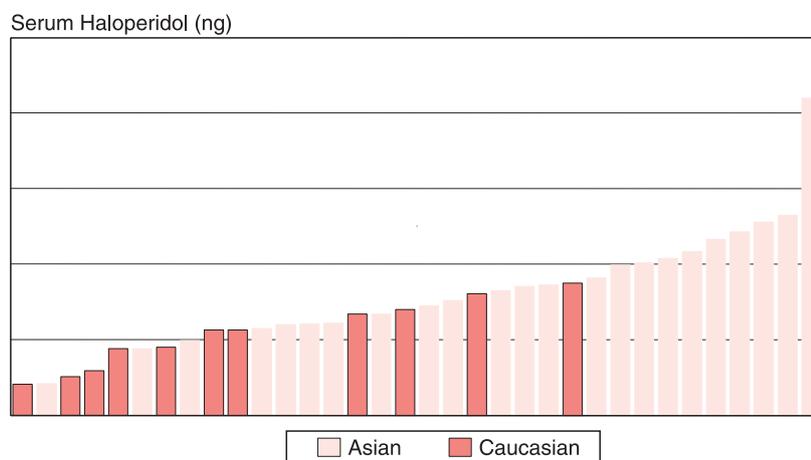

**Figure 76.2** Pharmacokinetics and pharmacodynamics.

**Table 76.2 Major Human Cytochrome P-450 Enzymes and Their Psychotropic Substrates**

	Substrates	Genetic Polymorphisms
CYP1A2	Antidepressants: amitriptyline, clomipramine, imipramine, fluvoxamine	No report of polymorphism until 1999; the significance of the following findings remain unclear (Nakajima, 1999)
	Neuroleptics: haloperidol, phenothiazines, thiothixine, clozapine, olanzapine Others: tacrine, caffeine, theophylline, acetaminophen, phenacetin	*1C: reduced activity; 23% in Japanese *1F: higher inducibility; 32% in Caucasians
CYP2C19	Benzodiazepines: diazepam	*2: no activity; 23–39% in Asians; 13% in Caucasians; 25% in African-Americans *3: no activity; 6–10% in Asians; 0% in others
	Antidepressants: imipramine, amitriptyline, clomipramine, citalopram Others: propranolol, hexobarbital, mephobarbital, proguanil, omeprazole, <i>S</i> -mephenytoin	*6 *7 and *8 contain mutations that result in the poor metabolizer phenotype in Caucasians (Ibeanu, 1998, 1999)
CYP2D6	Antidepressants: amitriptyline, clomipramine, imipramine, desipramine, nortriptyline, trimipramine, <i>N</i> -desmethyl-clomipramine, fluoxetine, norfluoxetine, paroxetine, venlafaxine, sertraline	*2: accounts for 60% of intermediate metabolizers in Caucasians (Raimundo, 2000).
	Neuroleptics: chlorpromazine, thioridazine, perphenazine, haloperidol, reduced haloperidol, risperidone, clozapine, sertindole Others: codeine, opiate, propranolol, dextromethorphan	*3: no activity; 1% in Caucasians (Shimada, 2001) *4: no activity; 25% in Caucasians; 0–10% in others *5: no activity; 2–10% in all groups *10: reduced activity; 47–70% in Asians, ≤5% in others (Mendoza, 2001) *17: reduced activity; 25–40% in blacks, 0% in others (Wan, 2001) *2XN: increased activity; 19–29% in Arabs and Ethiopians; ≤5% in others
CYP3A4	Antidepressants: mirtazepine, nefazadone, sertraline	Several single nucleotide polymorphisms have been identified with racial variability in their frequency. However, functional significance of these polymorphisms have not been clearly elucidated (Dai <i>et al.</i> , 2001)
	Neuroleptics: thioridazine, haloperidol, clozapine, quetiapine, risperidone, sertindole, ziprasidone Mood stabilizers: carbamazepine, gabapentin, lamotrigine Benzodiazepines: alprazolam, clonazepam, diazepam, midazolam, triazolam, zolpidem Calcium channel blockers: diltiazem, nifedipine, nimodipine, verapamil Steroids: androgens, estrogens, cortisol Others: erythromycin, terfenadine, cyclosporine, dapsone, ketoconazole, lovastatin, lidocaine, alfentanil, amiodarone, astemizole, codeine, sildenafil	Recent reports of the functional significance of a variant with mutation in the regulatory region (*1B) has been suggested. The prevalence of *1B is 10% in Caucasians, and unknown in other ethnic groups.  There are preliminary reports of two other promising alleles (*2 and *3), but details of these mutations are not yet available.  *4, *5, *6 have been suggested to possibly decrease 3A4 activity in Chinese subjects but the incidences of these mutations are rare and their prevalence in other ethnic groups is unknown (Hsieh, 2001)

Other important human CYPs include CYP2A6, CYP2B6, CYP2C8, CYP2C9, and CYP2E1. CYP2A6 is involved in the metabolism of nicotine and cotinine, CYP2C9 is responsible for the biotransformation of drugs including phenytoin and warfarin, CYP2E1 metabolizes acetaminophen, theophylline as well as alcohol and is associated with the production of free radicals.

**Figure 76.3** Variability of haloperidol concentrations in normal volunteers after the administration of haloperidol (0.5 mg, IM). The graph shows: 1) substantial interindividual variability within each of the ethnic groups; 2) dramatic differences in the pharmacokinetics of haloperidol between the two ethnic groups; and 3) overlap of the pharmacokinetics between the two groups. (Source: Lin KM, Poland RE, Lan JK et al. [1988] Haloperidol and prolactin concentrations in Asians and Caucasians. *J Clin Psychopharmacol* 8, 195–201.)

For example, studies have shown that Asian Indians and Africans were significantly slower in metabolizing substrates of CYP1A2, such as theophylline, antipyrine and clomipramine. However, after they immigrated to Europe and adapted to the new dietary habits, their metabolic profiles for these drugs became indistinguishable from the “native” Westerner’s (Allen et al., 1977).

### Genetic Polymorphism of Genes Encoding Receptors, Transporters, or Other Therapeutic Targets

Along with the cloning and sequencing of the genes encoding the receptors and transporters that mediate and regulate the function of important neurotransmitters, it has become apparent that, contrary to earlier predictions (Kalow, 1990), these genes are almost without exception highly polymorphic, and the pattern of these polymorphisms vary significantly across ethnicity (Gelenter et al., 1997; Goldman et al., 1996; Hodge, 1994; Dean et al., 1994; Chang et al., 1996). For example, the frequency of the TaqI A RFLP polymorphism of the dopamine D<sub>2</sub> receptor (DRD2), one of the most extensively investigated brain receptors, ranges from 5 to 18% in Caucasians to approximately 36% in African-Americans and 37 to 42% in Asians (Blum et al., 1995). Similarly, dramatic ethnic variations exist in the pattern of genetic polymorphism of many other receptor and transporter genes. These include other DRD2 mutations (TaqI B, 311Ser/Cys and exon 8 A/G substitution), other dopamine receptors such as DRD4 and DRD3 (Parsian et al., 1999; Sander et al., 1995; Sullivan et al., 1998), the dopamine transporter gene (DAT1; locus symbol SLC6A3) (Vandenberg et al., 1992), the serotonin transporter gene (5-HTT), and a number of serotonin receptors (5-HT<sub>2A</sub>-1438 A/G and 5-HT<sub>2A</sub>-102 T/C) (Greenberg et al., 1998; Smeraldi et al., 1998; Michaelovsky et al., 1999).

These polymorphisms may have functional significance and hence might be associated with the risk for psychopathology as well as the response to treatment regimens. We await further research to confirm this possibility.

### Summary

This brief discussion serves to highlight the significance as well as the complexity of issues surrounding the influence of cultural and ethnic forces on psychotropic responses. At the same time, it is equally important that any findings regarding ethnic variations in pharmacological responses not be interpreted stereotypically. In this regard, it is useful to keep in mind that almost all ethnic and cultural contrasts are superimposed on usually very substantial inter-individual variations in all human groups. This is true not only in regard to biological traits such as the ones reviewed above, but equally so (or even more so) with regard to “cultural” and psychosocial variables. Stereotypic interpretations of cultural and ethnic differences in either psychological or biological characteristics are not only misleading but also potentially divisive and dangerous.

Further, in interpreting biological diversity, both within and across populations, it is important to keep in mind that biological systems are dynamic rather than static, and the expression of genetic predisposition is constantly modified by environmental exposure. Although it is reasonable to believe that social and psychological events would similarly exert powerful influences on the functioning of relevant genes, such influences are likely to be subtle and complex, and have remained largely unexplored.

Future progress in pharmacogenetics might stimulate research on “nonbiological” issues such as cultural influences on adherence and other factors that determine patients’ perception and help-seeking behavior, which in turn contribute toward their sense of satisfaction and their being able maximally to benefit from psychotropic treatment. With such an integrative approach, we would be best able to define elements for optimal pharmacotherapeutic practices that would take both cultural and biological diversity into consideration and tailor treatment to individual characteristics rather than relying on global guidelines.

## Introduction

Information about antipsychotic drugs and theoretical developments in the treatment of psychosis is rapidly expanding, and more agents with antipsychotic efficacy are being developed. The advent of newer second-generation antipsychotics in the wake of clozapine represents the first significant advances in the pharmacologic treatment of schizophrenia and related psychotic disorders, and many clinicians in the USA are prescribing these second-generation antipsychotics as the first-choice agent for acute and maintenance therapy for these illnesses (Buckley, 2001; McEvoy *et al.*, 1999).

## Pharmacology of Antipsychotic Agents

### First-generation Antipsychotic Agents

The first-generation antipsychotic agents are equally effective in the treatment of psychotic symptoms of schizophrenia, while they vary in potency, their pharmacological properties, and their propensity to induce side effects (Davis *et al.*, 1980; American Psychiatric Association, 2000). The effect that is common to all first-generation antipsychotics is a high affinity for dopamine D<sub>2</sub> receptors (Marder and Van Putten, 1995). In addition, all of the first-generation agents produce EPS, including parkinsonism, dystonia, akathisia and TD, to a varying degree and increase serum prolactin concentration in the usual clinical dose range (Meltzer, 1985). These are described in greater detail in the section “Adverse Effects”.

The first-generation agents are usually classified into three groups: phenothiazines, butyrophenones (e.g., haloperidol) and others (e.g., thiothixene, molindone and loxapine), based on their structure.

### Phenothiazines

The phenothiazine antipsychotics are usually categorized into three classes according to substitutions at position 10 (Marder and Van Putten, 1995). The aliphatic class (e.g., chlorpromazine) consists of agents that have relatively low potency at D<sub>2</sub> receptors compared with other first-generation antipsychotics, more antimuscarinic activity, more sympathetic and parasympathetic activity, and more sedation. The piperidine class (e.g., thioridazine) has a similar clinical profile to the aliphatic class, with somewhat reduced affinity for D<sub>2</sub> sites. The piperazine class (e.g., fluphenazine) has fewer antimuscarinic and autonomic effects, but greater potency at D<sub>2</sub> sites, and thus can produce more EPS.

### Butyrophenones

The butyrophenone antipsychotics, represented by haloperidol, tend to be potent D<sub>2</sub> antagonists and have minimal anticholinergic and autonomic effects (Marder and Van Putten, 1995). PET studies demonstrate that low doses of haloperidol (2–5 mg/day) would be expected to induce 60 to 80% dopamine D<sub>2</sub> receptor occupancy (Kapur *et al.*, 1996, 1997). While theoretically this dosage should be enough for optimal clinical efficacy correlated to an optimal D<sub>2</sub> receptor antagonism, dosages five to 20 times as high are prescribed in current clinical practice (Stip, 2000) (see section “Dose of Antipsychotic Agent”).

### Second-generation and Novel Antipsychotic Agents

The pharmacological properties that confer the unique therapeutic properties of second-generation antipsychotic drugs are poorly understood despite intensive research efforts by the pharmaceutical industry and the psychopharmacology research community. Since clozapine is the prototype “atypical” drug, defining the role of the individual complex actions of this drug, that are responsible for its unique therapeutic profile, is necessary for rational design of new and improved second-generation (clozapine-like) antipsychotics (Miyamoto *et al.*, 2002a). In this chapter, second-generation antipsychotics refer to clozapine, risperidone, olanzapine, quetiapine, ziprasidone, sertindole, amisulpride, zotepine, aripiprazole and iloperidone. The relative receptor affinities for these medications all shown in Table 77.1.

### Antipsychotic Medications for Different Indications

Antipsychotic agents are effective for treating nearly every medical and psychiatric condition where psychotic symptom or aggression is the predominant feature. The development of second-generation antipsychotics has been a major clinical advance for the treatment of schizophrenia. At present, these second-generation drugs are being used for schizophrenia as the first-line treatment, and are being used increasingly for various conditions beyond schizophrenia as happened with the first-generation antipsychotics (Marder, 1997; Glick *et al.*, 2001). The low incidence of EPS and TD associated with second-generation agents is highly beneficial in several neuropsychiatric conditions. A summary of various indications for second-generation antipsychotics is shown in Table 77.2. Some uses have gained general acceptance, whereas others depend on moderate or preliminary evidence.

**Table 77.1** Relative Neurotransmitter Receptor Affinities for Some Antipsychotics at Therapeutic Doses

Receptor	Clozapine	Risperidone	Olanzapine	Quetiapine	Ziprasidone	Sertindole	Amisulpride	Zotepine	Aripiprazole	Iloperidone	Haloperidol

**Table 77.2 Indications for Second-generation Antipsychotic Use Other than Schizophrenia**

Strong Evidence	Moderate Evidence	Preliminary Evidence
<b>Risperidone</b> Dementia Pervasive developmental disorders	Bipolar disorder, Stuttering Conduct disorder, Tourette's disorder	Pediatric psychoses
<b>Olanzapine</b> Bipolar disorder	Dementia Substance-induced psychosis	Borderline personality disorder Depression, Pediatric psychoses Childhood schizophrenia
<b>Quetiapine</b> Bipolar disorder L-dopa-induced psychosis	Dementia	Borderline personality disorder Substance-induced psychosis
<b>Clozapine</b> L-dopa-induced psychosis	Pediatric psychoses Prophylaxis of treatment resistant bipolar disorder	
<b>Ziprasidone</b>		Bipolar disorder Tourette's disorder
<b>Zotepine</b>		Psychotic depression
<b>Amisulpride</b>		

### Schizophrenia and Schizoaffective Disorder

Nearly all acute episodes of schizophrenia and schizoaffective disorder, including first episode psychosis and recurrence in chronic schizophrenia, should be treated with antipsychotic medications (American Psychiatric Association, 2000). The psychiatrist should evaluate the patient's mental status and physical condition before establishing a baseline for the administration of antipsychotic medications. Once the patient is diagnosed, pharmacotherapy should be applied as early in this phase as possible.

Continuous medications may be preferable for most patients with schizophrenia, even if they are symptom free, to reduce the likelihood of relapse.

### Major Depression with Psychotic Features

Clear psychotic symptoms, such as delusions or hallucinations, are observed in approximately 25% of patients with major depressive disorder (Rothschild, 1996). These symptoms often respond poorly to antidepressants when they are administered alone, and may require the use of adjunctive antipsychotic agents (Marder, 1997). Conventional antipsychotic drugs are likely to expose patients to the development of TD and EPS, which may occur more frequently in patients with affective disorders than in those with schizophrenia (Casey, 1999). Thus, second-generation antipsychotics may have a more beneficial effect for this patient population.

There is clinical evidence that some of the second-generation antipsychotics may have antidepressant effects in addition to their antipsychotic properties, and thus may improve depressive symptoms in schizophrenia (Tollefson *et al.*, 1999; Buckley, 2001). Although depressive symptoms have traditionally been treated with antidepressants, a number of case reports and open trials have shown risperidone and olanzapine to be efficacious as monotherapy or adjunctive treatment for the treatment of depression without psychotic features (Jacobsen, 1995; Ostroff and Nelson, 1999) (for review, see Buckley, 2001).

### Mania

In almost 50% of manic episodes, clear psychotic symptoms, such as delusions or hallucinations, are observed (Goodwin and Jamison, 1990). Antipsychotic medications can effectively treat the symptoms of acute mania, particularly in patients, who present with prominent agitation, in advance of the onset of action of lithium or mood stabilizers (Marder, 1997; Buckley, 2001). Over the past few years, second-generation antipsychotics have gained increasing favor over the conventional neuroleptics for the treatment of bipolar disorder because of their fewer EPS, a presumably lower risk of TD, and antimanic or mood stabilizing effects (Thase and Sachs, 2000). Currently, second-generation antipsychotics are being used as second-choice treatments for bipolar disorder and/or adjunctive therapy with lithium, carbamazepine, or sodium valproate (Ghaemi, 2000).

### Tourette's Disorder

Tourette's disorder is a neurobehavioral disorder characterized clinically by motor and vocal tics (Jimenez-Jimenez and Garcia-Ruiz, 2001). Tics are usually present in childhood and may persist throughout life. The pathophysiology of the illness is not well known. When the tics interfere with the functioning of the patient, an antipsychotic medication can be effective in reducing the severity of both motor and vocal tics (Marder, 1997). Although haloperidol and pimozide have been the most commonly used agents for the disease, second-generation antipsychotics are considered as promising agents for the control of tics, because of their better adverse event profiles.

### Substance-related Disorders

A variety of substances, including amphetamines, cocaine, alcohol and phencyclidine, can cause schizophrenia-like symptoms that occur while the patient is intoxicated or during drug withdrawal (Marder, 1997). While clinical trials have not yet established the efficacy of the second-generation antipsychotics for substance use disorders, several case reports and open-labeled

studies offer suggestions of the effectiveness of new agents in these off-label uses (Misra and Kofoed, 1997; Smelson *et al.*, 1997).

### Behavioral Disturbances in the Elderly

Dementia, whether due to Alzheimer's disease or other causes, is frequently associated with behavioral disturbance, agitation and psychotic phenomena (e.g., persecutory delusions, hallucinations) (Stoppe *et al.*, 1999). The management of behavioral disturbance and psychosis in the elderly is complicated by age-related decline in drug metabolism, vulnerability to drug–drug interactions, high incidence of concomitant physical illnesses and heightened sensitivity to EPS and TD (Marder, 1997; Buckley, 2001). Usually, lower dosages are more necessary for the elderly than for younger patients. Although evidence from a number of double-blind studies supports the efficacy of traditional antipsychotics for treating agitated elderly patients, the use of older agents is limited by EPS, TD, anticholinergic adverse effects, sedation, and orthostatic hypotension, which may result in falls and fractures.

### Other Organic Syndromes

Patients with Parkinson's disease (PD) are sometimes accompanied with psychotic symptoms. Second-generation antipsychotics can offer a true benefit to this patient population (Friedman and Factor, 2000). Patients with Huntington's disease (HD) can also benefit from antipsychotic medications (Marder, 1997). As with PD, the use of conventional agents worsens chorea movement disturbance (Buckley, 2001).

### Childhood Schizophrenia

Children with schizophrenia may need neuroleptics for a long term. At present, no controlled trials have been published on the use of risperidone, olanzapine, quetiapine, or ziprasidone for the pediatric population with schizophrenia, thus definitive evidence is lacking. A number of open clinical trials and case reports of these new agents, however, indicate a possible effectiveness, though pediatric patients seem to have a greater propensity than adults for side effects, particularly EPS, weight gain and dysphoria, but also prolactin increase and white blood count aberrations (Kumra *et al.*, 1998; Toren *et al.*, 1998; Wudarsky *et al.*, 1999; McConville *et al.*, 2000).

## Effects of Antipsychotic Agents on Symptoms of Schizophrenia

### Positive Symptoms

Antipsychotic agents have a specific effect on positive symptoms of schizophrenia including hallucinations, delusions and thought disorder (Hirsch and Barnes, 1995). First-generation antipsychotic drugs (e.g., chlorpromazine and haloperidol) are effective for alleviating positive symptoms and in preventing their recurrence in many schizophrenic patients (Miyamoto *et al.*, 2000, 2002a).

Although the proportion of patients who improve and the magnitude of therapeutic effects vary greatly, second-generation antipsychotics appear to be at least as effective for psychotic symptoms as conventional drugs (Markowitz *et al.*, 1999; Remington and Kapur, 2000).

Within a short period of time, clozapine, risperidone, olanzapine, quetiapine and ziprasidone have become the drugs of choice over conventional antipsychotic drugs in the treatment

of schizophrenia and schizoaffective disorder (Buckley, 2001). There is, however, still considerable debate with regard to the clinical superiority of second-generation over conventional antipsychotics. The CATIE study (Lieberman, 2005) failed to resolve this debate, with all medications tested demonstrating comparable clinical efficacy.

### Negative Symptoms

Negative symptoms can be divided into three components that are usually difficult to distinguish: 1) primary or deficit-enduring negative symptoms, 2) primary nonenduring negative symptoms, and 3) secondary negative symptoms that may be associated with positive symptoms, EPS, depression and environmental deprivation (Buchanan and Gold, 1996; Collaborative Working Group on Clinical Trial Evaluations, 1998a). Studies of the early course of illness have shown that about 70% of schizophrenics develop primary negative symptoms, such as affective blunting, emotional withdrawal, poverty of speech, anhedonia and apathy, before the onset of positive symptoms (Hafner *et al.*, 1992). Negative symptoms may represent core features of the illness, and may be associated with poor outcome and prolonged hospitalization for patients (Buchanan and Gold, 1996).

Conventional antipsychotics are generally less effective against negative than positive symptoms of schizophrenia (Miyamoto *et al.*, 2002a). Thus, the efficacy of second-generation antipsychotics on negative symptoms compared with that of first-generation drugs has received much attention. Although second-generation antipsychotics have been shown to be more effective than conventional agents in treating negative symptoms, there is a continuing debate as to whether these effects are related to a reduction in EPS, or to a direct effect on primary negative symptoms (Marder and Meibach, 1994; Kane *et al.*, 2001; Remington and Kapur, 2000; Carpenter *et al.*, 1995; Conley *et al.*, 1994; Meltzer, 1995).

A summary of the clinical profile of second-generation drugs on a range of symptoms is provided in Table 77.3.

### Mood Symptoms and Suicidal Behavior

Depressive symptoms frequently occur in the context of psychotic symptoms or intercurrently between psychotic episodes (Siris, 2001). Antidepressant medication used adjunctively to antipsychotic drugs is generally indicated and effective (Siris, 2001). Atypical antidepressants have been reported to have selective benefits against mood symptoms in schizophrenia, both manic and depressive (Sartorius *et al.*, 2002).

Suicidal behavior presents a particular problem in patients with schizophrenia. Recently the FDA approved clozapine for use in suicidal patients with schizophrenia on the basis of results in the InterSePT study. This study found that clozapine treatment produced a lower rate of suicidal behavior than the comparison treatment olanzapine in patients with active or histories of suicidal behavior (Meltzer *et al.*, 2003).

## Treatment of Different Phases of Schizophrenia

### Treatment During the Acute Phase

#### Route of Administration

In clinical situations, antipsychotic medications can be administered in oral forms, including oral tablets, oral liquid concentrates

**Table 77.3** Clinical Profile of Second-generation Antipsychotic Drug Efficacy

and orally dissolving formulations, as short-acting intramuscular preparations, or as long-acting depot preparations (American Psychiatric Association, 2000). In most cases, patients who are cooperative prefer oral administration to parenteral medications. A summary of dosing recommendations for newer agents is provided in Table 77.4. Oral antipsychotic medications tend to be rapidly and well absorbed from the gastrointestinal tract, and reach a peak plasma concentration in 1 to 10 hours (Burns, 2001). The long average half-life (12–24 hours) and active metabolites of most oral antipsychotic drugs allow for once- to twice-daily dosing (Marder, 1997; Burns, 2001). Among the second-generation agents, quetiapine and ziprasidone have relatively shorter half-lives (Table 77.4), and should be administered in divided doses (Markowitz *et al.*, 1999). A single or twice-daily dose of an oral preparation will result in steady-state blood levels in 2 to 5 days (Dahl, 1990).

Short-acting intramuscular (IM) medications are particularly useful in the management of acute pathologic excitement and agitation (Buckley, 1999). The main indication for the use of a short-acting parenteral form in the acute situation is to treat severely disturbed patients who cannot be verbally redirected, who may be violent, and who may have to be medicated over objection. Short-acting IM preparations can reach a peak concentration 30 to 60 minutes after the medication is administered (Dahl, 1990).

### Selection of an Antipsychotic Agent

Selection of an agent in emergency settings for the management of the gross agitation, excitement and violent behavior associated with psychosis might be based on clinical symptoms, differences in efficacy or side effects of candidate drugs, or, more pragmatically, the formulation of a drug as it affects route of administration, onset and duration (Hirsch and Barnes, 1995; Allen, 2000). Most agitated patients will assent to oral medication and, in a survey of 51 psychiatric emergency services, the medical doctors

estimated that only 10% of emergency patients require injectable medications (Currier, 2000). Practice and legal requirements concerning injectable medications differ substantially across the globe. The US Health Care Finance Administration's (HCFA) regulations regarding so-called "chemical restraint" call for it to be a last resort, which would suggest that oral medication should be offered whenever it is possible to speak with the patient (Allen, 2000). Intramuscular treatments, however, remain necessary for some agitated or aggressive patients who refuse oral medications of any kind (Allen *et al.*, 2001). In these situations, many clinicians avoid high doses on antipsychotic medications in favor of a combination of an antipsychotic and a benzodiazepine (Miyamoto *et al.*, 2002b).

### Dose of Antipsychotic Agent

**Effective Doses of First-generation Antipsychotics** The goal of pharmacotherapy is to maximize efficacy and minimize adverse effects with the lowest effective dose. When groups of patients are assigned to higher doses, such as more than 2000 mg chlorpromazine or 40 mg haloperidol equivalent, the rate and amount of improvement are no greater than for those assigned to more moderate doses (Marder, 1996).

**Effective Doses of Second-generation Antipsychotics** The dosage recommendations for second-generation antipsychotic drugs are summarized in Table 77.4. Although clinical trial data show that second-generation antipsychotics are efficacious and cause fewer EPS than the conventional agents, optimal dosing constitutes a critical issue in their effective use.

### Treatment Resistance

Patients with schizophrenia may manifest poor response to treatment because of intolerance to medication, poor compliance, inappropriate dosing, as well as true resistance of their illness to antipsychotic medications. It has been consistently reported

**Table 77.4 Recommended Dosages for Second-generation Antipsychotic Agents**

	Half-life (hr)	Starting Dose	Average Dose Range (mg/day)		Average Maintenance Dose (mg/day)	Routes of Administration
	(Mean)	(Total mg/day)	First Episode	Recurrent Episode		
<b>Clozapine</b>	10–105 (16)	25–50	150–300	400–600	400	Oral
<b>Risperidone</b>	3–24 (15)	1–2	2–4	3–6	3–6	Oral, depot
<b>Olanzapine</b>	20–70 (30)	5–10	10–20	15–30	10–20	Oral, IM

that approximately 10 to 15% of patients with first-episode schizophrenia are resistant to drug treatment (Lieberman *et al.*, 1993), and between 30 to 60% of patients become only partially responsive or completely unresponsive to treatment during the course of the illness (Davis and Casper, 1977; Essock *et al.*, 1996; Lieberman, 1999). Before a patient is considered treatment-resistant, an optimized medication and treatment trial should be employed (Conley and Kelly, 2001). The most accepted criteria for defining treatment resistance in schizophrenia were initially utilized by Kane and collaborators (1988) in the Multicenter Clozapine Trial (MCT), and the modified criteria have been used to define treatment resistance (Table 77.5). Although most definitions of treatment resistance focus on the persistence of positive symptoms, there is growing awareness of the problems of persistent negative symptoms and cognitive impairments, which may have an important impact on level of functioning, psychosocial integration and quality of life (Conley and Kelly, 2001; Peuskens, 1999).

Only clozapine has consistently demonstrated efficacy for psychotic symptoms in well-defined treatment refractory patients. The mechanism responsible for this therapeutic advantage remains uncertain. Thus, clozapine remains the “gold standard” for treatment of this patient population. The evidence is strongest in support of clozapine monotherapy as an intervention for treatment-resistant patients; serum levels of 350 µg/mL or greater have been associated with maximal likelihood of response (Miller, 1996).

Since the approval of clozapine, attention has shifted to a greater focus on the use of other second-generation antipsychotics for managing treatment resistance in schizophrenia, but the relative efficacy of other second-generation antipsychotics is less clear.

Given the risk of agranulocytosis, the burden of side effects and the requirement of white blood cell monitoring, the second-generation agents (risperidone, olanzapine, quetiapine and ziprasidone) should be tried before proceeding to clozapine in almost all patients (Conley and Kelly, 2001; Miyamoto *et al.*, 2002a). Many clinicians express the impression that certain patients do respond preferentially to a single agent of this class. Sequential controlled trials of the newer agents in treatment-resistant patients will be necessary fully to examine this issue.

## Treatment During the Resolving Phase

During the resolving phase, the goals of treatment are to minimize stress on the patient, to facilitate the patient’s return to community life, and to establish a long-term maintenance plan (Marder, 1999; American Psychiatric Association, 2000). If a particular antipsychotic medication has improved the acute symptoms, it should be continued at the same dose for the next 6 months, before a lower maintenance dose is considered for continued treatment (American Psychiatric Association, 2000). Rapid dose reduction or discontinuation of the medications during the resolving phase may result in relatively rapid relapse (American Psychiatric Association, 2000). If the psychiatrist has decided to switch the therapy to a long-acting depot antipsychotic agent, this can often be accompanied during this phase. This may also be a reasonable time to educate the patient and family regarding the course and outcome of schizophrenia, as well as factors that influence the outcome such as drug compliance (Marder, 1997; American Psychiatric Association, 2000). Patients should be helped to begin formulating a rehabilitation plan through realistic goal setting (Marder, 1997).

## Treatment During the Stable Phase (Maintenance Treatment)

The goals of treatment during the stable or maintenance phase are to maintain symptom remission, to prevent psychotic relapse, to implement a plan for rehabilitation and to improve the patient’s quality of life (Marder, 1999; American Psychiatric Association, 2000). Current guidelines recommend that first-episode patients should be treated for 1 to 2 years; however, 75% of patients will have relapses after their treatment is discontinued (Kissling, 1991; Davis *et al.*, 1994; Lehman and Steinwachs, 1998; American Psychiatric Association, 2000). Patients who have had multiple episodes should receive at least 5 years of maintenance therapy (Kissling, 1991; Davis *et al.*, 1994; American Psychiatric Association, 2000). Patients with severe or dangerous episodes should probably be treated indefinitely (American Psychiatric Association, 2000).

For conventional antipsychotics, the risk of long-term side effects such as the development of TD inspired a search for strategies to reduce patients’ exposure to these agents, and strategies for preventing relapse during the maintenance phase has focused on finding dosages that minimize drug adverse effects and provide adequate protection against psychotic relapse (Marder, 1999). Maintenance studies of the dose–response relationship found that lowering the dose prescribed for acute treatment by about 80% may be relatively safe for maintenance, although relapse rates are excessively high when doses are reduced to about 10% of an acute dose (Marder *et al.*, 1987; Hogarty *et al.*, 1988; Kane *et al.*, 1983). The international consensus conference recommended a gradual reduction in antipsychotic dose of approximately 20% every 6 months until a minimal maintenance dose is reached (Kissling, 1991).

## Use of Plasma Levels of Antipsychotic Drugs

The use of plasma levels as a guide for dosing or determining lack of response to an antipsychotic medication is relatively common in clinical settings, yet it remains controversial (Marder, 1997). There is a wide interindividual difference in blood levels in patients on the same dose of an antipsychotic drug, and a narrow dose range between therapeutic efficacy and increasing risk of adverse effects (Van Putten *et al.*, 1991; Kane and Marder,

1993; Marder, 1997). Although plasma levels among first-generation antipsychotics have been established for several compounds, there is at best a moderate correlation between these levels and clinical effects (Kane and Marder, 1993).

It may be useful to monitor the plasma level of an antipsychotic medication under certain circumstances (Fleischhacker, 2001). For example, before deciding that the agent is ineffective despite an adequate trial at a sufficient dose, it is important to determine whether it may be due to alterations in the pharmacokinetics of the drug or nonadherence to medications (Van Putten *et al.*, 1991; Conley and Kelly, 2001). A low plasma level (e.g., less than 5 µg/mL of haloperidol) may require raising the dose or addressing compliance issues. A higher plasma level (e.g., greater than 15 µg/mL of haloperidol) may require lowering the dose because medication side effects may be overshadowing therapeutic effects (Marder, 1997). Other instances when plasma level monitoring may be useful is when decreasing the dose of drug during maintenance therapy, since too low plasma levels may indicate an increased risk of relapse (Marder, 1997).

### Drug Interactions and Antipsychotic Agents

Most antipsychotics are metabolized by hepatic microsomal oxidases (cytochrome P450 system). The major isoenzyme systems involved are CYP1A2, CYP2C19, CYP2D6 and CYP3A4 (Ereshefsky, 1996). Induction or inhibition of these enzymes by other drugs may occasionally produce clinically important drug interactions (Burns, 2001). Table 77.6 summarizes clinically significant pharmacokinetic drug interactions involving second-generation antipsychotic drugs.

There are other common interactions that will concern clinicians. Antacids can decrease the absorption of the antipsychotic agent from the gut. Antipsychotic medications can antagonize the effects of dopamine agonists or levodopa when these drugs are used to treat parkinsonism. Antipsychotic agents may also enhance the effects of central nervous system depressants such as analgesics, anxiolytics and hypnotics. If patients require preanesthetic medication or general anesthetics, the doses of these drugs may need to be reduced (Marder, 1997).

### Antipsychotic Medications and Pregnancy

Most antipsychotic agents readily cross the placenta and are secreted in breast milk to some degree (Trixler and Tenyi, 1997). There is little data to demonstrate whether prenatal exposure to antipsychotic agents is linked to spontaneous abortion, congenital malformations, carcinogenesis, intrauterine growth retardation, or behavioral teratogenicity (Trixler and Tenyi, 1997). It has, however, been suggested that fetal exposure over the course of pregnancy may affect development of the dopamine system (Altshuler *et al.*, 1996). Physicians must consider the benefits of controlling psychotic symptoms during pregnancy versus the possible risks to the mother and the fetus of withdrawing treatment and the risks to the fetus of continuing treatment (Trixler and Tenyi, 1997). Thus far, second-generation antipsychotics have not been shown to be teratogenic in animal studies or in preliminary human reports (Goldstein *et al.*, 2000; Stoner *et al.*, 1997; Trixler and Tenyi, 1997). However, if possible, use of antipsychotic medication should be avoided, at least during the first trimester, especially between weeks 6 and 10, unless the patient's psychosis

places the mother and/or her fetus at significant risk (Trixler and Tenyi, 1997; American Psychiatric Association, 2000). Antipsychotic medications may be relatively safe during the second and third trimesters of pregnancy. If a first-generation antipsychotic agent is used, high-potency agents appear to be preferable for first-line management, because they have a lower propensity to cause orthostasis (Trixler and Tenyi, 1997). Low doses should be given, administration of antipsychotic medication should be as brief as possible, and the medication should be discontinued 5 to 10 days before delivery to minimize the chances of the newborn experiencing EPS (Trixler and Tenyi, 1997; American Psychiatric Association, 2000). This notion, however, has been reevaluated (Altshuler *et al.*, 1996), since discontinuation of medication before delivery may put the mother at risk for decompensation (Trixler and Tenyi, 1997). Anticholinergic agents should also be avoided during pregnancy, especially for the first trimester (American Psychiatric Association, 2000). Since antipsychotics are also secreted into breast milk, the infants should not be breast-fed if the mother resumes taking antipsychotic medication postpartum.

## Adverse Effects

### Acute Extrapyramidal Side Effects (Dystonia, Parkinsonism, Akathisia)

Antipsychotic-induced EPS occur both acutely and after chronic treatment. All antipsychotic medications are capable of producing EPS. In general, first-generation antipsychotics are more likely to cause EPS than second-generation antipsychotics when the drugs are used at usual therapeutic doses. Among second-generation drugs, clozapine and quetiapine have been shown to carry minimal to no risk for EPS within the therapeutic dosage range. The side-effect profiles for second-generation drugs and comparison with selected other agents are summarized in Table 77.7.

### Tardive Dyskinesia and Other Tardive Syndromes

TD is a repetitive, involuntary, hyperkinetic movement disorder caused by sustained exposure to antipsychotic medication. TD is characterized by choreiform movements, tics and grimaces of the orofacial muscles, and dyskinesia of distal limbs, often the paraspinal muscles, and occasionally the diaphragm (Glazer, 2000). Younger patients with TD tend to exhibit slower athetoid movements of the trunk, extremities and neck (Marder, 1997). In addition to the more frequently observed orofacial and choreoathetoid signs of TD, tardive dystonias (sustained abnormal postures or positions) and tardive akathisia (persistent subjective and/or objective signs of restlessness) have been described (Casey, 1999). The abnormal movements of TD are usually increased with emotional arousal and are absent when the individual is asleep (Marder, 1997). According to the diagnostic criteria proposed by Schooler and Kane (1982), the movements should be present for at least 4 weeks, and exposure to antipsychotic drugs should have totaled at least 3 months. The onset of the abnormal movements should occur either while the patient is receiving an antipsychotic agent or within a few weeks of discontinuing the offending agent.

Prevalence surveys indicate that mild forms of TD occur in approximately 20% of patients who receive chronic treatment with conventional antipsychotic medication (Kane and Lieberman, 1992; Casey, 1995). Among the most significant predictors

of TD are older age, female gender, presence of EPS, diabetes mellitus, affective disorders and certain parameters of neuroleptic exposure such as dose and duration of therapy (Casey, 1999).

For most patients, TD dose not appear to be progressive or irreversible (Gardos *et al.*, 1994). The onset of TD often tends to be insidious with a fluctuating course (American Psychiatric Association Task Force, 1992). With time, TD will either stabilize or improve even if the antipsychotic medication is continued, although there are reports of TD worsening during continued drug therapy (American Psychiatric Association Task Force on TD, 1992; Gardos *et al.*, 1994). After discontinuation of antipsychotic medication, a significant proportion of patients with TD will have remission of symptoms, especially if the TD is of recent onset or the patient is young (Glazer *et al.*, 1984). Unfortunately, withdrawal of antipsychotic agents is seldom an option for patients with serious psychosis (Marder, 1997).

The American Psychiatric Association Task Force on TD (1992) issued a report in which a number of recommendations were made for preventing and managing TD. These include 1) establishing objective evidence that antipsychotic medications are effective for an individual; 2) using the lowest effective dose of antipsychotic drugs; 3) prescribing cautiously for children, elderly patients, and patients with mood disorders; 4) examining patients on a regular basis for evidence of TD; 5) considering alternatives to antipsychotic drugs, obtaining informed consent and also considering a reduction in dosage when TD is diagnosed; and 6) considering a number of options if the TD worsens, including discontinuing the antipsychotic medication, switching to a different drug, or considering a trial of clozapine.

Although a large number of agents have been studied for their therapeutic effects on TD, there is no definitive drug treatment for it (American Psychiatric Association, 2000). Second-generation antipsychotics, in particular clozapine, have been used in clinical practice to treat TD, but there have been no adequately controlled trials to date support this practice. Casey (1999), however, suggested that second-generation antipsychotics should be used as first-line treatment for patients who have TD or are at risk for TD. Guidelines for treating TD recommend using second-generation agents for mild TD symptoms, and clozapine or a newer agent for more severe symptoms (McEvoy *et al.*, 1999).

### Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome (NMS), another type of acute EPS, is characterized by the triad of rigidity, hyperthermia (101–104°F), and autonomic instability in association with the use of an antipsychotic medication (American Psychiatric Association, 1994). NMS is often associated with elevation of creatine kinase (greater than 300 U/mL), leukocytosis (greater than 15 000 mm<sup>3</sup>) and change in level of consciousness (American Psychiatric Association, 2000). NMS can be of sudden and unpredictable onset, usually occurring early in the course of antipsychotic treatment, and can be fatal in 5 to 20% of untreated cases (American Psychiatric Association, 2000).

The incidence of NMS varies from 0.02 to 3.23%, reflecting differences in criteria (Caroff and Mann, 1993). Prevalence rates are unknown, but are estimated to vary from 1 to 2% of patients treated with antipsychotic medication (American Psychiatric Association, 2000). The relative risk of second-generation antipsychotics for NMS is likely to be lower, but conclusive data is not yet available (Burns, 2001). NMS has been reported with clozapine, risperidone, olanzapine and quetiapine (Burns, 2001). Proposed risk factors include prior episode of NMS, younger age,

**Table 77.7 Side-Effect Profile of Second-generation Antipsychotic Drugs**

National Institute of Mental Health Division of Services and Intervention Research Workshop (July 14, 1998). *Schizophr Bull* 25, 395–404; Burns MJ (2001) The pharmacology and toxicology of atypical antipsychotic agents. *J Clin Toxicol* 39, 1–14.

male gender, physical illness, dehydration, use of high-potency antipsychotics, rapid dose titration, use of parenteral (IM) preparations and preexisting neurological disability (Caroff and Mann, 1993; American Psychiatric Association, 2000).

If NMS is suspected, the offending antipsychotic agent should be discontinued and supportive and symptomatic treatment started (Marder 1997). Both dantrolene and dopamine agonists such as bromocriptine have also been used in the treatment of NMS (American Psychiatric Association, 2000). These agents, however, have not shown greater efficacy compared with supportive treatment (Caroff and Mann, 1993; Levenson, 1985).

The usual course of treatment is between 5 and 10 days. Long-acting depot preparations will prolong recovery time. After several weeks of recovery, treatment may be cautiously resumed with a different antipsychotic medication with gradually increased doses (American Psychiatric Association, 2000).

### Metabolic Effects

Various degrees of weight gain have been recognized as a common problem with conventional antipsychotic medications. Weight gain is an important issue in the management of patients, because this adverse effect may be associated with noncompliance and certain medical illnesses, such as diabetes mellitus, cardiovascular disease, certain cancers and osteoarthritis (Lader, 1999; Sussman, 2001; Kurzthaler and Fleischhacker, 2001).

Differences have been discovered among second-generation antipsychotics with respect to their ability to induce weight gain (Table 77.7). There is currently no standard approach to the management of weight gain induced by antipsychotic medication. Patient education prior to initiating treatment should be provided, and regular exercise should be encouraged in all patients receiving antipsychotic medication. Switching to other second-generation antipsychotics with fewer propensities for producing weight gain may be the most efficient way to deal with antipsychotic-induced weight gain.

### Hematologic Side Effects

Antipsychotic medications may cause blood dyscrasias, including neutropenia, leukopenia, leukocytosis, thrombopenia and agranulocytosis. Leukopenia, usually transient, commonly occurs early in treatment, and resolves spontaneously. Chlorpromazine has been associated with benign leukopenia, which occurs in up to 10% of patients (American Psychiatric Association, 2000; Kane and Lieberman, 1992). This phenomenon is even more common following clozapine administration (Hummer *et al.*, 1994).

Agranulocytosis (granulocyte count less than 500/mm<sup>3</sup>) is a fatal side effect of antipsychotic drugs. Approximately 0.32% of patients receiving chlorpromazine, and 1% treated with clozapine will experience agranulocytosis (American Psychiatric Association, 2000; Lieberman *et al.*, 1989). The risk of agranulocytosis is greatest early in treatment, usually within the first 8 to 12 weeks of treatment (Novartis Pharmaceuticals, 2000). It tends to occur slightly more often in women, the elderly and young patients (less than 21 years old). Agranulocytosis from clozapine is usually reversible if the drug is withdrawn immediately (Lieberman *et al.*, 1988). Olanzapine is not associated with severe agranulocytosis (Beasley *et al.*, 1996a, 1996b; Dossenbach *et al.*, 2000). Despite these encouraging studies, there are a number of case studies reporting agranulocytosis during treatment with olanzapine (and quetiapine) in patients who had suffered this adverse event during previous clozapine exposure (Tolosa-Vilella *et al.*, 2002).

Before initiating treatment with clozapine, patients in the USA must be registered in a program that ensures that they receive weekly monitoring of their white blood cell (WBC) count during the first 6 months of treatment (Marder, 1997). Clozapine is prescribed on a weekly basis unless the WBC count is less than 3500/mm<sup>3</sup> or if there is a substantial drop in the WBC count (Marder, 1997). If the WBC count is 3000 to 3500/mm<sup>3</sup> and the absolute neutrophil count (ANC) is greater than 1500/mm<sup>3</sup>, patients should be monitored twice weekly. If the WBC count is 2000 to 3000/mm<sup>3</sup> or the ANC count is 1000 to 1500/mm<sup>3</sup>, clozapine treatment should be discontinued and patients should be monitored daily. If the WBC count falls below 2000/mm<sup>3</sup> or the ANC is less than 1000/mm<sup>3</sup>, clozapine should be discontinued and bone marrow aspiration should be considered (American Psychiatric Association, 2000). If this occurs, the patient should be given immediate intensive treatment and considered protective isolation. Current guidelines require weekly monitoring for 1 month after the termination of clozapine treatment (American Psychiatric Association, 2000). Guidelines on the use of clozapine vary between different countries.

### Other Side Effects

Sedation is the single most common side effect among low-potency conventional antipsychotics, as well as clozapine, zotepine and quetiapine (American Psychiatric Association, 2000; Young *et al.*, 1998). Although sedation is often beneficial at the beginning of treatment to calm down an anxious or aggressive patient, it usually impairs functioning during long-term treatment (Hummer and Fleischhacker, 2000). Most patients usually develop tolerance over time, or it may be possible to minimize sedation by dose reduction or by shifting most of the medication to night to reduce daytime sleepiness (Hummer and Fleischhacker, 2000).

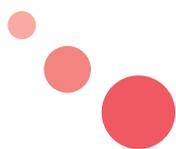

Antipsychotic medications can lower the seizure threshold to some degree (Kane and Lieberman, 1992). Seizure is more common with low-potency first-generation antipsychotics and clozapine (American Psychiatric Association, 2000). Clozapine is associated with dose-related increase in seizures. For example, Devinsky and colleagues (1991) reported that doses of clozapine below 300 mg/day have a seizure rate of about 1%, doses between 300 and 600 mg/day have a seizure rate of 2.7%, and doses above 600 mg/day have a rate of 4.4%. Strategies to reduce the risk for seizures include slower dose titration, a lower dose and the addition of an anticonvulsant agent (i.e., valproic acid) (Hummer and Fleischhacker, 2000).

## Acute Mania

### General Management Considerations

The goal of treatment should be to suppress completely all symptoms of mania and return the patient to his or her mental status *quo ante*. Mood, thinking and behavior should normalize. The patient should act and feel like herself or himself. For economic or social reasons, it is sometimes necessary to discharge a patient before total remission of symptoms has occurred. In such cases it is imperative that a patient continues to take medication as prescribed and is protected from a recrudescence of manic symptoms or a rapid slide into acute depression.

### Pharmacotherapy

The mechanism of action of antimanic drugs is poorly understood. It is not as clear what neural systems are involved in the mechanism of antimanic drugs. That few significant changes in neurotransmitter levels have been measured suggests that the site of action may be at the receptor, intracellular level, or second-messenger systems.

### Lithium

For many patients with hypomania, lithium by itself can induce a total remission. For patients with full-blown mania, however, an adjunctive antipsychotic or antianxiety agent may be required to treat intolerable psychosis or excitement.

Lithium is rapidly and completely absorbed after oral administration. It is not protein bound and does not undergo metabolism. Peak plasma levels are achieved within 1.5 to 2 hours for standard preparations or 4 to 4.5 hours for slow-release forms. Lithium's plasma half-life is 17 to 36 hours. Ninety-five percent of the drug is excreted by the kidneys, with excretion proportionate to plasma concentrations. Because lithium is filtered through the proximal tubules, factors that decrease glomerular filtration rates will decrease lithium clearance. Sodium also is filtered through the proximal tubules, so a decrease in plasma sodium can increase lithium reabsorption and lead to increased plasma lithium levels. Conversely, an increase in plasma lithium levels can cause an increase in sodium excretion, depleting plasma sodium. Many other drugs affect lithium levels (Table 78.1).

Tests that should be done before lithium is started include a complete blood count, electrocardiography, electrolyte determinations, and renal and thyroid panels (Table 78.2). Lithium dosage may be based on a plasma concentration sampled 12 hours after the last dose, or the drug may be gradually titrated to a dose that is tolerated and within the range usually considered "therapeutic". As with any drug, approximately five half-lives must elapse for steady state to be achieved. For an average adult, this takes about 5 days for lithium (longer in the elderly or in patients

with impaired renal function). To treat acute mania, plasma concentrations should typically be greater than 0.8 mEq/L, but to avoid toxicity, the level should not usually exceed 1.5 mEq/L. It is important to know what other medications a patient may be taking, because many drugs interact with lithium and can lead to increased or decreased lithium levels and possibly adverse effects (Table 78.2).

To reach therapeutic levels rapidly in healthy younger patients with normal renal and cardiac function, the psychiatrist may prescribe 300 mg of lithium carbonate four times daily from the outset, sampling the first plasma level after 5 days (or sooner should toxic signs become apparent). Thereafter, the dose should be adjusted to achieve a 12-hour plasma concentration between 0.8 and 1.3 mEq/L at steady state.

In a patient with mild hypomanic symptoms, by contrast, it may be wiser to begin with a lower lithium dose, such as 300 mg b.i.d., taking longer to achieve therapeutic levels but, at the same time, minimizing side effects that could trouble the patient and hamper cooperation. Once steady state has been achieved at therapeutic concentrations and the patient is clinically stable, lithium can be administered to most patients in a once-daily dose, usually at bedtime. Not only is this schedule easier to remember, but it tends to decrease such common side effects as tremor and polyuria.

The most common acute adverse effects from lithium are nausea, vomiting, diarrhea, postural tremor, polydipsia and polyuria (Table 78.2). If troublesome, these can usually be mitigated by a slower dosage increase or other measures. More severe symptoms and signs, including confusion and ataxia, may herald lithium intoxication and should prompt an immediate blood assay and, if necessary, temporary discontinuation or dosage reduction (see Table 78.3).

### Anxiolytic Agents

Among current anxiolytic agents, benzodiazepines are usually selected as adjuncts to treat acute mania because of their safety and efficacy. Benzodiazepines have a wide margin of safety and can be safely administered in even very high doses, suppressing potentially dangerous excitement and allowing patients much needed sleep. When used together with an antipsychotic agent, benzodiazepines counteract the antipsychotic agent's tendency to provoke extrapyramidal reactions and seizures. For lorazepam, 1 to 2 mg can be administered by mouth or intramuscularly as frequently as hourly.

### Valproate

Valproate is available in the USA as valproic acid or divalproex sodium, a compound containing equal parts valproic acid and sodium valproate. Divalproex is better tolerated than valproic acid, has been studied more extensively and is more commonly

**Table 78.1 Drug Interactions with Lithium**

Increase Levels of Lithium	Decrease Levels of Lithium	Increase Adverse Reactions
Angiotensin-converting enzyme(ACE) inhibitors	Aminophylline (Aminophyllin and others)	Atracurium (Tracurium): prolonged neuromuscular blocking effects
Alprazolam (Xanax)	Caffeine	Carbamazepine (Tegretol and others): antithyroid effects
Amiloride (Midamor)	Carbonic anhydrase inhibitors	Chlorpromazine (Thorazine and others): extrapyramidal symptoms, delirium, cerebellar function impairment
Antipsychotic agents?	Dyphylline (Lufyllin, Dilor)	Clozapine (Clozaril): neurotoxicity
Ethacrynic acid (Edecrin)	Laxatives	Diltiazem (Cardizem): neurotoxicity
Fluoxetine (Prozac)	Osmotic diuretics	Electroconvulsive therapy: confusion
Ibuprofen (Motrin and others)	Oxtriphylline (Choledyl)	Fluoxetine (Prozac): lithium toxicity
Indapamide (Lozol)	Theobromine diuretic (Athenol and others)	Fluvoxamine (Luvox): seizures
Indomethacin (Indocin)	Theophylline (Tedral and others)	Haloperidol (Haldol): neurotoxicity
Mefenamic acid (Ponstel)		Hydroxyzine (Atarax, Vistril, and others): cardiovascular toxicity
Naproxen (Naprosyn)		Iodine: antithyroid effects
Nonsteroidal anti-inflammatory drugs (NSAIDs)		Methyldopa (Aldomet and others): hypertension, toxic symptoms at normal blood levels
Phenylbutazone (Butazolidin and others)		Metronidazole (Flagyl and others): lithium toxicity
Some antibiotics		Neuroleptics: extrapyramidal symptoms, somnambulism, neurotoxicity
Spironolactone (Aldactone, and others)		Pancuronium (Pavulon): prolonged neuromuscular blocking effects
Sulindac (Clinoril)		Succinylcholine (Anectine and others): prolonged neuromuscular blocking effects
Thiazide diuretics		Verapamil (Calan and others): neurotoxicity
Triamterene (Dyrenium and others)		
Zomepirac (no longer available)		

used. All valproate preparations are rapidly absorbed after oral administration, reaching peak plasma levels within 2 to 4 hours of ingestion. Food may delay absorption but does not affect bioavailability. Valproate is rapidly distributed and highly bound (90%) to plasma proteins. Its half-life ranges from 9 to 16 hours, depending on whether it is taken alone or with other medications, and it takes 1 to 4 days to attain steady state.

**Table 78.2 Adverse Effects of Lithium**

Common	Less Common	Rare
Dermatitis	Ataxia	Hyperoathyroidism
Fatigue	Autonomic	Hyperthyroidism
Gastrointestinal upset	slowing of bladder and bowel function	Metallic taste
Headache		Nystagmus
Hypothyroidism	Cardiovascular complications	Organic brain syndrome
Memory and concentration difficulties	Diabetes mellitus	Parathyroid hyperplasia and parathyroid adenomas
Muscle weakness	Dysarthria	Tearing, itching, burning, or blurring of the eyes
Polydipsia	Edema	Tinnitus
Polyuria	Elevated WBC count	Vertigo
Tremor	Extrapyramidal reactions	Visual distortion
Weight gain	Goiter	
	Hypercalcemia	

Experts usually rank lithium as the treatment of choice for a patient with classic mania, but divalproex is an acceptable first-line alternative. It may be used singly in patients who cannot tolerate lithium. For patients who do not respond to lithium, there are no secure data on whether divalproex should be added as an adjunct or substituted, but many psychiatrists would choose the former in a patient who appears to respond at least partially to lithium and the latter in patients for whom lithium seems to afford no benefit. Increasingly, psychiatrists are turning to divalproex first for manic patients with organic brain impairment, rapid cycling, mixed or dysphoric mania, or comorbid substance abuse (Bowden *et al.*, 1994; Calabrese *et al.*, 1993).

Before initiating divalproex, the psychiatrist should obtain a comprehensive medical history and insure that a physical examination has been performed, with particular attention to suggestions of liver disease or bleeding abnormalities (see Table 78.4).

**Table 78.3 Lithium Intoxication**

Patients Should	When These Symptoms Occur
Call psychiatrist	Gastrointestinal symptoms
Stop lithium and see psychiatrist	Increased tremor, confusion, ataxia
Patients should report any other medications they are considering taking (prescribed or over-the-counter) and be wary of diet changes (especially decreased sodium intake).	

**Table 78.4 Pretreatment Tests**

Atypical Antipsychotics	<ul style="list-style-type: none"> <li>• Blood glucose</li> <li>• Blood lipids</li> </ul>

Baseline liver and hematological functions are measured before treatment, every 1 to 4 weeks for the first 6 months, and then every 3 to 6 months. Evidence of hemorrhage, bruising, or a disorder of hemostasis–coagulation suggests a reduction of dosage or withdrawal of therapy. The drug should be discontinued immediately in the presence of significant hepatic dysfunction.

A typical starting dose for healthy adults is 750 mg/day in divided doses. The dose can then be adjusted to achieve a 12-hour serum valproate concentration between 50 and 125 µg/mL. The time of dosing is determined by possible side effects and, if tolerated, once-a-day dosing can be employed. As with lithium, the antimanic response to valproate typically occurs after 1 to 2 weeks.

Adverse effects that appear early in the course of therapy are usually mild and transient, and tend to resolve in time. Gastrointestinal upset is probably the most common complaint in patients taking valproate and tends to be less of a problem with the enteric-coated divalproex sodium preparation. The administration of a histamine H2 antagonist such as famotidine (Pepcid) or cimetidine (Tagamet) may alleviate persistent gastrointestinal problems (Stoll *et al.*, 1991). Other common complaints include tremor, sedation, increased appetite and weight, and alopecia. Weight gain is even more of a problem when other drugs are administered that also promote weight gain, such as lithium, antipsychotic and other antiepileptics. Less common are ataxia, rashes and hematological dysfunction, such as thrombocytopenia and platelet dysfunction. Platelet count usually recovers with a dosage decrease, but the occurrence of thrombocytopenia or leukopenia may necessitate the discontinuation of valproate. Serum hepatic transaminase elevations are common, dose related, and usually

self-limiting and benign. Fatal hepatotoxicity is extremely rare, is usually restricted to young children, and usually develops within the first 6 months of valproate therapy. Other serious problems include pancreatitis and teratogenesis (McElroy *et al.*, 1989). There is also a concern that polycystic ovary syndrome, possibly associated with weight gain, may be a risk for young women who take valproate. If at any point during administration the side effects of valproate become intolerable, the psychiatrist may need to discontinue it and try one of the other treatments described in this section as an alternative. If valproate is tolerated but not totally effective, the psychiatrist might use one of the other treatments as an adjunct.

### Carbamazepine

In light of the less well-substantiated evidence for the efficacy of carbamazepine, we place this anticonvulsant fourth in the antimania algorithm – behind lithium, valproate, and olanzapine. The decision to move on to carbamazepine – and whether to use it alone or in addition to lithium, valproate, or olanzapine – hinges on the same treatment considerations listed earlier. If a patient has been treated with one or more of these agents in a previous manic episode, that experience may guide treatment of a current episode.

Carbamazepine's absorption and metabolism are variable. Peak plasma levels occur within 4 to 6 hours after ingestion of the solid dosage form. Bioavailability is estimated at 85% but may be less when the drug is taken with meals. Eighty percent of plasma carbamazepine is protein bound, and its half-life ranges from 5 to 26 hours (after 3–4 weeks of treatment). Carbamazepine's active metabolite, 10,11-epoxide, has a half-life of about 6 hours.

Carbamazepine is metabolized by the hepatic cytochrome P450 2D6 system. It causes an induction of the cytochrome P450 enzymes, often resulting in an increased rate of its own metabolism over several weeks, as well as that of other drugs metabolized by the P450 system (Table 78.5). Because of enzyme induction, the dose of carbamazepine often must be raised after 2 to 4 months of treatment. Steady state may be attained within 4 to 5 days, but when clearance increases as a result of autoinduction, steady state may not be achieved for 3 to 4 weeks. Concomitant administration of drugs that inhibit P450 (see Table 78.6) will increase plasma levels of carbamazepine. Conversely, drugs that induce P450 enzymes – such as phenobarbital, phenytoin, or primidone – can decrease carbamazepine levels. Before carbamazepine is started, baseline blood and platelet counts, urinalysis, and liver and kidney function tests are in order (see Table 78.4). Although earlier guidelines called for routine monitoring of some or all of these indices, and some psychiatrists still obtain blood counts once or twice during the first few months of treatment and when plasma concentrations are sampled, a more general consensus at present is to instruct patients and family members to contact the psychiatrist immediately if petechiae, pallor, weakness, fever, or infection occur, at which time the psychiatrist should order relevant tests.

Used as a monotherapy, the typical starting dose for carbamazepine is 200 to 400 mg/day in three or four divided doses, increased to 800 to 1000 mg/day by the end of the first week. If clinical improvement is insufficient by the end of the second week, and the patient has not had intolerable side effects to the drug, increases to as high as 1600 mg/day may be considered. Although there are no good studies of the correlation between blood level and clinical response, a common target range for mania is 4 to 15 ng/mL. If carbamazepine is combined with lithium

Lithium and carbamazepine: may increase neurotoxicity

or neuroleptics, lower doses and blood levels of carbamazepine are often used. If valproate and carbamazepine are administered simultaneously, blood levels of each should be monitored carefully because of complex interactions between the two agents.

When the dose of carbamazepine is built up rapidly, side effects are more likely. The most common effects in the first couple of weeks are drowsiness, dizziness, ataxia, diplopia, nausea, blurred vision and fatigue (Table 78.6). These tend to diminish in time or to respond to a temporary reduction in dose. Less common reactions include gastrointestinal upset, hyponatremia and a variety of skin reactions, some of which are severe enough to require discontinuation of carbamazepine. About 10% of patients experience transient leukopenia, but unless infection develops, carbamazepine may be continued. More serious hematopoietic reactions, including aplastic anemia and agranulocytosis, are rare.

### Other Drug Treatments

Since carbamazepine and valproate are efficacious for acute mania, new antiepileptic medications are often tested for mania. Lamotrigine, which appears useful in maintenance, bipolar depression and rapid-cycling (see below), has not shown efficacy in acute mania, with the exception of one recent double-blind trial (Berk, 1999; Anand *et al.*, 1999; Bowden *et al.*, 2000).

### Nonpharmacotherapy:

#### Electroconvulsive Therapy

The specifics about electroconvulsive therapy (ECT), safety data and precautions concerning administration are covered in Chapter 74. When an acutely manic patient is unresponsive to or intolerant of

**Table 78.6 Adverse Effects of Carbamazepine**

SIADH, Syndrome of inappropriate secretion of antidiuretic hormone.

medication, or if medication presents other risks (e.g., during pregnancy), ECT should be seriously considered and may be lifesaving. Although there are no coherent theories about why ECT is effective in acute mania, it has been used for more than half a century, and there are widespread clinical impressions of its safety and efficacy.

### Acute Bipolar Depression

#### General Management Considerations

Bipolar depression is usually indistinguishable from other forms of major depression, except that the episodes are typically shorter and more frequent. Other clues that the disorder may be bipolar include onset at a young age, a positive family history for bipolar disorder (particularly in first-degree relatives), and the occurrence of a hypomanic phase before the onset of the depressive episode.

For the most part, the treatment of a bipolar patient during an acute episode of depression is similar to that of a nonbipolar

**Table 78.7** Treatments for Acute Depression

Treatment	Advantages	Disadvantages
Antidepressants	Efficacious	Possibly trigger switch into mania
Lamotrigine	Efficacious, possibly no switch into mania	Risk of side effects
Mood stabilizers	Enhance effectiveness of antidepressants, possibly protect against switch into mania	Not specifically antidepressant
ECT	Efficacious, safe for patients unable to take medication	More difficult to administer, possible cognitive side effects

patient. The same concerns about protecting the patient from suicide and maintaining physical health and safety apply, and for the most part, the same antidepressants or ECT will be useful (Table 78.7). These antidepressants are covered in Chapter 79. Because of fears about speeding up cycling and/or precipitating mania in patients with bipolar disorder, most doctors avoid prescribing tricyclics in bipolar depression. The short section that follows addresses issues unique to treatment of bipolar depression.

### Pharmacotherapy

There is a widespread clinical impression that administering some antidepressants to bipolar patients can trigger switches into mania. Some experts also believe that antidepressants speed up mood cycles, although this point is more controversial. Because of both concerns, psychiatrists are often cautious about prescribing an antidepressant at the first sign of depression in a bipolar patient. If symptoms are mild and short-lived, many clinicians choose watchful waiting, while maintaining close contact to detect clinical deterioration.

Current guidelines by the American Psychiatric Association list lithium, as well as the anticonvulsant lamotrigine, as first-line monotherapy for acute bipolar depression (Hirschfeld *et al.*, 2002). This is a result of recent research that suggests that lamotrigine may be an effective treatment for bipolar depression, while carrying a low risk of triggering a switch into mania.

Lamotrigine is completely absorbed after oral administration, with a bioavailability of 98%, which is not affected by food. Peak plasma concentrations occur between 1.4 and 4.8 hours after administration. Lamotrigine is approximately 55% protein bound, making clinical interactions with other protein-bound drugs unlikely. Its half-life is 14 to 49 hours, with steady-state levels reached in 3 to 10 days.

Lamotrigine is metabolized predominately by glucuronic acid conjugation in the liver, with the conjugate and the remaining 10% of the unmetabolized drug excreted in the urine. Clearance is markedly increased with the administration of other drugs that induce hepatic enzymes, including phenytoin, carbamazepine and phenobarbital (Table 78.8). Adding lamotrigine to carbamazepine

**Table 78.8** Effects of Combining Lamotrigine with Other Anticonvulsants

Carbamazepine decreases levels 40%
Oxcarbazepine decreases levels 30%
Phenobarbital decreases levels 40%
Phenytoin decreases levels 50%
Valproate increases levels 100%

can decrease steady-state concentrations of lamotrigine by approximately 40%. Adding lamotrigine to valproate, however, can decrease steady-state levels of valproate by approximately 25%, while the steady-state levels of lamotrigine increases approximately twofold. In this case, the starting dose of lamotrigine should be lowered, and the titration made slowly.

The only contraindication to lamotrigine use is hypersensitivity to the drug, though there is a box warning about dermatologic events, particularly rashes. These rashes, that occurred in approximately 10% of patients, generally occur after 2 to 8 weeks and are usually macular, papular, or erythematous in nature. Of those who develop a rash, one in 1000 adults can precede to a Stevens–Johnson type syndrome. Because it is impossible to distinguish which rashes will develop into this serious condition, it is advised to discontinue the medication at any sign of drug-induced rash. Otherwise the most frequently encountered side effects include dizziness, ataxia, somnolence, headache, blurred vision, nausea, vomiting and diplopia.

To reduce the risk of rash and other side effects lamotrigine should be started at low doses and titrated slowly, especially if combined with valproate therapy. Patients are commonly started on 25 to 50 mg p.o.q.d. doses for 2 weeks, with doses increased by 25 to 50 mg every 1 to 2 weeks until maintenance levels between 100 to 250 mg/day are reached. Maximum doses are lower with valproate at about 100 to 150 mg/day. Initial labs for those undergoing lamotrigine therapy should include liver function tests, renal function tests, a pregnancy test if applicable and a complete medical work-up.

Probably all available antidepressant drugs are effective in alleviating the symptoms of depression in a bipolar patient, and in fact a recent 1-year retrospective chart review by Altshuler and colleagues (2001) suggests that antidepressant discontinuation may increase the risk of depressive relapse in bipolar patients.

When a patient is known to have bipolar disorder, administration of an antidepressant to reverse an acute depression is almost always used together with one of the mood-stabilizing agents, usually lithium, valproate, carbamazepine (or a combination), or possibly one of the newer putative agents. Most bipolar patients will be taking these drugs in maintenance therapy. Moreover, mood stabilizers may enhance the effectiveness of the antidepressant and might protect against the possibility of a switch into mania.

The adverse effects, pharmacology and interactions of antidepressants are covered in Chapter 79.

### Nonpharmacotherapy: Electroconvulsive Therapy

ECT is a useful alternative to antidepressants, particularly when a patient appears not to be responding quickly or is intolerant of the medication. Early studies that claimed that ECT works faster than medication in depressed patients are now considered to be

methodologically flawed. However, two later studies found a more rapid decrease in depressive symptoms with ECT than is usually observed with medications. In a total of 72 patients with major depression, approximately six ECT treatments administered in a period of about 2 weeks led to a decrease in mean Hamilton Depression Rating Scale scores from between 24 and 30 to below 10 (Abrams *et al.*, 1991; Pettinati, 1994). The authors attributed the efficacy of treatment to the use of high suprathreshold dosages. Sackeim and colleagues (1993) found that higher dosage results in more rapid improvement in both bipolar and unipolar depressed patients. There are indications that bilateral electrode placement is superior to unilateral placement (Abrams *et al.*, 1991; Sackeim *et al.*, 1993), but there may be an increased risk of severe cognitive side effects with bilateral ECT at ultrahigh dosages.

### Mixed States

The coexistence of manic and depressive symptoms, the so-called mixed state, is associated with poorer treatment response and prognosis than acute mania or depression (Himmelhoch *et al.*, 1976; Keller *et al.*, 1986; Dilsaver *et al.*, 1993). The optimal treatment of the mixed state has not been rigorously studied, so these recommendations must be considered tentative (Table 78.9).

### Maintenance Therapy

#### General Management Considerations

As in all psychiatric disorders, maintenance therapy of bipolar disorder is a treatment carried out for a long period, with a goal of decreasing the probability, frequency, or severity of future

**Table 78.9** Treatments for Mixed Episodes

General	Lithium, valproate, carbamazepine, lamotrigine (alone or in combination)
For severe excitement or psychosis	Antipsychotics
For depressive symptoms	Antidepressants, lamotrigine
Alternative to medication	ECT

episodes. Because bipolar disorder is by its nature a recurrent condition, some would argue that as soon as it is definitively diagnosed (e.g., after a single manic episode not attributable to a medical or neurological cause), maintenance therapy is indicated (Table 78.10). More conservative psychiatrists advocate waiting until the frequency and severity of a patient's disorder become apparent, hoping to avoid long-term exposure to medication that may not be required. The counter to this concern is evidence suggesting that recurrent episodes in themselves may worsen treatment response and long-term outcome (Gelenberg *et al.*, 1989).

#### Rapid Cycling

Patients with rapid-cycling bipolar disorder – defined as four or more affective episodes in 1 year, with or without an intervening period of euthymia – tend to be less responsive to lithium treatment (Dunner and Fieve, 1974). Whether rapid cycling is a natural progression of the illness or a separate disorder has yet to be determined. The onset of rapid cycling has been associated with

**Table 78.10** Advantages and Disadvantages of Specific Maintenance Treatments

Treatment	Advantages	Disadvantages
Lithium	Most robust data set and clearly very effective for prevention of mania Specific anti-suicide effect	Side effects, low therapeutic index Lethality on overdose Risk of renal damage
Valproate	Possibly comparable to lithium May be more effective for patients with rapid cycling, mixed episodes and comorbidity	Weight gain and other side effects Teratogenicity, for female patients in reproductive years
Olanzapine	Possibly comparable to lithium for prevention of mania	Weight gain and metabolic risks Tardive dyskinesia risk
Lamotrigine	Probably more effective than other mood stabilizers for depression Generally better tolerated than other mood stabilizers	Probably somewhat less effective for prevention of mania
Carbamazepine	Profile comparable to valproate Less risk of weight gain	More maintenance data needed
Typical antipsychotics	Likely good for prophylaxis of mania	May worsen depression High risk of tardive dyskinesia
Antidepressants	May prevent recurrence of depression	May precipitate mania and provoke rapid cycling
ECT	Accutely effective for both mania and depression	Not adequately studied Maintenance of acute response may be poor
Psychotherapy	As adjunct, increases medication compliance, overall functioning	Not efficacious alone

antidepressant drugs (especially tricyclic antidepressants) and hypothyroidism (Wehr and Goodwin, 1987; Roy-Byrne *et al.*, 1984). Some people also experience ultrarapid cycling, switching between moods in a period of days or even hours. Various therapeutic approaches have been investigated for treating patients with rapid-cycling bipolar disorder.

The discovery of antidepressants did more than provide a revolutionary therapy for depression; it changed the way we view mood disorders and, by analogy, the mind itself. It permanently transformed the appraisal of our ability to influence areas of existence previously thought unreachable through physical manipulation. Antidepressants are now used to treat a variety of disorders (see Table 79.1).

### Mechanisms of Actions

All known antidepressants affect monoamine neurotransmission, and this is believed to be their mechanism of action. As imipramine, iproniazid and related antidepressants shared an ability to augment the monoamine norepinephrine, the early neurochemical theories of depression focused on this neurotransmitter. Later, newer agents were introduced that seemed to exert their primary effect on another monoamine, serotonin. Research into these two neurotransmitters evolved into the monoamine hypothesis of depression. The monoamine theory of depression suggests, in its simplest form, that depression relates to abnormal levels of monoamines: neurotransmitters thought important in the regulation of mood. Antidepressants themselves provide the strongest evidence supporting the role of monoamines in mood, as all known antidepressants affect the levels of monoamines in the brain. Other evidence for the monoamine hypothesis included the observation that reserpine (which depletes norepinephrine and serotonin) frequently causes depression.

The relationship between neurotransmitter activity and the mechanism of antidepressant action is depicted in Figure 79.1.

### Antidepressants: Taxonomy and Relation to Mechanism of Action

There are several ways in which antidepressants are grouped. One is historically, in which antidepressants are roughly divided by the period in which they were introduced (e.g., such terms as “first-generation” antidepressants). Another is by chemical structure (e.g., “tricyclic antidepressants”). Alternatively, they are classified by their presumed mechanism of action (“selective serotonin reuptake inhibitors”). In practice, a combination of these is used: thus, some TCAs, which primarily act through serotonin reuptake inhibition (e.g., clomipramine), are usually included with other TCAs rather than as a serotonin reuptake inhibitor, even though they could rightly claim membership in either category.

#### First-generation Antidepressants

These are, historically, the first antidepressants, and were discovered primarily through serendipity. They include the monoamine antidepressants and the TCAs.

#### Monoamine Antidepressants (MAOIs)

Historically, these are the first antidepressants discovered. However, owing largely to their side effects, and dietary restrictions, they have rarely enjoyed popular use. They are all characterized by their unique mechanism: they inhibit the action of monoamine oxidase (MAO), the primary catabolic enzyme for the monoamines. The end result is an overall increase in available monoamines.

#### Tricyclic Antidepressants (TCAs)

These medications all have a structural similarity in common. They are subdivided by the number of amine groups they possess, and are usually referred to as either “tertiary” or “secondary” TCAs. Several are related by metabolism, thus the tertiary amines – amitriptyline and imipramine – are metabolized to the secondary amines – nortriptyline and desipramine – respectively. They all act through reuptake inhibition, and are generally selective for the norepinephrine transporter; several, however, have equal or greater affinity for the serotonin transporter. Normally, excess monoamine is taken up through monoamine transporters into the neuron, where it can be stored, or, more often, catabolized by intracellular MAO. Reuptake inhibitors prevent this through inhibition of the transporter; the excess neurotransmitter remains in the synaptic space where it can bind with receptors. That this is the mechanism of action of these and many other antidepressants is reinforced by the fact that correlations have been demonstrated between transporter inhibition and clinical improvement in depressive symptoms (Hrdina *et al.*, 1997). The TCAs were the drugs of choice for depression through the 1980s. Though very effective, their somewhat nonselective actions, acting on cholinergic, presynaptic adrenergic receptors, for example, resulted in a number of side effects.

#### Second-generation Antidepressants

These medications were developed using knowledge gained from the first-generation antidepressants. An effort was made to produce medications that were more selective for certain actions. The primary benefit of such selectivity was a decrease in unintended side effects.

#### Selective Serotonin Receptor Inhibitors (SSRIs)

The SSRIs were first introduced in the late 1980s, and within a few years eclipsed the TCAs as the drugs of choice for depression. As the name suggests, they all act through inhibition of the serotonin transporter. Though very similar, they have some subtle differences, mainly in terms of their half-life, their potency for reuptake inhibition, and their affinity for some other receptors.

**Table 79.1** Various uses of Antidepressants

Major depression
Acute depression
Prevention of relapse
Other depressive syndromes
Bipolar depression
Atypical depression
Dysthymia
Other uses
<b>Tricyclic Antidepressants</b>
Strong evidence
Panic disorder (most)
Obsessive-compulsive disorder (clomipramine)
Bulimia nervosa (imipramine, desipramine)
Enuresis (imipramine)
Moderate evidence
Separation anxiety
Attention-deficit/hyperactivity disorder
Phobias
Generalized anxiety disorder
Anorexia nervosa
Body dysmorphic disorder
Migraine (amitriptyline)
Other headaches
Diabetic neuropathy, other pain syndromes (amitriptyline, doxepin)
Sleep apnea (protriptyline)
Cocaine abuse (desipramine)
Tinnitus
Evidence for but rarely used for these disorders
Peptic ulcer disease
Arrhythmias
<b>Monoamine Oxidase Inhibitors</b>
Strong evidence
Panic disorder
Bulimia
Moderate evidence
Other anxiety disorders
Anorexia nervosa
Body dysmorphic disorder
<b>Atypical Agents</b>
Trazodone
Insomnia
Dementia with agitation
Minor sedative-hypnotic withdrawal
Bupropion
Attention-deficit/hyperactivity disorder
<b>Serotonin Reuptake Inhibitors</b>
Strong evidence
Obsessive-compulsive disorder (high-dose fluoxetine, sertraline)
Bulimia (fluoxetine)
Panic disorder
Moderate evidence
Generalized anxiety disorder

Obesity (high-dose fluoxetine)
Substance abuse
Impulsivity, anger associated with personality disorders
Pain syndromes, including diabetic neuropathy
Preliminary evidence
Obsessive jealousy
Body dysmorphic disorder
Hypochondriasis
Behavioral abnormalities associated with autism and mental retardation
Anger attack associated with depression
Depersonalization disorder
Social phobia
Attention-deficit/hyperactivity disorder (as an adjunct)
Chronic enuresis
Paraphilic sexual disorders
Nonparaphilic sexual disorders
<b>Selective Serotonin Noradrenaline Reuptake Inhibitors</b>
Duloxetine
Moderate evidence
Diabetic peripheral neuropathic pain
Venlafaxine
Moderate evidence
Generalized anxiety disorder
Social phobia
Panic disorder

These medications are not only the most popular antidepressants, but also some of the most popular drugs of any type. The US sales data demonstrate that the SSRIs remain one of the most lucrative of drugs. In 2001, for example, the producer of sertraline reported global sales of over \$2 billion from the product.

### Selective Norepinephrine Reuptake Inhibitors (NRIs)

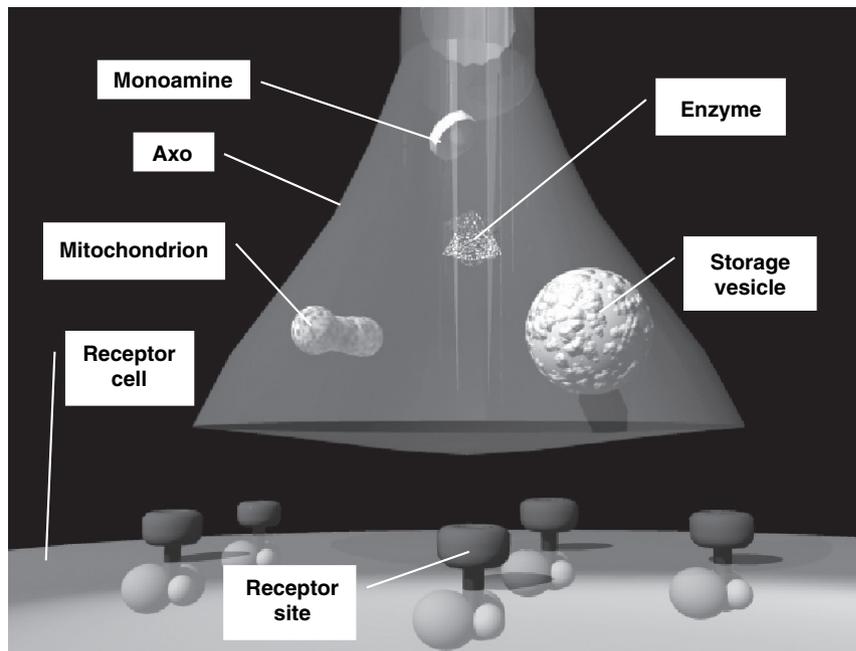

Like the SSRIs, medications in this class share a similar mechanism with the SSRIs, but act on the norepinephrine transporter and have little affinity for the serotonin transporter. Reboxetine (currently available in Europe, and expected to be available soon in the USA) is an example of such a medication.

### Other Second-generation Agents

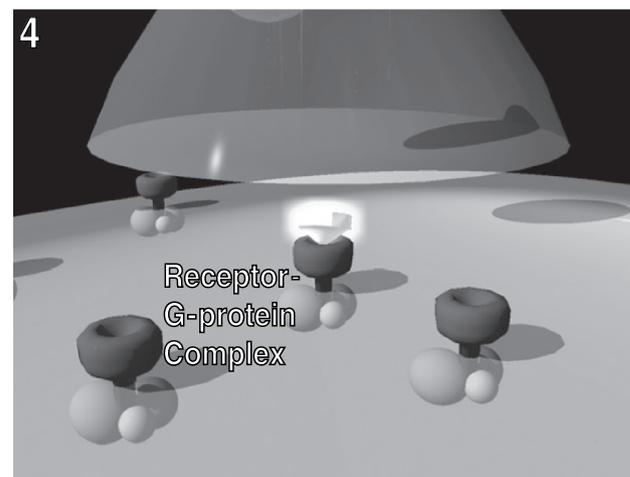

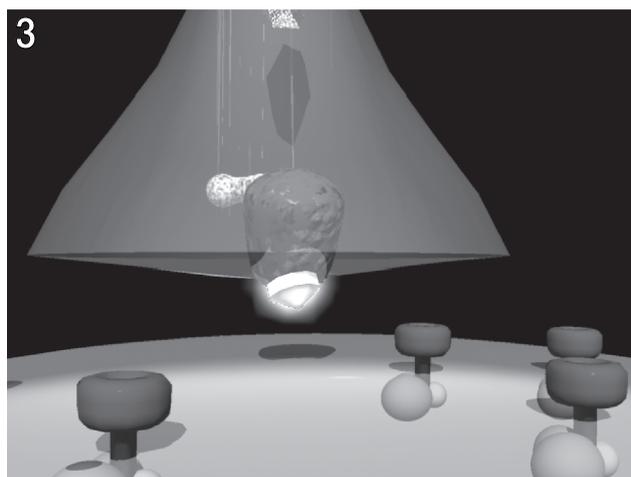

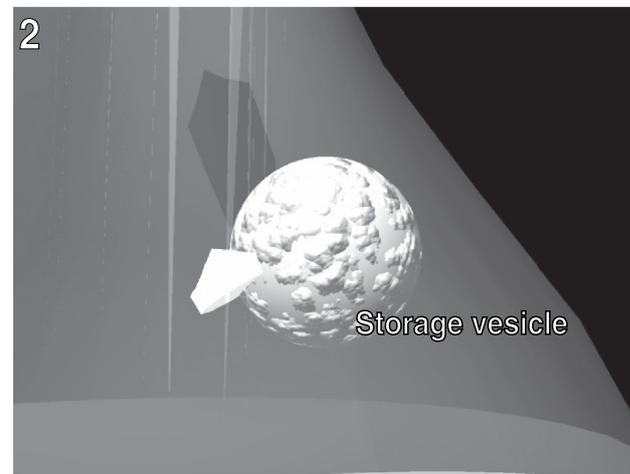

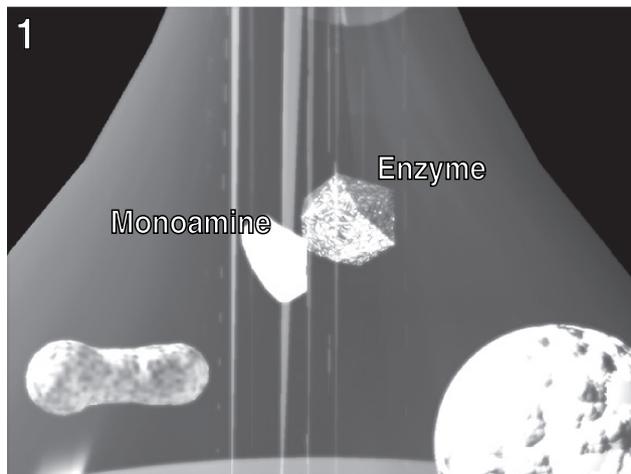

Sometimes referred to as “atypical antidepressants” several were introduced during the same period as the SSRIs. These include bupropion, which seems to exert primarily a dopaminergic effect, and trazodone, which was structurally related to the TCAs but has a primary serotonergic mechanism. Nomifensine, which is not commercially available after international reports of severe hemolytic anemias were reported, would be in a class similar to bupropion.

### Third-generation Antidepressant

The next generation of antidepressants involved various attempts to expand the potential of second-generation compounds. One

B

*continues*

C

**Figure 80.1 (A) and (B)** The “life-cycle” of a monoamine neurotransmitter and potential sites for pharmacological intervention.

This presents a schematic of monoamine activity. An overview of the neuronal axon–receptor relationship is shown in the overview 1(A), with several key structures pointed out, including the axon and receptor cell, whose membranes are rendered here as transparent to illustrate key intracellular components.

The monoamines – norepinephrine, serotonin, and dopamine – are synthesized within the neuron (1); from dietary amino acids, and then stored within vesicles (2). This vesicle can then bind with the axonal membrane, releasing its contents into the synapse (3).

Upon binding to a receptor complex (4); a resultant cascade of reactions is possible. In general, the binding process causes a destabilization of the subunits comprising the receptor–G-protein complex (5). G-protein, now activated, can then regulate a number of second-messenger systems, such as adenylate cyclase and phospholipase C. The potential results can involve alterations at various levels of neuronal function: from physical structure and membrane permeability to direct regulation of genetic transcription. In this way, it is possible for the many brief and simultaneous inputs to be transduced into coherent and lasting influences on neuronal function. Neurotransmitters can even regulate their own production through binding to presynaptic autoreceptors.

Once the reaction is complete, the receptor–G-protein complex restabilizes, and the monoamine is released from the receptor site. The neurotransmitter can then be metabolized in the extracellular space or, more commonly, taken back in the axon through a transporter site (6). Monoamines undergoing such reuptake can be again stored within vesicles, or be deaminated by intracellular monoamine oxidase (MAO) residing on the wall of mitochondria (7).

Virtually all of these steps can be influenced pharmacologically. For example, enzymatic synthesis can be inhibited by such agents as alpha-methyltyrosine which inhibits tyrosine hydroxylase (1). Reserpine and tetrabenazine can inhibit uptake into the storage vesicles (2), and amphetamines increase the release of norepinephrine from synaptic vesicles (3). A number of drugs can inhibit receptor sites, such as phentolamine and phenoxybenzamine which act at alpha-receptors (4), and most antipsychotics medication, which block dopamine. The lithium ion may act directly on G-protein and second-messenger systems (5).

Most antidepressants appear to act either by inhibiting MAO (e.g., the monoamine oxidase inhibitors [MAOIs] which can inhibit step (7), or by preventing the reuptake on one, or more, monoamines – the TCAs and SSRIs, venlafaxine and bupropion (6). Several of the newer generation antidepressants may have a direct effect on the receptor site (4).

important feature of this group is that many of them have multiple actions. In some cases, this involves actions on multiple neurotransmitters. In other cases, it involves multiple mechanisms of action. Though, in a way this may seem a return to the broader acting first-generation compounds, the attempt with these drugs is to maximize the presumed “clinically relevant” effects of the drugs, while minimizing the less important (and potentially adverse) actions.

### Serotonin–Norepinephrine Reuptake Inhibitors (SNRIs)

Medications in this class share a common mechanism with the SSRIs, but differ in that they have equal affinity for the norepinephrine and serotonin transporter. Currently, the only medications of this type available in the USA are venlafaxine and duloxetine. Other medications (available in other countries), such as milnacipran, have similar mechanisms of action. Though, like several of the TCAs, venlafaxine has multiple receptor effects, it is relatively free of the anticholinergic and antihistaminic side effects that are common with the TCAs.

### Mixed Serotonin Antagonist/Reuptake Inhibitors

These agents have multiple mechanisms of action, all of which appear to be of clinical importance. Nefazodone is an example of such an agent, with both serotonin (as well as norepinephrine) transporter inhibition as well as antagonism of 5-HT<sub>2A</sub> and alpha<sub>1</sub>-receptors. Trazodone may be similar; however, its effects are somewhat less specific, and as a result, it resembles the TCAs in some respects.

### Mixed Serotonin/Noradrenaline Antagonists

Currently, the only agent in this class is mirtazapine. This agent is unique in that it appears to work primarily through receptor blockade, specifically through blockade of the alpha<sub>2</sub>-autoreceptors on presynaptic noradrenergic neurons, which enhances noradrenergic output. They may exert a similar effect toward autoreceptors on serotonin neurons. Antagonism of 5-HT<sub>2</sub> and 5-HT<sub>3</sub> receptors may also concentrate the effect of serotonin on 5-HT<sub>1A</sub> receptors.

Most studies comparing antidepressants have not found significant differences in efficacy between agents. In general, studies comparing TCAs and SSRIs have shown equal efficacy, and meta-analyses of these studies have generally confirmed these findings (Anderson, 2000; Workman and Short, 1993). However, there have been some trends in this data, with TCAs showing, perhaps, greater efficacy in patients with severe depression (Perry, 1996).

Meta-analyses lend some support to the contention that drugs with multiple actions have a greater efficacy than those that are more highly selective. There is some suggestion that the antidepressants that are selective for norepinephrine and serotonin may be more effective than the SSRIs alone. Though these meta-analyses are compelling, the fact that improved efficacy has yet to be demonstrated by the “gold standard” of a placebo-controlled study likely explains why the third generation of antidepressants does not yet enjoy a reputation for improved efficacy. And, even if some of the newer drugs do show improved efficacy, the proposed reason for this – multiplicity of action – may not be correct. In fact, at least one meta-analysis investigating this hypothesis, in which multiple action drugs were compared with selective drugs, did not find a difference between the two (Freemantle *et al.*, 2000). As such, our treatment recommendations, as outlined in the summary, make the assumption that the efficacy of antidepressants is approximately equal for all agents.

## The Formulation of Treatment

### Indications

All antidepressants are indicated for the treatment of acute major depressive episodes. Beyond the acute period, there is also evidence for the use of antidepressants in the prevention of relapse and recurrence.

There are a number of more minor forms of depression, many of which may also respond to antidepressant medication. Best studied of these is dysthymic disorder. Previously thought to be unresponsive to somatic therapy, a growing literature attests to the responsiveness of this chronic, minor depressive disorder to a variety of medications, including TCAs (Kocsis *et al.*, 1985; Stewart *et al.*, 1993) and serotonin reuptake inhibitors (Hellerstein *et al.*, 1993; Thase *et al.*, 1996; Ravindran *et al.*, 1994; Vanelle, 1997). As with major depression, there is no definitive data to suggest that any one agent is more efficacious than the other. The bulk of data suggests, instead, that any available agent used for major depression is likely to be effective for these other disorders.

Other minor depressive disorders include minor depression and recurrent brief depression. Though rigorous data is largely lacking in the treatment of these disorders, they seem to show an at least modest response to antidepressant medications.

### Other Uses for Antidepressants

Although the bulk of this chapter will describe the use of antidepressants in the treatment of major depression, they are also used to treat a number of other conditions (Orsulak and Waller, 1989; Brotman, 1993). Some uses have gained general acceptance while other uses rely on moderate or preliminary evidence. A summary of various indications is presented in Table 79.2.

### Selection of an Antidepressant

The decision whether to treat depressive symptoms with pharmacotherapy requires an assessment of both the need for intervention and the likelihood that treatment will be successful. Assessing the need for intervention involves longitudinal and cross-sectional factors. Assessing the likelihood that treatment will be successful is somewhat more difficult, but may rely on clinical, demographical and biological factors.

### Assessing the Need for Intervention

This involves assessing the likely result if pharmacological treatment is not given. It is essential in making a useful risk–benefit assessment.

**Longitudinal Factors** The physician should consider the course and duration of previous episodes of depression. Such episodes can predict the potential severity of the current episode, the likely time to recovery, and the probability of a subsequent recurrence. The physician should also consider the likely complications of depression for the individual patient, which may include substance abuse and suicide.

**Cross-sectional Factors** The physician should consider the severity of symptoms and the degree of functional impairment. Suicidal ideation is of particular concern and needs rapid and intensive treatment. Such treatment often includes hospitalization. Even with less pressing symptoms, but significant occupational or social impairment, the risk–benefit ratio generally still favors a trial of antidepressants, particularly now that safer and more easily tolerated agents are available.

**Table 79.2 SSRI, SNRI and TCA Side Effects**

Side Effects of Serotonin Blockade
Jitteriness, activation Insomnia Anorexia, weight loss Nausea, vomiting, diarrhea Sexual dysfunction Extrapyramidal-like side effects Increase in suicidal ideas
Signs And Symptoms of Central Serotonergic Syndrome
Confusion, disorientation Headache Autonomic instability Lethargy Restlessness Abdominal cramps, diarrhea Tremor, myoclonic jerks
Side Effects of Norepinephrine Blockade
Tremors Jitteriness Tachycardia Diaphoresis Augmentation of pressor effects of sympathomimetics Sexual dysfunction
Anticholinergic Side Effects
Dry mouth Constipation (rarely – paralytic ileus) Urinary hesitancy (rarely – dystonic bladder) Blurred vision Sinus tachycardia Memory impairment Worsening of narrow-angle glaucoma
Anticholinergic Delirium
“Mad as a hatter”: confusion, disorientation, visual hallucinations “Hot as a hare”: hyperpyrexia “Blind as a bat”: loss of visual accommodation “Red as a beet”: peripheral vasodilatation “Dry as a bone”: drying of mucous membranes

**Selection of a Particular Agent** Although, as noted earlier, the various antidepressants seem to have equal efficacy in the treatment of depression, a given patient may respond preferentially to one, or a class of agents. Again, cross-sectional and longitudinal factors should be taken into account.

### Pharmacokinetic Concerns

**First-generation Antidepressants** The pharmacokinetics of TCAs is complex. This complexity is reflected in the diversity of half-lives reported, which vary roughly from 10 to 40 hours. TCAs are primarily absorbed in the small intestine. They are usually well absorbed, and reach peak plasma levels 2 to 6 hours

after oral administration. Absorption can be affected by changes in gut motility. The drugs are extensively metabolized in the liver on first pass through the portal system. They are lipophilic, have a large volume of distribution and are highly protein-bound (85–95%). TCAs are metabolized in the liver by hepatic microsomal enzymes, by demethylation, oxidation, or hydroxylation. They are generally metabolized to active metabolites, and are excreted by the kidneys. There is a large range of elimination half-lives among the antidepressants.

MAOIs are also well absorbed from the gastrointestinal tract. Their metabolism, although quite efficient (they have a half-life of 1 to 2 hours), is not well understood. The short half-life of these compounds is not entirely relevant however, as they bind irreversibly with MAO. Thus, the activity of these drugs depends less on pharmacokinetics, and more on the synthesis of new MAO to restore normal enzyme activity. This synthesis requires approximately 2 weeks.

**Second-generation Antidepressants** All of the available serotonin reuptake inhibitors are well absorbed, and not generally affected by food administration. Sertraline is an exception to this rule, and its blood level may be increased by food. All serotonin reuptake inhibitors have large volumes of distribution and they are extensively protein-bound. They are metabolized by hepatic microsomal enzymes and are potent inhibitors of these enzymes (a fact which will be discussed later in greater detail).

The only serotonin reuptake inhibitor with an active metabolite is fluoxetine, whose metabolite norfluoxetine has a half-life of 7 to 15 days. Thus, it may take several months to achieve steady state with fluoxetine. This is considerably longer than citalopram, which has a half-life of about 1.5 days, or sertraline and paroxetine, which have half-lives of about a day.

As previously discussed, there is no correlation between half-life and time to onset. Drugs with shorter half-lives have an advantage in cases where rapid elimination is desired (for example, in the case of an allergic reaction). Drugs with a longer half-life may also have advantages: fluoxetine, for example, has been successfully given in a once-weekly dosing during the continuation phase of treatment (Burke *et al.*, 2000), and a once-weekly formulation of this drug is currently available. All serotonin reuptake inhibitors are eliminated in the urine as inactive metabolites. Both fluoxetine and paroxetine are capable of inhibiting their own clearance at clinically relevant doses. As such, they have nonlinear pharmacokinetics: changes in dose can produce proportionately large plasma levels.

As with most of the other antidepressants, bupropion undergoes extensive first pass metabolism in the liver. Although the parent compound has a half-life of 10 to 12 hours, it has three metabolites that appear to be active. One, threohydrobupropion, has a half-life of 35 hours and is relatively free in plasma (it is only 50% protein-bound). There is considerable individual variability in the levels of bupropion and its metabolites. Trazodone has a half-life that is relatively short, having a range of 3 to 9 hours. Given this, and its apparent lack of active metabolites, the plasma levels of trazodone can be quite variable during a day. For this reason, the medication requires divided dosing.

**Third-generation Antidepressants** Venlafaxine has a short half-life (4 hours); however, it is available in an extended release formulation that allows once-daily dosing. It appears to have a dual effect, in which at lower doses it primarily acts on the serotonin transporter, and clinically significant norepinephrine reuptake inhibition is not seen until higher doses are used (150 mg/day and above).

**Table 79.3** Suggested Diet for Patients Taking Monoamine Oxidase Inhibitors (MAOIs)

Proposed Restrictions	Analysis	Can Use
Most cheese and cheese products Sour cream, yogurt	M: accounts for most tyramine reactions P: except in excess if stored too long	Cream, cottage, or ricotta cheese
Fermented meats (sausage, salami, pepperoni)	M: dry fermented sausage (summer sausage) has the most tyramine	Hard sausage has not been associated with hypertensive crises
Aged meats	M: many reports of crises for meats stored for only 2–3 d	Fresh meats
Liver	M: chicken liver has significant tyramine; avoid pate and other prepared dishes	Fresh beef liver
Smoked or pickled herring, caviar	M: high tyramine content	Fresh fish
Broad bean pods (Italian green beans, fava beans)	M: high levodopa content	Other fresh vegetables
Avocado	P: avoid if overripe; no reported reactions	
Sauerkraut	M	
Bananas	P: especially if overripe; peel has highest tyramine (eaten in the only reported case)	Other fresh fruits
Raisins, figs	I: based on one case report	
Chocolate	I: few reported cases	
Yeast extract (brewer's yeast, "Marmite", some packaged soups)	M	Yeast breads
Soy sauce	P: few case reports may be Chinese restaurant syndrome	
Meat tenderizers	I	
Chianti wine	M: most valid of alcohol restrictions	Other wines (moderate amounts)
Vermouth	M: may be similar to Chianti in tyramine	
Beers and ales	P: small amounts allowed; one ration to Irish whiskey	Other alcoholic drinks (moderate amounts)
Other beverages: coffee, tea, caffeinated sodas	I: a nonspecific recommendation (no reports link caffeine to reactions)	

M, must be avoided; P, probably acceptable in moderate amounts; I, insufficient evidence to justify any restriction.

Nefazodone has relatively low bioavailability, and a short half-life (2–8 hours), and thus it is usually given in twice-daily doses. Mirtazapine has a half-life of 13 to 34 hours.

## Preparation of the Patient

### Side Effects of Antidepressants

#### General Concerns

Good preparation and reassurance are essential. Side effects – even relatively benign ones – are a major cause of treatment non-adherence. Drop-out rates ranging from 7 to 44% have been reported in various studies of TCAs, and from 7 to 23% in studies of serotonin reuptake inhibitors (Cookson, 1993). Proper education and reassurance about side effects can help reduce this rate. It should help reassure the patient that many of the side effects diminish with time, or with an adjustment of dose. It may also help frame side effects in a positive light, as they represent concrete evidence that the medication is exerting its effect on the body.

The best approach may be to consider both frequency and clinical importance. That is, one should discuss those side effects that are likely to occur, as well as considering the rare but potential dangerous or irreversible side effects that should be discussed (Table 79.3 and Table 79.4).

#### Specific Side Effects

It is useful to divide side effects into “predictable” and idiosyncratic effects. Predictable side effects result from known pharmacological actions of the drug. Idiosyncratic side effects are not well understood. A number of authors have written important, and very complete reviews of medication-related side effects (e.g., Cookson, 1993; Nierenberg, 1992; Mir and Taylor, 1997; Richelson, 2001); what is intended in the following paragraphs and figures is a brief summary that incorporates data from those works.

#### Predictable Side Effects

These side effects are the result of the action of the agent at various neurotransmitters and enzyme sites. The major neurotransmitters affected by antidepressants are as follows.

Table 79.4 Antidepressant Drug Interactions

### Muscarinic Acetylcholine Receptors

Blockade of this receptor produces a variety of peripheral and central effects. Gastrointestinal effects include decreased salivation and decreased peristalsis. Decreased salivation is the most common of these effects and can cause drying of the mucous membranes. Such drying can exacerbate gum disease and dental caries. Decreased peristalsis can cause constipation and, in the extreme, paralytic ileus. Contraction of the bladder wall is inhibited, causing urinary hesitancy and even urinary retention. In the case of TCAs, concomitant sympathomimetic effects that cause constriction of the bladder neck and urethra worsen this effect on urination. Inhibition of the parasympathetically mediated

accommodation reflex, in which the ciliary body muscles normally contract to thicken the lens and focus near objects on the retina, results in blurry vision and mydriasis. Such accommodation paresis can occur without other anticholinergic side effects. A more serious ocular effect is the precipitation of acute narrow-angle glaucoma, through pupillary dilatation. The iatrogenic precipitation of narrow-angle glaucoma through antidepressant use is quite rare. Anticholinergic cardiac effects include decreased vagal tone that can cause tachycardia. Central nervous effects include impaired memory and cognition. In severe cases, such cognitive impairment can reach the point of a delirium. Central anticholinergic effects can also worsen existing tardive dyskinesia.

These effects are usually dose-related, and are worse in people with preexisting defects. For example, the cardiac effects are of most concern in those with preexisting cardiac defects, and urinary blockade generally occurs only in the presence of prostatic hypertrophy. These side effects are also more common in patients taking other anticholinergic medications, which is a common feature of many over-the-counter preparations.

MAOIs have little direct effect on receptors, and their side effects relate to enzymatic inhibition, thus they are not included in this section.

## Histamine

Blockade of the histamine  $H_1$ -receptor is typically associated with sedation. Histamine blockade may also cause orthostatic hypotension and weight gain. It can impair psychomotor coordination and cause falls in the elderly. Cognitive impairment can occur as well.  $H_2$ -receptor blockade causes decreased gastric acid production. This is the mechanism of many anti-ulcer medications.

## Norepinephrine

Synaptic increases in norepinephrine, through either inhibition of norepinephrine reuptake or decrease in MAO degradation, cause sympathomimetic effects. Increases in norepinephrine can cause anxiety, tremors, diaphoresis and tachycardia. This tachycardia can potentiate anticholinergic cardiac effects. As noted, sympathomimetic effects on the bladder neck and urethra can potentiate the anticholinergic inhibition of normal urinary function.

## Receptor Blockade

Blockade of  $\alpha_1$ -receptors occurs as a chronic effect through both downregulation and desensitization of the beta- and  $\alpha_2$ -receptors. Blockade of the noradrenergic  $\alpha_1$ -receptor is responsible for postural hypotension. In the elderly or medically ill, this postural hypotension can be significant, and lead to dizziness or falls. It may also be responsible for ejaculatory delay or impotence. Other potential effects include reflex tachycardia and memory dysfunction.

## Serotonin

Potiation of serotonin can cause anorexia, nausea, vomiting, diarrhea, "jitteriness" and anxiety. Akathisia, a syndrome of motor restlessness usually associated with antipsychotics, may result from either the general effect of serotonin potentiation or the direct effects on the basal ganglia. The latter hypothesis is supported by the fact that the serotonin reuptake inhibitors – fluoxetine (Stein, 1993), sertraline (Shihabuddin and Rapport, 1994) and paroxetine (Choo, 1993) – have all been reported to cause or exacerbate extrapyramidal reactions. Sedation, which has been reported with all serotonin reuptake inhibitors, appears to be a primary serotonin effect (Cookson, 1993). Insomnia, however, is more

common at higher doses, particularly with fluoxetine. A number of sexual side effects have been attributed to serotonin reuptake blockade, including anorgasmia, ejaculatory difficulties and even spontaneous orgasms associated with yawning (Modell, 1989).

## Receptor Antagonism

Blockade of the 5-HT<sub>2</sub>-receptors may result in hypotension and ejaculatory disturbances. Antagonism of serotonin receptors may also be responsible for weight gain and carbohydrate craving.

## Dopamine

Increases in dopamine resulting from reuptake blockade can have an antiparkinsonian effect. It can also cause psychomotor activation and aggravation of psychosis.

## Receptor Antagonism

The blockade of dopamine receptors can result in extrapyramidal symptoms. These symptoms include cogwheel-type rigidity, tremor, dyskinesia, masked facies and acute dystonia. Prolonged dopamine blockade appears to be responsible for tardive dyskinesia. Dopamine receptor blockade has also been associated with endocrine changes and sexual dysfunction.

## Monoamine Oxidase

MAO is the main enzyme responsible for the metabolism of monoamines. There are two main types of MAOs, identified as types A and B. Type A is selective for serotonin and norepinephrine, and accounts for 80% of the MAO in the brain. Type B selectively deaminates phenylethylamine. Both forms oxidize dopamine and tyramine.

**Dietary Restrictions** The dietary restrictions required when using MAOIs represent the major limitation to widespread use of these effective antidepressants. Nonselective inhibition of MAO prevents the normal hepatic metabolism of tyramine containing foods or sympathomimetic agents. The increased level of tyramine in the circulation stimulates the release of norepinephrine from sympathetic terminals. This sudden increase in norepinephrine is the basis for the "tyramine–cheese" reaction, so named because cheese is the most common source of the tyramine that causes this reaction. In fact, other pressor amines, such as levodopa, can also cause the reaction, but tyramine – a natural product of food fermentation and bacterial decarboxylation – is the most common in foods. The result of a tyramine–cheese reaction can be a hypertensive crisis. Thus, patients should be well educated as to the foods that must be avoided while using MAOIs. In the past, there has been a tendency towards conservative dietary restrictions, often based on single case reports or indirect analogies. More research and experience have suggested that not all the foods commonly restricted are equally likely to precipitate a reaction (McCabe and Tsuang, 1982). Better compliance is likely if a more reasonable diet is prescribed (as suggested in Table 79.5).

Despite the best of preparation, some patients may err and suffer a hypertensive crisis. This is often experienced as a severe, pulsating, occipital headache that then generalizes. It may be alleviated with 10 mg of nifedipine, either oral or sublingual (Golwyn and Sevlie, 1993).

MAOIs can cause an increase in standing systolic blood pressure, absent of tyramine containing foods or sympathomimetics. Generally, this effect is not clinically significant; however, serious unprovoked hypertensive episodes have been reported

**Table 79.5** Typical Antidepressant Therapeutic Doses and Side Effects

Category And Trade Name	Generic Name	Usual Therapeutic Daily Doses (mg)	Sedative Effects	Hypotensive Effects (Decreased Blood Pressure)	Anticholinergic Effects (Dry Mouth, Constipation)	Cardiac Effects (Slowed Heart Rate)
<b>Tricyclic Antidepressants</b>						
Tertiary amines						
Anafranil	Clomipramine	150–300	High	High	High	Yes
Elavil	Amitriptyline	150–300	High	High	High	Yes
Sinequan, Adapin	Doxepin	150–300	High	Moderate	Moderate	Yes
Surmontil	Trimipramine	150–300	High	Moderate	Moderate	Yes
Tofranil	Imipramine	150–300	Moderate	High	Moderate	Yes
Secondary amines						
Norpramin	Desipramine	150–300	Low	Moderate	Low	Yes
Pamelor	Nortriptyline	50–150	Low	Low	Low	Yes
Vivactil	Protriptyline	30–60	Low	Low	High	Yes
<b>Monamine Oxidase Inhibitors</b>						
Marplan	Isocarboxazid	20–60	Low	Moderate	Low	Low
Nardil	Phenelzine	45–90	Low	Moderate	Low	Low
Parnate	Tranlycypromine	30–60	Low	Moderate	Low	Low
<b>Atypical Agents</b>						
Asendin	Amoxapine	200–300	Moderate	Moderate	Low	Yes
Desyrel	Trazodone	300–600	High	Low	Minimal	Low
Ludomil	Maprotiline	150–200	Moderate	Low	Low	Yes
Wellbutrin	Bupropion	150–450	Minimal	Low	Minimal	Low
<b>Selective Serotonin Reuptake Inhibitors</b>						
Paxil	Paroxetine	20–50	Low	Minimal	Minimal	Low
Prozac	Fluoxetine	20–80	Minimal	Minimal	Minimal	Low
Zoloft	Sertraline	50–200	Minimal	Minimal	Minimal	Low
Luvox	Fluvoxamine	150–300	Low	Low	Low	Low
Celexa	Citalopram	20–50	Low	Minimal	Minimal	Low
Lexapro	Escitalopram	10–20	Low	Minimal	Minimal	Low
<b>Serotonin-norepinephrine Reuptake Inhibitor</b>						
Effexor	Venlafaxine	75–300	Low	None (increased blood pressure)	None (blood pressure)	Minimal
<b>Serotonin Transport Blocker And Antagonist</b>						
Serzone	Nefazodone	200–600	Moderate	Low	Minimal	Low

(Lavin *et al.*, 1993), and blood pressure should be monitored for 1 to 2 hours after beginning or increasing an MAOI. Hypotension is also a reported effect of MAO, but the mechanism is not known. MAO inhibition can also cause sedation or overstimulation. Once again, the mechanism of this is not well understood.

### Membrane Stabilizing Activity

TCA's have effects on cardiac conduction that are independent of anticholinergic or noradrenergic effects. Destabilization of the cardiac membrane can cause dysrhythmia and asystole, particularly in overdose.

### Other Effects

#### Allergic Reactions

Allergic reactions can occur with any of these agents. Effects include dermatological (rashes, urticaria, photosensitivity, Stevens-

Johnson syndrome) and hematological (agranulocytosis) sensitivities. Several case reports have described a photosensitivity reaction apparently caused by desipramine that results in a blue-gray pigmentation (Narurkar *et al.*, 1993; Steele and Ashby, 1993). Fluoxetine has been associated with bleeding, inflammation (Gunzberger and Martinez, 1992), and, most seriously, a fatal systemic vasculitis. It should be stopped if a rash develops.

In most cases of allergic reactions, the primary treatment is to stop the agent. In one report, granulocyte colony stimulating factor was used successfully to treat severe clomipramine-associated agranulocytosis (Hunt and Resnick, 1993).

#### Liver Effects

Abnormal liver function tests have been associated with a number of antidepressants, which can be independent of dose. The risk for such effects may be worsened by chronic alcohol or anticonvulsant use.

## Seizures

A preexisting seizure disorder increases an antidepressant's likelihood of precipitating a seizure. Other predisposing factors include a family history of a seizure; an abnormal pretreatment electroencephalogram; brain damage; previous electroconvulsive treatment; abuse or withdrawal from sedatives; alcohol, or cocaine; and concurrent use of CNS-activating medications (Rosenstein *et al.*, 1993). Seizures may be more likely to occur early in treatment, or after a large escalation in dose.

The risk of seizure with TCAs is usually reported as 0.1–1.1%. In unselected populations the risk may be as high as 2 to 2.5% (Davidson 1989). Serotonin reuptake inhibitors appear to have a lower incidence of seizures. Bupropion has a high rate of seizures in patients with a preexisting seizure history, and in patients with bulimia. In patients without these predisposing factors, the risk appears to be about 0.4%; thus, it may have a two- to fourfold risk of seizures compared with other antidepressants. Bupropion's effect on the seizure threshold has never been directly compared with other antidepressants.

## Precipitation of Mania

Antidepressants have been associated with the precipitation of mania, and rapid cycling bipolar disorder. This appears to be most common in patients with a preexisting history of mania and in unipolar depression the rate of antidepressant-induced mania is very low (<1%). The problem has been most frequently reported in TCAs, but has been seen in SSRIs as well (Cookson, 1993). A similar problem has been found with newer agents, including nefazodone and venlafaxine, though the data for this is more limited. Bupropion may have a lower incidence of mania (Shopsin, 1983).

## Sexual Dysfunction

A variety of sexual side effects can be caused by antidepressants, and they can affect all aspects of sexual response. Thus, antidepressants can decrease libido, increase impotence and anorgasmia, and cause delayed or retrograde ejaculation (Segraves, 1992).

SSRIs have a high incidence of delayed orgasm or anorgasmia. Sexual side effects can occur at even low therapeutic doses, and dose reduction may not be possible. A change of agent may be the only alternative. Bupropion appears to have the lowest incidence of sexual side effects among the antidepressants, often not differing from placebo in studies of sexual functioning.

Trazodone has been associated with penile priapism; the risk is around 1 in 6000 to 8000 men. Although rare, it is notable that a third of these cases required surgical intervention, and some resulted in permanent impairment. Clitoral priapism has been reported as well (Pescatori *et al.*, 1993).

Occasionally antidepressants can enhance sexual function. This is usually due to the alleviation of depression; however, there have been case reports of improved libido or potency after initiation of an antidepressant, which occurred independent of any antidepressant effect (Smith and Levitte, 1993).

## Miscellaneous

Fine tremors have been noticed with both TCAs and serotonin reuptake inhibitors. The syndrome of inappropriate secretion of antidiuretic hormone has been seen with fluoxetine, as well as with a number of other antidepressants.

## Drug Interaction Effects

Drug interactions are summarized in Table 79.4.

## First-generation Antidepressants

### Tricyclic Antidepressants

As with any combination therapy, the side effects described previously can be additive with other similar drugs. Most problematical are the anticholinergic effects of the TCAs. Such cholinergic – particularly muscarinic – blockade is a property shared by many other medications, including numerous over-the-counter preparations. The general sedative properties of these medications can also augment any soporific. The slowing of cardiac conduction can also potentiate other medications that produce similar effects, such as type IA antiarrhythmics and anticholinergic medications. Adrenergic receptor blockade can worsen the orthostatic hypotension caused by other medications, including vasodilators and low-potency antipsychotic medications.

Absorption of TCAs can be inhibited by cholestyramine, which therefore must be given at different time intervals than the antidepressants. TCA levels can be raised by substances that inhibit enzyme activity, and lowered by substances that induce it. Specific substances reported to increase TCA levels include fluoxetine, antipsychotic medications, methylphenidate and cimetidine. In a controlled trial, methylphenidate was combined with desipramine to treat attention deficits and depression in children. Enzyme “inducers” that can lower tricyclic agent levels include phenobarbital and carbamazepine. The nicotine from cigarettes can also induce enzyme activity.

Guanethidine is contraindicated with TCAs, as it relies on neuronal reuptake for its antihypertensive effect. Clonidine, a presynaptic  $\alpha_2$ -receptor noradrenergic agonist, is also contraindicated, as it works in an antithetical fashion to tricyclic medications.

### Monoamine Oxidase Inhibitors

As with the dietary proscriptions, any medication that increases tyramine can precipitate a hypertensive crisis. Such medications include numerous over-the-counter preparations for coughs, colds and allergies. The same rule applies to sympathomimetic drugs (such as epinephrine and amphetamines) and dopaminergic drugs (such as anti-Parkinsonian medications).

The combination of MAOIs and narcotics – particularly meperidine – may cause a fatal interaction. The reaction can vary from symptoms of agitation and hyperpyrexia to cardiovascular collapse, coma and death. The mechanism of this reaction is poorly understood. A similar reaction has also been reported when propoxyphene, diphenoxylate hydrochloride and atropine are used with MAOIs.

The combination of an MAOI with a potentiator of serotonin (such as a serotonin reuptake inhibitor) can cause the serotonin syndrome (described later in the chapter).

Similar to the dietary restrictions, some of the drug restrictions associated with MAOIs are based on few actual data. Best established are the restrictions against the combination of MAOIs with amines, meperidine, dextromethorphan, hypoglycemic agents, l-dopa, reserpine, tetrabenazine and tryptophan. TCAs are frequently included on this list as causing a “central excitatory syndrome” in combination with MAOIs, although the two have been combined safely. Blackwell (1991) published a comprehensive review of MAOI drug interactions.

## Second-generation Antidepressants

### Serotonin Reuptake Inhibitors

Serotonin reuptake inhibitors are potent inhibitors of the CYP2D6 pathway, and the drug–drug interactions that can result from this have been the subject of a number of books and articles.

Serotonin reuptake inhibitors can slow the metabolism of any drug that is also metabolized by the same cytochrome P450 pathway. Such drugs include TCAs, carbamazepine, phenothiazines, butyrophenones, opiates, diazepam, alprazolam, verapamil, diltiazem, cimetidine and bupropion. Paroxetine appears to be the most potent inhibitor of this metabolic pathway, with fluoxetine also showing high potency. Sertraline is a somewhat less potent inhibitor.

These pharmacokinetic interactions are best managed with dosage adjustment. Fluoxetine, for example, can be safely used with tricyclic medications if TCA blood levels and, possibly, electrocardiograms are monitored. In the case of bupropion, this relative increase in the blood level can increase the risk for seizures.

Particular caution should be used when a patient using multiple medications starts a serotonin reuptake inhibitor, as the interactions with other drugs can cause dangerous increases in levels. For example, in the cardiac patient, levels of warfarin should be monitored as fluoxetine has been reported to raise these levels (Woolfrey *et al.*, 1993). Several case reports exist of increased antiarrhythmic levels after introduction of fluoxetine, which resulted in potential serious bradyarrhythmias.

Fluoxetine has also been reported to raise lithium levels. The mechanism for this is not clear, as lithium is primarily excreted through the kidneys.

### Serotonin Syndrome

Of particular concern is the serotonin syndrome. This syndrome occurs when a serotonin reuptake inhibitor is combined with another drug that can potentiate serotonin, such as MAOIs, pentazocine and l-tryptophan. It has also been reported with the adjunctive use of less obvious serotonergic drugs, such as lithium (Muly *et al.*, 1993) and carbamazepine (Dursun *et al.*, 1993). This creates a toxic effect with symptoms of abdominal pain, diarrhea, diaphoresis, hyperpyrexia, tachycardia, hypertension, myoclonus, irritability, agitation, epileptic seizures and delirium. In its severest form, it can result in coma, cardiovascular shock and death. For this reason, a clearance period is required before switching between a serotonin reuptake inhibitor and an MAOI. Switching from fluoxetine to an MAOI is particularly difficult, given fluoxetine's long clearance time – about 6 weeks. Clearance is considerably more rapid for sertraline or paroxetine, and a 2-week “wash-out” period is advised when changing from one of these agents to an MAOI. Occasionally, case reports have suggested that some patients tolerate a quicker switch; however, a full waiting period remains the most prudent course, as several deaths have occurred after an MAOI was begun too soon after fluoxetine was discontinued (Beasley *et al.*, 1993).

### Other Second-generation Antidepressants

Few reports exist of interactions with other drugs and trazodone, although trazodone may increase levels of digoxin, phenytoin and possibly warfarin. Bupropion causes few drug–drug interactions. The main interactions reported have occurred when bupropion is combined with another dopaminergic agent. For example, when bupropion was used with l-dopa, the combination caused excitement, restlessness, nausea, vomiting and tremor (Goetz *et al.*, 1984).

## Third-generation Antidepressants

Venlafaxine does not substantially inhibit the CYP enzyme, and is not highly protein-bound, thus it tends to have few clinically significant drug–drug interactions. Nefazodone is highly protein-bound, and has several active metabolites. It is also a strong inhibitor of CYP3A4, and affects other drugs also metabolized by that pathway; however, it has little affinity for the CYP2D6 enzyme. Mirtazapine is highly protein-bound as well, but appears only weakly to affect the cytochrome enzymes.

## Initiation of Treatment

### Choosing a Drug

On average, all antidepressants are equally effective. Although an individual patient may preferentially respond to a certain antidepressant, it is difficult to predict this in advance. Without a personal or family history of such a response, side effects are the most influential factors in choosing an agent. Side effects may be particularly relevant in the following groups of patients.

### Cardiovascular Patients

#### Tricyclic Antidepressants

There is a high rate of depression in patients who have had a myocardial infarction and the presence of depression adversely affects the prognosis of cardiac disease.

The major cardiovascular side effect of TCAs is orthostatic hypotension. This can be clinically significant in both the hypertensive patient and the elderly patient. Some of the tricyclic medications may have a lower risk of orthostatic hypotension, notably nortriptyline and doxepin. The evidence for nortriptyline causing little or no hypotension is convincing; for doxepin it is weaker (Roose and Dalack, 1992).

TCAs do not show a negative inotropic effect and do not seem to worsen congestive heart failure. Patients with congestive heart failure may, however, be at a higher risk for orthostatic hypotension. Again, nortriptyline is the safest TCA in this case.

TCAs slow conduction at the bundle of His. Their effect is analogous to type IA antiarrhythmic agents such as quinidine and procainamide. In therapeutic doses they can slow cardiac conduction and in overdose they can cause atrioventricular blockade. These effects are of most concern in patients with preexisting cardiac conduction defects. There is no evidence that any one tricyclic medication is safer than another.

Glassman and coworkers (1993) recommend caution when using TCAs in all patients with ischemic heart disease, particularly patients with ventricular arrhythmias that follow a myocardial infarction.

### Serotonin Reuptake Inhibitors

The serotonin reuptake inhibitors differ from the TCAs in that they do not prolong the PR or heart wave (QRS) interval. Thus, they probably lack any of the proarrhythmic and antiarrhythmic activities associated with TCAs. They do not cause orthostatic hypotension. Most studies that exist suggest that SSRIs should be safe in patients with heart disease.

### Other Agents

Trazodone has less proarrhythmic effect than the TCAs. However, there have been reports of trazodone-related ventricular ectopy

and complete heart block (Martyn *et al.*, 1993). In patients with preexisting heart disease, bupropion does not appear to cause the cardiac side effects attributed to TCAs (Roose *et al.*, 1991).

## Elderly Patients

### Pharmacokinetic Concerns

Two pharmacokinetic changes are of great importance in aging patients: decreased efficiency of the hepatic microoxidase system and a decreased muscle–fat ratio. Decreased efficiency of hepatic microoxidases results in the slower metabolism of antidepressants and other drugs. Normal increases in body fat and a loss of muscle mass result in an alteration of the volume of distribution for a substance. Thus, lipophilic drugs, including all antidepressants, are more widely distributed in the elderly body.

Both the resulting slower metabolism and the increased volume of distribution increase the half-lives of the various antidepressants. The elderly, therefore, are likely to have a greater incidence of side effects.

The half-lives and steady state concentrations of the serotonin reuptake inhibitors are only minimally affected by age. Paroxetine may be an exception to this, and it may have an increased half-life in the elderly (Leonard, 1993).

### Pharmacodynamic Concerns

The assumption that elderly patients require lower blood levels of antidepressant medication is not correct. Although pharmacokinetic concerns may require lowering of the medication dose, plasma levels are comparable to those in young adults.

It appears that antidepressants are as effective in the elderly as in the young, although the elderly may have more difficulty tolerating these medications.

## Medically Ill Patients

Few studies are available on the pharmacological treatment of depression in medically ill patients, and even less on medically ill elderly patients. In initiating treatment, the physician should understand the effects of various illnesses on pharmacokinetics and the potential side effects that may result.

## Child and Adolescent Patients

Next to stimulants, antidepressants are the most common psychotropic medications prescribed in children (Zito *et al.*, 2000) and adolescents (Jensen *et al.*, 1999) and the trend to use these medications in that group is on an increase. It should be noted that the FDA has placed a “black box” warning related to suicidal ideation in adolescents treated with SSRIs.

In addition to depression, antidepressants are used in a number of nonaffective disorders in children and adolescents, including enuresis, attention-deficit/hyperactivity disorder, OCD and bulimia nervosa. They are used to mitigate behaviors that are not part of a disease, for example, in suicidal adolescents who do not have a concomitant depressive disorder (American Academy of Child and Adolescent Psychiatry, 2001); however, there is little empirical evidence that suggests that they can lower suicide risk (Zametkin *et al.*, 2001). Similarly, they are used to dampen other impulsive behaviors.

## Dosage Concerns

Children should generally be treated with levels of medication comparable to those used in adults, with the doses adjusted for

body weight. As children have large livers (relative to body weight), they tend to be efficient metabolizers of substances, and may even need higher doses of medications (relative to body weight) than do adults.

## Adverse Effects

Well after the introduction of SSRIs, TCAs remained the most popular antidepressants used in children. However, there have been concerns regarding the safety of these medications. Several case studies have documented adverse cardiac effects in children treated with TCAs, especially with desipramine. The Work Group on Research of the American Academy of Child and Adolescent Psychiatry (1990) conducted an extensive review of the available literature and concluded that there is minimal or no increased risk of “sudden death” in children with desipramine. It is probably wise, however, to perform an adequate cardiac work-up before starting an antidepressant in a child.

Given these issues concerning cardiotoxicity, the serotonin reuptake inhibitors have become more popular for the treatment of children and adolescents. Most of the newer agents have evidence for safety and efficacy in children, including fluoxetine (Emslie *et al.*, 1997) and paroxetine (Keller *et al.*, 2001). Others of the SSRIs have data for their usefulness in anxiety disorders, such as fluvoxamine (in OCD) (Riddle *et al.*, 2001) and sertraline (which has open label data for social anxiety disorder and OCD) (Compton *et al.*, 2001). Bupropion has been found safe and effective in children as well, although it may exacerbate tics in Tourette’s disorder. Other antidepressants, including most of the first-generation antidepressants, lack any positive efficacy studies in children or adolescents.

## Pregnant and Postpartum Patients

Of the commonly used antidepressants, none show compelling evidence of teratogenicity. Nonetheless, as is true for most medications, it is usually best to discontinue antidepressants if a patient becomes pregnant. For all the antidepressants, one must consider a risk–benefit decision, measuring the risk of possible pregnancy-related side effects against the morbidity of a prolonged untreated depressive episode during pregnancy (Wisner *et al.*, 2000). The FDA, in late 2005, classified paroxetine as a class “D” medication, indicating it should be used only with great caution in pregnancy.

## Nursing Mothers

All antidepressants are secreted in breast milk. The levels of these agents are difficult to predict, and their effect on the developing infant is not known (Cohen *et al.*, 1991). There are no systematic investigations of this issue. Given the level of uncertainty, nursing should be deferred if antidepressant treatment is required.

## Suicidal Patients

Meta-analysis of both world (Mann and Kapur, 1991) and the USA (Kapur *et al.*, 1992) and a more recent study using prospective data (Leon *et al.*, 1999) showed no unique relationship between fluoxetine (or any antidepressant) and suicidal behaviors. However, as with any rare event, one cannot totally discount the possibility that antidepressants may “trigger” suicidal ideation, either through a direct neurochemical effect (e.g., through an acute decrease in serotonergic transmission) or through nonspecific side effects of the drug (e.g., the induction of akathisia). If

such a phenomenon exists, it is very uncommon, and probably not specific to any one antidepressant. There is, however, now a “black box” warning regarding the emergence of suicidal ideation in some adolescents taking SSRIs.

These concerns must be balanced over the well-proven and much greater risk of suicidal ideation and attempts when depression is not treated. Given this, and the propensity of suicidal patients to choose medication overdose as the method of suicide, the wide safety margin of the second- and third-generation antidepressants makes them preferable to first-generation agents when suicide is a concern. Bupropion has generally not been fatal in overdose, although about a third of such cases experience a seizure.

## Starting Doses

See Table 79.7 for usual therapeutic dosages.

## First-generation Antidepressants

### Tricyclic Antidepressants

TCAs are usually begun at a relatively low dose. For the majority of TCAs, including imipramine, amitriptyline, desipramine, maprotiline and doxepin, the initial starting dose is in the range of 50 to 75 mg/day. Notable exceptions include nortriptyline and protriptyline, which are more potent agents. In the case of nortriptyline, the usual starting dose is 25 to 50 mg/day, and for protriptyline, 10 to 15 mg/day (Schatzberg and Cole, 1991). The lower doses are preferred in patients who are elderly. In the frail elderly, further dose reductions may be needed (about one-half or less of the usual starting dose).

Once a medication is initiated, it is gradually increased to a therapeutic level. A number of strategies have been suggested for this increase. Most TCAs can be increased to 150 mg/day by the second week, and then to a range of 300 mg/day by the third or fourth week. This can be achieved through small daily increase of 25 mg or weekly increase of 75 mg. Younger patients will tolerate larger and more rapid increases, whereas the elderly benefit from smaller (25 mg/day) and less frequent (every other day) increases with a lower target dose (150 mg/day).

For nortriptyline, increases of 50 mg/week are usually tolerated in the young, with the elderly requiring smaller increases (25 mg/week). Of particular interest is nortriptyline's therapeutic window: doses above and below a certain range appear to be less effective. The effective range is approximately 50 to 150 mg/day. Some authors suggest a lower range (for example, from 30 to 100 mg (Brotman *et al.*, 1987); however, plasma blood monitoring is a more accurate indicator of the proper level.

### Monoamine Oxidase Inhibitors

Patients taking MAOIs must adhere to a special diet to reduce the risk of a hypertensive crisis (see Table 79.7) Phenelzine is usually begun at a dose of 30 mg/day. It is increased by 15 mg after 3 days, then weekly to a target range of 45 to 90 mg/day. Tranylcypromine is started at 20 mg/day. It is increased by 10 mg after 3 days, with additional daily increases of 10 mg after 1 week, to a target range of 30 to 60 mg/day. Isocarboxazid is usually begun at 20 mg/day. It is titrated in a manner similar to tranylcypromine to a target of 30 mg/day. Schatzberg and Cole (1991) suggested that most patients require doses in the higher range, and that some may require doses above the normally recommended limits (e.g., phenelzine at 120 mg/day tranylcypromine at 110 to 130 mg/day, and isocarboxazid at 50 mg/day).

## Second-generation Antidepressants

### Serotonin Reuptake Inhibitors

Although dosing strategies are less well understood with these agents, the wisest choice is to start a patient at the lowest effective dose and increase as indicated by clinical response. Reasonable doses are 20 mg/day for fluoxetine, 50 mg/day for sertraline, 20 mg/day for paroxetine and citalopram. For children, adolescents, the elderly and patients who find medications generally difficult to tolerate, 50% reductions in these doses are reasonable starting doses.

A number of studies have shown increasing response with increasing doses of SSRIs (Leonard, 1993), but the dropout rate due to side effects also increases with increasing dose. Fluoxetine, paroxetine and citalopram should be started at a dose of 10 or 20 mg for 3 weeks (20 mg for a normal healthy adult, 10 mg for patients who are young, elderly, or particularly sensitive to medications), after which they can be increased in 10 or 20 mg increments to a dose of 40 mg/day if there is no response. A maximum dose of 60 mg/day of fluoxetine is recommended for the treatment of depression. A similar strategy can be used for sertraline, which can be begun at 25 to 50 mg, and increased in 25 to 50 mg increments to a target dose of 50 to 150 mg. Other disorders, particularly OCD and bulimia nervosa, may require 80 mg/day or more for maximal effect. The issue of dosage for SSRIs remains complicated, as some studies have suggested that fluoxetine may not have a linear dose–response curve; some patients may respond better to lower doses of the medication, such as 10 mg/day (Leonard, 1993). Other studies have documented responses to fluoxetine at incredible doses and blood levels (320 mg/day and over 2000 ng/mL, respectively) without adverse effects (Stoll *et al.*, 1991).

As with tricyclic medications, there is a significant delay between initiation of medication and response, and there is no reason to believe that increasing the dose hastens response.

### Other Second-generation Antidepressants

Trazodone is generally dosed in a manner similar to TCAs, with starting doses of 50 to 75 mg/day, and target ranges of 150 to 300 mg/day, with doses not exceeding 400 mg/day in outpatients and 600 mg/day in inpatients. Unlike many of the TCAs, trazodone's short half-life requires divided doses, usually twice daily.

Bupropion, like trazodone, requires divided doses. It is available in a short acting form that requires three times a day dosing, or a longer acting form that allows twice-daily dosing. It should be begun at 100 mg b.i.d., and increased to a target of 300 mg/day after a few days. The recommended dose of the medication is 300 mg/day; however, patients not responding to that dose can be increased to 450 mg/day. Patients should be instructed to avoid taking more than 150 mg in a single dose. In the elderly, a usual starting dose is 75 mg/day of the shorter acting preparation. This is then increased to 75 mg b.i.d.

## Third-generation Antidepressants

### Venlafaxine

It is currently available in a slow release preparation that enables once-daily dosing. Venlafaxine is usually begun at a dose of 37.5 mg and is increased within half to 1 week to a dose of 75 mg. If further increases are needed, it can be titrated at a rate of 75 mg every 4 days or more. Though a maximum dose of 225 mg per day is recommended by the manufacturer, doses as much as 300 to 450 mg/day have been employed to good effect in some patients.

### Duloxetine

It is available in 20, 30, and 60 mg capsules. Starting dose is usually 20 mg twice a day. Maximum recommended effective dose is 60 mg/day.

### Mirtazapine

Adults should be started on a dose of 15 mg/day. It is usually given as a before bedtime dose. The dosage generally needs to be increased in 15-mg intervals every half to 1 week to a target dose. The effective dose is usually between 15 and 45 mg/day; however, higher doses, such as 60 mg have been useful in some patients.

### Nefazodone

Nefazodone is given in twice-daily doses. Patients can be started at a dose of 100 mg b.i.d. and increased at a rate of 100 to 200 mg a week. The recommended effective dose is 300 to 600 mg/day. Some clinical experience suggests that once-daily doses (given at night) are acceptable for some patients (Marathe *et al.*, 1996).

### Therapeutic Drug Monitoring

Although blood levels are available for many antidepressants, those for imipramine, desipramine, and nortriptyline have been best established (see Table 79.6). Imipramine and desipramine appear to have a curvilinear dose–response curve with an optimal range of 150 to 300 ng/mL. Nortriptyline appears to have a therapeutic window in the range of 50 to 150 ng/mL (Preskorn *et al.*, 1993). These blood levels are nominal, as some patients do respond above or below these ranges, and blood level monitoring should not be a substitute for clinical observation.

Drug levels have not been well established for the MAOIs and the serotonin reuptake inhibitors.

**Table 79.6 Therapeutic Blood Levels of the TCAs**

TCA	Therapeutic blood level
Imipramine (IMI)	>225 ng/dl of IMI + DMI
Desipramine (DMI)	>125 ng/dl of DMI
Amitriptyline	Conflicting evidence
Nortriptyline	>50 ng/dl and <150 ng/dl

### Antidepressant Augmentation

Typical augmentation strategies (Table 79.7) include the addition of lithium carbonate, thyroid hormone, or a stimulant. These may be considered when response is inadequate to initial treatment using an adequate dose for an adequate time of a single agent.

### Changing to a New Agent

For the patient who shows no response or whose condition deteriorates during therapy, the physician should initiate a new trial of an alternative single agent. There remains some debate as to what type of agent should be used next. Some studies have suggested that patients who do not respond to one SSRI may respond to another (Thase *et al.*, 1997). However, the most convincing study continues to support the more commonly held belief that it is best to switch to an agent of a different class, and approximately 50% of patients unresponsive to a first trial respond to an antidepressant of a different class (Phillips and Nierenberg, 1994; Thase *et al.*, 2002).

When the switch involves an MAOI, sufficient time must be given for medication clearance. Although seldom used, MAOIs may

**Table 79.7 Augmentation Strategies**

Agent	Dosing Strategy	Length of Trial	Reported Response Rate	Comments
Lithium carbonate	Start at 300 mg b.i.d., increase to therapeutic blood level (0.8–1.2 mEq/L)	3–6 wk	As high as 65%	Best documented strategy; has been combined with most agents
Triiodothyronine	Start at 25 µg/d, may increase to 50 µg/d	At least 3 wk	At 25%	Equal to lithium in one placebo controlled trial
Stimulants (methylphenidate dextroamphetamine)	†	†	†	Few systematic data
Atypical antipsychotics	Begin with low dose (e.g. olanzapine 2.5 mg/day, aripiprazole 5 mg/day, gradually increase to full therapeutic dose if needed)	†	†	Mainly open trials; controlled studies in progress
Combined antidepressant therapy	May need lower doses than usual (due to enzyme inhibition)†	†	†	Mainly open trials; controlled studies in progress
Psychotherapy	N/A	Varies by therapy	Varies by therapy	Good data for both cognitive–behavioral therapy and interpersonal therapy

†Inadequate data.

be very effective in patients not responsive to other classes of antidepressants (McGrath *et al.*, 1993). Generally, 10 to 14 days for either medication is required for clearance of TCAs and MAOIs. Fluoxetine requires a much longer period – 6 weeks – whereas sertraline and paroxetine require about 2 weeks when switching to an MAOI.

### Continuation Period

This period usually lasts 5 to 8 months after the end of the acute treatment period. The goal at this phase is the prevention of relapse. There is a high risk of relapse if treatment is discontinued after the acute treatment phase. The National Institutes of Health Consensus Development Conference on the Mood Disorders (1985) reported a cumulative relapse rate of 15% after 6 months and 22% after 12 months. Keller and colleagues (1982) found that the two best predictors of relapse were a high number of previous depressive episodes (greater than three predicted relapses) and underlying dysthymic disorder.

Once a patient has responded to a medication, the medication should be continued for a minimum of 4 to 6 months, beginning from the point of initial response. The World Health Organization (1989) recommended 6 months as a minimum period for continuation of treatment after the acute phase, and the American Psychiatric Association (2000b) recommended a minimum of 16 to 20 weeks of treatment following the full remission of symptoms. This period should be lengthened for the patient with a history of longer depressive episodes.

Surprisingly, few studies exist that directly look at the efficacy of antidepressants for continuation therapy. However, there exists at least one placebo-controlled study for each of the SSRIs (Montgomery *et al.*, 1988, 1993; Montgomery and Dunbar, 1993; Doogan and Caillard, 1992), nefazodone (Feiger *et al.*, 1999) and mirtazapine (Montgomery *et al.*, 1998).

In the past, it was suggested that, on achievement of euthymia, doses could be reduced. However, it is more likely that levels similar to those needed at the acute stage of treatment will be required throughout the continuation period.

### Discontinuance of Treatment

After the continuation period, somatic therapy is usually discontinued in the patient with a single episode of major depression. Before discontinuing, however, it is important to remember that depression is often a lifelong disease with a chronic course. One should always weigh the benefits of discontinuance against the risks of recurrent depression.

In the past, a distinction between exogenous and endogenous depression was used to predict the risk of recurrence. Inferences about etiology, however, are not an accurate predictor of recurrence. More useful information are the age of onset during the initial episode and the number of episodes. Patients with a single episode of acute depression, who have an onset before age 50 years, are the best candidates for discontinuance (Greden, 1993).

### Tapering and Withdrawal

For the TCAs, the usual strategy is to taper the medications at a rate of 25 to 50 mg/day every 2 to 3 days. Too rapid a discontinuation may produce symptoms of cholinergic “rebound” or supersensitivity. Such a rebound includes severe gastrointestinal symptoms (nausea, vomiting and cramping), other signs of autonomic hyperactivity (diaphoresis, anxiety, agitation, headaches) and insomnia (often with vivid nightmares). In severe cases, a full delirium may result. Cholinergic rebound may occur as early

as 48 hours or as late as 2 weeks after discontinuation. These symptoms may account for some cases of presumed early relapse from antidepressant discontinuation.

MAOIs may also have a withdrawal syndrome, including symptoms of psychosis, on abrupt withdrawal; however, this syndrome is rarer than that seen with TCAs.

Fluoxetine has a long half-life, and abrupt discontinuation should be permissible. Sertraline, citalopram and paroxetine, with shorter half-lives of around a day, may require a 7- to 10-day taper. With the shorter-acting agents, a withdrawal syndrome including symptoms of fatigue, insomnia, abdominal distress and influenza-like symptoms have been reported when they are too abruptly discontinued. The same may be true for venlafaxine.

Some investigators question current tapering schedules, which are based on pharmacokinetic rather than pharmacodynamic (i.e., receptor) effects. Given an antidepressant’s long-term effects, they suggest that receptors will “need” more time to readjust to a new medication-free environment. Greden (1993), for instance, recommended a one-fourth reduction in dose every third month for tricyclic medication. For fluoxetine, he recommended slowly increasing the dosing interval: from daily to every other day for 3 months, then every third day for 3 months. After 3 months of dosing every 3 days, he recommended switching to a liquid form to permit 25% dose reductions each quarter year. Obviously, such a strategy would dramatically increase the taper period from several weeks to approximately a year. It will be interesting to see whether studies support the contention that extended tapers are more likely to prevent recurrence.

On discontinuance, the goal is to enable early intervention should symptoms recur. A first episode of depression has a high risk of recurrence, and the risk of recurrence is even higher in patients who show only partial response to medication. The patient should be educated to recognize symptoms of depression. The patient’s own history suggests which symptoms were prodromal to the patient’s full depressive episode.

### Maintenance Period

The goal of the maintenance period is to prevent the recurrence of depression. There are a number of reasons to consider long-term prophylactic therapy for depression rather than medication withdrawal. Depression is a lifelong disease, with recurrence being the norm rather than the exception (Keller *et al.*, 1992). As the number of acute episodes increases, the risk of future episodes increases as well, and the interval between episodes shortens. Each subsequent episode carries a higher morbidity and disability. Although better understood in bipolar disorder, there is a fear that treatment response may decrease with an increasing number of depressive episodes (Greden, 1993).

A number of factors can influence the decision of when it is appropriate to maintain long-term prophylaxis for depression. The seriousness of previous episodes, the severity of impairment caused by such episodes, the degree of response to previous treatments and the ability of the patient to tolerate the drug all play a role. Central in the decision process is the concept of recurrent depression: that some patients are more likely than others to have a recurrence of the disease. Three previous episodes of depression make recurrent depression likely. The best predictors of the likelihood of recurrence appear to be older age of onset and number of episodes. Greden (1993) proposed that long-term maintenance is the treatment of choice for the following groups of patients: 1) those who were 50 years old or more at the time of the first depressive episode, 2) those who were 40 years old or

more at first episode and have had at least one subsequent recurrence, and 3) anyone who has had more than three episodes.

The recommended length of maintenance treatment needs further clarification as well. Recommended lengths of time vary from 5 years of treatment to indefinite continuation. There are only a handful of studies on maintenance antidepressant treatment.

Equally important in preventing recurrence of depression is the problem of maintaining adherence to medication long after the acute episode has resolved. Proper education and support will help with compliance. Toleration of side effects is important and evidence suggests that patients are more likely to comply with the agents that have more favorable side-effect profiles. The serotonin reuptake inhibitors are generally the best tolerated antidepressants.

Although lower doses for prophylaxis have been recommended, there are few data to support this contention. Even though lower doses may increase compliance, full doses should be used until new information indicates otherwise.

### Treatment Failure

Failure to respond to treatment is most often due to inadequate treatment rather than “true” nonresponse. Inadequate treatment can be due to an inadequate length of treatment or an inadequate dose. These can result from the physician’s error (either improper dosing strategies or impatience in waiting an appropriate amount of time) or the patient’s error (through misunderstanding or nonadherence).

Patients will often not acknowledge nonadherence as they fear rejection from treatment, and they are certainly unlikely to admit to it if their physician does not ask them. The best remedy for nonadherence is prevention, through proper education of the patient about likely side effects that might otherwise unnerve the patient. A flexible approach is also necessary. Gentle reassurance and encouragement can be helpful; however, dogmatic insistence on adherence to a prescription leaves the patient with no choice except to hide nonadherence, or look elsewhere for treatment.

Thus, “true” nonresponse can be defined as the lack of response to an adequate dose for an adequate time. Many strategies have been suggested for treatment-resistant patients. Electroconvulsive therapy offers a safe, effective alternative somatic therapy for depression. A prior good response to electroconvulsive therapy, a need for rapid response as with life-threatening depressive symptoms (food refusal, suicide attempts) or a medical contraindication to antidepressants warrants early consideration of this treatment. It should be considered for any patient with major depression who has not responded to antidepressant medication.

### Summary

There remain a number of important limitations regarding the pharmacotherapy of depression. Some of these limitations can be addressed by continued progress on current research. Other limitations await truly novel research into the mechanism of depression.

### Recommendations for the Use of Antidepressants

Allowing for the many limitations, we can generalize from available data to make the following recommendations:

1. All patients with acute major depression should be considered reasonable candidates for pharmacotherapy.
2. There is adequate evidence to make the same recommendation for other forms of depression. This is particularly true for dysthymia, and may be true for other minor forms of depression as well.
3. There is good evidence for the use of antidepressants for non-mood disorders as well, particularly the anxiety disorders.
4. There remains no strong evidence from choosing one medication over another, and treatment recommendations should be made on the basis of tolerability and, if appropriate, cost.
5. Extended treatment should be recommended both for patients with chronic depression and recurrent depression.
6. Maintenance treatment should consist of the same dose of antidepressant as used to achieve acute phase remission.
7. The exact length of maintenance treatment is not known. The decision for indefinite treatment should be a risks-benefit decision, made with the informed consent of the patient, who is entitled to be informed of the limitations in our knowledge.

Finally, cases like this emphasize the art as well as the science of pharmacotherapy. Though some treatment-related decisions have a clear scientific basis, others are more rooted in judgment and experience. Certainly the switch to bupropion to minimize sexual side effects has a clear pharmacodynamic rationale. However, the subsequent adjunctive use of an SSRI likely relied less on science, and more on the psychiatrist’s experience in interpreting the irritability as a symptom that might be more amenable to a serotonergic agent. Though the practice of clinical medicine should be informed by research, the greatest clinicians are still those unique individuals who can integrate research into their own observations and wisdom.

In the last decade, there has been a substantial increase in the number of medications demonstrated to be effective for the treatment of anxiety and anxiety disorders (Table 80.1).

There was a cascade of anxiolytic research in the 1990s. The selective serotonin reuptake inhibitors (SSRIs) as a class were demonstrated to be efficacious treatments for most of the anxiety disorders described in the DSM-IV-TR. Although these agents have a delayed onset when contrasted with the benzodiazepines, they have a broader spectrum of action, no problems with dependence, and much less of a problem with withdrawal syndromes. The 1990s also saw the approval of venlafaxine as a treatment for generalized anxiety disorder.

### A General Approach to Using Medication with Anxious Patients

Making an appropriate differential diagnosis which includes a DSM-IV-TR anxiety disorder is critical to the success of any psychopharmacological intervention. The diagnosis dictates the class of medication to be used and the length of pharmacotherapy. An important rule in general is “to start low and go slow” when initiating pharmacological treatment for patients with anxiety disorders. Interestingly, although treating patients with anxiety disorders frequently requires a more gradual initial titration schedule, patients frequently attain maintenance dosages of antidepressant medications that are greater than the dosage commonly used to treat major depressive disorder.

### Antidepressant Medication

It has been known that medications initially identified because of their antidepressant properties are frequently effective treatments for anxiety disorders as well. The basic action of the majority of the antidepressants is to increase the availability of neurotransmitters in the synaptic cleft. These agents have the broadest spectrum of activity which spans the entire spectrum of DSM-IV-TR anxiety disorders. The relative differences in terms of major pharmacokinetic and pharmacodynamic properties are outlined in Tables 80.2 and 80.4. As illustrated in Table 80.1, a variety of serotonin receptor subtypes have been implicated in the modulation of anxiety disorders, depressive disorders, migraine, pain and neuropsychiatric disorders.

### Indications for Selective Serotonin Reuptake Inhibitors

Initial data from randomized, placebo-controlled treatment trials suggest that SSRIs may be useful in the treatment of adults and children with generalized anxiety disorder. SSRIs have emerged

as a first-line treatment for social anxiety disorder. Most of the efficacy data are derived from multicenter, double-blind trials of paroxetine, sertraline and fluvoxamine.

In addition, SSRIs are generally accepted as a first-line treatment for panic disorder. The major advantage of these agents is their tolerability and thus longer-term acceptance by patients. There is evidence that fluoxetine, sertraline, paroxetine, fluvoxamine and citalopram are effective in the acute treatment of panic disorder.

One of the advantages of SSRIs is that they tend to be fairly well tolerated in contrast to some of the other treatments available for panic disorder. Although a few individuals may have some initial problems with restlessness and increased anxiety, data suggest that starting at lower doses such as 25 mg/day of sertraline or 10 mg/day of paroxetine may decrease the risk of antidepressant “jitteriness”.

There have been open-label and double-blind, placebo-controlled studies demonstrating that SSRIs are effective for the treatment of post traumatic stress disorder (PTSD). Open-label trials with all of the SSRIs currently available suggest that each may be effective in decreasing the core symptoms of PTSD.

Large, well-designed, double-blind, placebo-controlled trials demonstrate that fluoxetine, paroxetine, fluvoxamine, citalopram and sertraline are effective acute treatments for obsessive-compulsive disorders.

### Indications for Serotonin–Norepinephrine Reuptake Inhibitors in Anxiety Disorders

#### Venlafaxine

There have been a number of placebo-controlled multicentered studies demonstrating that venlafaxine XR is an effective treatment of GAD.

Doses as low as 37.5 mg/day and as high as 225 mg/day are effective in decreasing symptoms of anxiety for patients with GAD. Side effects appear to be mild and tend to decrease in number and intensity over the course of treatment. Nausea, dry mouth and somnolence are the most commonly repeated side effects.

Case reports and open-label studies have been published for use of venlafaxine in social anxiety disorder (Kelsey, 1995).

There is only one double-blind, placebo-controlled study by Pollack and coworkers. (1996) suggesting that venlafaxine may be an effective treatment for patients with panic disorder.

### Indications for Tricyclic Antidepressant Medication and Monoamine Oxidase Inhibitors in Anxiety Disorders

A variety of tricyclic antidepressants (TCAs) have been demonstrated to be effective treatments for GAD. However, the side

**Table 80.1** The Efficacy of Psychotropic Medications for the Treatment of Anxiety Disorders

	Generalized Anxiety Disorder	Social Anxiety Disorder	Panic Disorder	Post traumatic Stress Disorder	Obsessive–Compulsive Disorder
Strong evidence	SSRIs Venlafaxine	SSRIs Bupropion-SR	SSRIs Venlafaxine	SSRIs TCAs MAOIs	SSRIs Clomipramine
	Trazodone TCAs Benzodiazepines Buspirone	MAOIs Benzodiazepines	MAOIs TCAs Benzodiazepines		
Some evidence	Nefazodone Mirtazapine	Venlafaxine Nefazodone	Mirtazapine Nefazodone Clonazepam + sertraline	Venlafaxine Lamotrigine Valproate	MAOIs Olanzapine augmentation of SSRI
		Gabapentin	Buspirone adjunct to benzodiazepine Valproic acid Gabapentin Tiagabine Pagoclone	Nefazodone Mirtazapine Clonidine	Risperidone augmentation of SSRI Venlafaxine Mirtazapine
Not effective		TCAs Buspirone Pindolol augmentation of SSRI	Trazodone Bupropion		Trazodone TCAs Buspirone
No data	MAOIs Bupropion	Trazodone Mirtazapine		Duloxetine Bupropion	

effects and difficulty titrating the dosage of these medications have made their use uncommon.

In general, TCAs have not been found to be effective for the treatment of social anxiety disorder, but there is evidence of effectiveness in panic disorder. Although surpassed by the SSRIs as first-line agents, there is no doubt that first-generation MAOIs are effective. Unfortunately, the risk of hypertensive crisis and the need for patients to follow a tyramine-free diet makes this class of drugs unappealing for the majority of patients.

Although TCAs have been widely used for the treatment of panic disorder, their side-effect profile and slow time to onset of action makes them a difficult class of medication for many patients to tolerate.

There have been seven meta-analyses comparing and contrasting clomipramine and SSRIs (Abramowitz, 1997; Cox *et al.*, 1993; Greist, 1998; Kobak *et al.*, 1998; Piccinelli *et al.*, 1995; Stein *et al.*, 1995). In each case, clomipramine has been found to be significantly more effective than the SSRIs. If one takes the entire body of evidence as a whole into account, analyses suggest that clomipramine is at least as effective as the SSRIs and may, in some instances, be more effective (Greist, 1998; Todorov *et al.*, 2000).

### Other Antidepressant Medication (Bupropion, Mirtazapine, Nefazodone, Trazodone) in Anxiety Disorders

Most evidence fails to support these medications as a first-line treatment for generalized anxiety disorders, social anxiety disorder, panic disorder, PTSD, or obsessive-compulsive disorder.

### Benzodiazepine Medication

The benzodiazepines as a class work by increasing the relative efficiency of the gamma-aminobutyric acid (GABA) receptor when stimulated by GABA. The benzodiazepines bind to a site located adjacent to the GABA receptor and cause an allosteric change to the receptor that facilitates the increased passage of the chloride ions intracellularly when GABA interacts with the receptor complex. This leads to a relative hyperpolarization of the neuronal membrane and inhibition of activity in the brain. The benzodiazepines as a group have different affinities for GABA receptors, in fact some agents bind to only one of the two types of GABA receptors. The relative pharmacodynamic and pharmacokinetic properties of the benzodiazepines are further outlined in comparison to the other medications in Table 80.2. As a class, benzodiazepines are efficacious for the treatment of panic disorder, social anxiety disorder, generalized anxiety disorder, alcohol withdrawal and situational anxiety. The choice of an agent should take into account the age, medical health and comorbid diagnosis of the patient. Although obsessive–compulsive disorder falls within the taxonomy of anxiety disorders, benzodiazepines do not seem to be particularly effective in treating these patients.

The limitations to these drugs are the same as when used in any indication. Due to the potential for abuse and drug withdrawal, their use must be monitored carefully. This is a particularly problematic issue in social anxiety disorder because of the high rate of comorbid substance abuse. Benzodiazepines may be best suited for patients with situational and performance anxiety on an as-needed basis.

Source: Dubovsky SL and Thomas M (1995) Serotonergic mechanisms and current and future psychiatric practice. *J Clin Psychiatr* 56(2), 38–48.

The two high potency benzodiazepines that have been approved by the FDA, alprazolam and clonazepam are widely used in the treatment of panic disorder. They may also be helpful as adjuncts in the treatment of obsessive-compulsive disorder, though not as first-line stand alone treatments.

### Buspirone

Buspirone is a member of the group of agents called azaspirodecanediones. It is believed to exert its anxiolytic effect by acting as a partial agonist at the 5-HT<sub>1A</sub> autoreceptor. Stimulation of the 5-HT<sub>1A</sub> autoreceptor causes decrease release of serotonin into the synaptic cleft. However, buspirone also exerts another effect through its active metabolite 1-phenylpiperazine (1-PP) that acts on alpha-2-adrenergic receptors to increase the firing rate of the locus coeruleus. Some not yet **well-characterized** combination of these effects may be re-

sponsible for anxiolytic effect of buspirone. It usually takes approximately 4 weeks for the benefit of buspirone therapy to be noticed in patients with GAD. It may also be a useful adjuvant in some patients with treatment resistant panic disorder. One major advantage of buspirone is that it does not cross react with benzodiazepines. The most common side effects associated with buspirone include dizziness, gastrointestinal distress, headache, numbness and tingling. The most common pharmacokinetic and pharmacodynamic actions of buspirone are described in Table 80.3.

### Beta-blocker Medication

Beta-adrenergic blockers competitively antagonize norepinephrine and epinephrine at the beta-adrenergic receptor. It is thought that the majority of positive effects of beta-blockers are due to their peripheral actions. Beta-blockers can decrease many of the peripheral manifestations of anxiety such as tachycardia, diaphoresis, trembling and blushing. The advent of more selective beta-blockers that only block the beta-2-adrenergic receptor has been beneficial since blockade of beta-1 adrenergic receptors can be associated with bronchospasm. Beta-blockers may be useful for individuals who have situational anxiety or performance anxiety. They generally have not been effective in treating anxiety disorders such as generalized social anxiety disorder, panic disorder, or obsessive-compulsive disorder.

### Anticonvulsant Medication

One of the areas of increasing research is the study of anticonvulsants in anxiety disorders. Currently, there are few published placebo-controlled studies investigating the efficacy of commonly used anticonvulsants for the treatment of anxiety or anxiety disorders. There is one published report of a large double-blind, placebo-controlled study of gabapentin for the treatment of social anxiety disorder. The precise mechanism of action of gabapentin is not fully appreciated, however, it is thought gabapentin somehow increases brain GABA levels.

### Antipsychotic Medication

The conventional or typical antipsychotic medication whose mechanism of action is primarily to block dopamine Type-2 receptors has been used as adjuvant medication for the treatment of anxiety disorders for years. However, because of problems with extrapyramidal side effects and the risk of developing tardive dyskinesia, these agents had fallen out of favor. The newer class of atypical antipsychotic medications have a decreased risk of both extrapyramidal side effects and tardive dyskinesia and so antipsychotic medications are beginning to be used again as adjuvants in patients with treatment resistant anxiety disorders. This simultaneous blockade of both neurotransmitter systems seems to decrease extrapyramidal side effects and the risk of developing tardive dyskinesia. Although the different atypical antipsychotic medications have different affinities for dopamine Type-2 and serotonin Type-2 receptors, this is the common mechanism of action of these agents. The atypical antipsychotic medications also differ dramatically in terms of their pharmacodynamic

**Table 80.4** A Summary of Pharmacologic Properties of Medications Commonly Used to Treat Anxiety

	Onset of Action	Titration	Abuse Liability	Need for Discontinuation Titration	Potential for Withdrawal Syndrome	Probability of Lethality in Overdose
Sertraline	Delayed (In 2 wk)	Yes	Very low	Yes, but not mandatory	Very low	Low

Alprazolam XR	Rapid	Yes	Moderate	Yes	Moderate–high	Low
Lorazepam	Very rapid	Yes	Moderate	Yes	Moderate–high	Low
Diazepam	Rapid	Yes	Moderate	Yes	Moderate	Low
β-blockers	Rapid	Sometimes	Low	No (acute use)	No (acute use)	Low–medium
Gabapentin	Moderate (d)	Yes	Low	Yes	Low–moderate	Low
Risperidone	Rapid	Probably	Low	Yes	Low	Low
Olanzapine	Rapid	Probably	Low	Yes	Low	Low

properties. There are very few published studies investigating atypical antipsychotic medication augmentation for the treatment of anxiety disorders, so it is not possible to recommend their use as a first-line treatment for anxiety disorders.

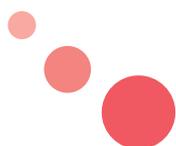

## Conclusion

Clinicians have a wide array of medications available for the treatment of anxiety and anxiety disorders. We have safe and effective treatments for everything from short-term treatment of pathological anxiety to previously intractable anxiety disorders like obsessive–compulsive disorder. Yet, the most important therapeutic agent we possess is still sound clinical skills and judgement. Appropriate diagnosis and rapport are the foundations of any pharmacological intervention we make with our patients.

Insomnia is a significant health care problem. It can create daytime fatigue, impaired social or occupational functioning, and reduced quality of life. Patients with insomnia are less productive workers, more prone to motor vehicle and workplace accidents, and utilize the general medical health care system to a greater degree than patients with normal sleep habits (Simon and VonKorff, 1997).

The elderly and patients with underlying psychiatric disorders are particularly prone to sleep difficulties. Schizophrenia, anxiety disorders and mood disorders frequently cause significant insomnia. Treatment of the underlying psychiatric illness often improves sleep. Sometimes, however, the medications used to treat the psychiatric illness may create insomnia as well. For example, selective serotonin reuptake inhibitors (SSRI) (particularly during the early weeks of treatment) may cause insomnia, even when they effectively treat an underlying depression.

### Nonprescription Agents

There are a number of over-the-counter (OTC) sleep aids used by patients suffering from insomnia (see Table 81.1). These agents typically contain the histamine ( $H_1$ ) receptor antagonist diphenhydramine (e.g., Benadryl, Somnex) or some other sedating antihistamine such as doxylamine (e.g., Nytol, Unisom). While these agents often cause significant drowsiness due to their antihistaminic properties, their effectiveness in treating insomnia has not been clearly established in randomized, placebo-controlled studies. They tend to have a prolonged duration of action leading to sedation and slowed reaction times during the day following their use. In addition, tachyphylaxis often develops within several days to a week or two limiting their use to only those patients with short-term problems with insomnia.

The OTC antihistamines are also highly anticholinergic and therefore may cause dry mouth, constipation, urinary retention and delirium quite easily. Geriatric patients are particularly susceptible to these anticholinergic effects. Patients already on other medications with significant anticholinergic activity should take these compounds quite judiciously as the anticholinergic effects could be magnified.

The common practice of combining an analgesic such as aspirin or acetaminophen and an antihistamine (e.g., Tylenol PM) is no more effective than the use of an antihistamine alone unless pain is present. As such, their use cannot be recommended for patients suffering from insomnia when pain is not a major complaint.

Melatonin is a naturally occurring pineal gland peptide hormone that is available in OTC formulations from a number of manufacturers. The Food and Drug Administration (FDA) classifies melatonin as a nutritive or dietary supplement. The Dietary Supplement Health and Education Act does not require

dietary supplements to be reviewed by the FDA and, as a result, the strength and purity of melatonin cannot be guaranteed. When purified or synthesized and taken orally, melatonin alters circadian rhythms, lowers core body temperature, and reduces daytime alerting phenomena originating in the suprachiasmatic nucleus. Some clinicians feel that melatonin may be particularly effective when the normal circadian cycle is disrupted (e.g., jet lag, shift work). A number of studies have yielded conflicting results regarding the efficacy and long-term safety of melatonin. Efficacy data may be somewhat conflicting due to the lack of solid data regarding appropriate dosing strategies. Efficacy has been reported with doses as low as 0.3 mg at bedtime. While there are no known long-term safety issues associated with the use of melatonin, treatment-emergent side effects include pruritus, tachycardia, headache and daytime drowsiness.

### Prescription Medications

Prescription medications for patients suffering from insomnia generally should be used only on a short-term basis. Benzodiazepines replaced barbiturates as the mainstay of treatment for much of the past 30 years. Benzodiazepines have a decreased abuse potential, fewer interactions with other drugs, a broader therapeutic index compared with the barbiturates, and pose a much lower risk in overdose. The adverse effect profile of benzodiazepines includes the risk for abuse and physiological dependence that develops with daily use, as well as problems with daytime sedation, motor incoordination and cognitive impairment. More recently the imidazopyridine, zolpidem and the pyrazolopyrimidine, zaleplon, have become increasingly popular as daytime sedation and the risk for abuse and physiological dependence appear to be somewhat less frequent with these two agents.

### Benzodiazepines

Benzodiazepines are clearly effective for transient and situational insomnias. A recent meta-analysis demonstrated that benzodiazepine treated patients reported improvement in sleep onset, number of awakenings at night, the total amount of sleep obtained, and the quality of sleep compared with placebo-treated patients (Nowell *et al.*, 1997). Although only five benzodiazepines are marketed as hypnotic agents (Table 81.2), any benzodiazepine could be used to induce sleep provided an appropriate dose is chosen. Benzodiazepines improve sleep by inducing drowsiness, relaxing muscles and decreasing mental agitation. As doses, and consequently brain concentrations, are increased, drowsiness and relaxation shift into decreased wakefulness and then sleep. Benzodiazepines increase total sleep time, increase non-rapid-eye-movement (non-REM) sleep, decrease sleep latency,

**Table 81.1** Some Over-the-Counter Sleep Aids Commonly Available in the USA

Unisom SleepGels	Diphenhydramine

\*Various strengths and formulations contain between 25 and 50 mg of the active antihistamine.

decrease stage 1 sleep and increase stage 2 sleep. Effects on stage 3 sleep vary based on the individual drug used, but stage 4 sleep is generally reduced.

Benzodiazepines are central nervous system depressants. Their likely mechanism of action relates to their ability to augment the opening of neuronal gamma-aminobutyric acid receptor-related chloride channels. By modulating the effects of gamma-aminobutyric acid, benzodiazepines increase the frequency of chloride channel openings. This effect is in contrast to the effects of barbiturates or alcohol, which seem to increase the duration

of chloride channel opening. While this distinction may appear minor, it accounts for the greater safety of benzodiazepines in overdose (i.e., there is less likelihood of respiratory depression or coma). When alcohol is mixed with a benzodiazepine overdose, the synergistic effects of respiratory depression can have potentially fatal consequences.

There is little convincing evidence that the five marketed benzodiazepine hypnotics differ in terms of efficacy or safety when they are administered appropriately (i.e., amounts, dosing intervals and duration of use). The current benzodiazepines marketed as hypnotic agents are similar in their effects on sleep architecture and differ only in onset of action and duration of action. The individual agent chosen should be based on the type of sleep difficulty being experienced, the age of the patient and comorbid diagnoses. Triazolam has a rapid onset and a short duration of action, making it a better choice for patients with sleep initiation difficulties, while flurazepam has a somewhat longer onset of action and a much longer duration of action, making it a better choice for patients with middle or terminal insomnia.

Shorter half-life benzodiazepine hypnotics cause less daytime sedation and residual cognitive affects the day following administration. Rebound insomnia often occurs with these agents, however, especially after use for several consecutive nights. Rebound insomnia can usually be avoided by tapering the dose or using lower dosages during treatment. There is some evidence to suggest that the likelihood of rebound insomnia is greater in patients who experience greater hypnotic efficacy.

Besides rebound insomnia, some patients receiving shorter half-life benzodiazepines have problems with middle or terminal

**Table 81.2** Hypnotic Agents

Generic Name	Trade Name	Dose Strengths (mg)	Half-Life (h)	Onset of Action	Comments
Chloral Hydrate	Noctec	500 mg/5ml	8–10	Intermediate	Active metabolite trichloroethanol has CNS depressive effect
Triazolam	Halcion	0.125, 0.25	1.5–5.5	Intermediate	May cause anterograde amnesia
Temazepam	Restoril	7.5, 15, 30	9–12	Slow	No active metabolites

Flurazepam	Dalmane	15, 30	30–100	Fast	Active metabolite desalkylflurazepam accumulates and causes additive sedation
Quazepam	Doral	7.5, 15	25–40	Intermediate	Same active metabolite as flurazepam
Eszopiclone	Lunesta	1, 2, 3	6	Fast	
Zalepalon	Sonata	5, 10	1	Fast	
Zolpidem	Ambien	5, 10	1.4–4.5	Fast	
Ramelteon	Rozerem	8	1–2.6	Slow	Unique MOA melatonin receptor subtype agonist

insomnia. Plasma levels are quite low several hours after taking these medications and, as a result, if there is a problem with sleep maintenance these agents are not as likely to be as helpful as hypnotics with longer half-lives. In addition, shorter half-life benzodiazepines can sometimes cause an increase in daytime anxiety, particularly in the morning. For at least some patients, this may reflect the development of physiologic dependence and a withdrawal phenomenon.

Shorter half-life hypnotics, particularly triazolam, appear to cause anterograde amnesia more commonly than the longer half-life agents. Numerous reports in the lay press regarding a greatly increased risk of hallucinations, confusion and anterograde amnesia with triazolam use does not appear to be supported by an examination of all available data. All benzodiazepines can cause anterograde amnesia, however, particularly at higher dosages. Anterograde amnesia commonly occurs following a benzodiazepine overdose. The prevalence of anterograde amnesia with appropriate dosing of sedative–hypnotic agents and risk factors for its development in patients are still open questions at this time.

Longer half-life benzodiazepines may be more appropriate for patients who suffer from middle or terminal insomnia since these agents retain significant sedative properties for many hours after initial administration. Some patients may have problems with daytime sedation or decreased reaction time the day following administration. Sedative agents such as flurazepam and quazepam that have active metabolites with long half-lives are particularly prone to causing such problems. The active metabolite often builds up over time causing an increase in daytime drowsiness, decreased reaction time and in coordination with repeated administration, particularly in the elderly. Patients with significant daytime anxiety may benefit from the longer acting benzodiazepines as the residual amount of medication left in the morning may still have anxiolytic benefits.

The elderly use benzodiazepine hypnotic agents to a much greater degree than the general adult population. While this is likely due to the greater prevalence of sleep disorders in the elderly, the use of hypnotic agents in this population poses particular challenges. The elderly as a group have a decrement in hepatically metabolized benzodiazepines (e.g., estazolam, flurazepam, quazepam, triazolam), which is often more pronounced among men. Incoordination, sedation and confusion can occur when such agents build up over time. Ray and colleagues found a much higher rate of falls and hip fractures in the elderly population that received long-acting benzodiazepine hypnotics. The risk of hip fracture increased in direct proportion to the daily dose of the long-acting benzodiazepine. Short-acting benzodiazepines were not found to have a similar problem in their two large case–control studies (Ray *et al.*, 1987, 1989). A generally safe clinical strategy when managing insomnia problems in the elderly is to halve the starting dose and titrate up slowly as tolerated following the longstanding advice “start low, go slow”. Avoiding long-acting benzodiazepines appears prudent as well.

Drug interactions with benzodiazepines are quite common. When mixed with other sedating compounds the effects are additive. Narcotic medications, alcohol and antihistamines are examples where the additive sedation can lead to confusion quite easily. In addition, acute alcohol ingestion slows hepatic metabolism and causes transiently higher concentrations of

oxidatively metabolized benzodiazepines leading to further sedation. Antacids that slow gastric emptying may decrease the rate of absorption of a hypnotic agent from its primary site of origin, the small intestine. This could alter both onset and peak concentration effects.

Benzodiazepines all undergo some form of hepatic metabolism, although some agents are much more extensively metabolized than others. Medications that inhibit hepatic microsomal oxidative metabolism may cause clinically meaningful drug interactions when combined with benzodiazepines. All currently available triazolobenzodiazepines (e.g., alprazolam, estazolam, midazolam, triazolam) and diazepam are metabolized by hepatic microsomes and are complete or partial substrates of the CYP 3A4 isoform. Medications that are potent inhibitors of this system will cause higher peak concentrations of the triazolobenzodiazepine, particularly triazolam, which is highly hepatically metabolized. Nefazodone, ketoconazole, cimetidine and macrolide antibiotics are examples of clinically relevant CYP 3A4 inhibitors which may cause a reduction in the clearance of these triazolobenzodiazepines and an increase in their blood and brain concentrations. This increase is greatest with higher hepatic clearance drugs such as triazolam or midazolam and somewhat less for drugs such as alprazolam or estazolam.

All benzodiazepine hypnotic agents are FDA Pregnancy Category X, meaning their use should be avoided during pregnancy, especially during the first trimester due to an increased risk of congenital malformations. A variety of congenital malformations, including cleft palate, delayed ossification of a number of bony structures and an increased occurrence of rudimentary ribs have been reported.

Benzodiazepines must be used in patients with obstructive sleep apnea only with extreme caution. Benzodiazepines may cause respiratory depression and can render patients less likely to mount an appropriate respiratory response to hypoxia. Hypnotic agents such as zolpidem, zaleplon, or trazodone are less likely to cause problems for sleep apnea patients and may be preferable alternatives. Aggressive evaluation and treatment of sleep apnea [e.g., (continuous positive airway pressure) CPAP] is extremely important to ensure adequate restorative sleep.

## Chloral Hydrate

Chloral hydrate was among the earliest sleeping pills. Its sedating qualities become evident within 30 minutes of administration, as it is rapidly absorbed from the gastrointestinal tract. At dosages between 0.5 and 1.5 g, it is an effective hypnotic agent. The elimination half-life of its active metabolite, trichloroethanol, is 6 to 8 hours, rendering it unlikely to cause significant next-day sedation or functional impairment. Despite the potential benefits of a rapid onset of action and relatively short elimination half-life, chloral hydrate is rarely used as a hypnotic agent today. It has a narrow therapeutic index (toxic dose–therapeutic dose), causes gastric irritation, nausea and vomiting easily, and may cause gastric necrosis at high doses. Overdose can be fatal due to respiratory depression.

## Zolpidem

Zolpidem is also a nonbenzodiazepine hypnotic. A member of the imidazopyridine class, it is available in 5 and 10 mg dosages. Its mechanism of action shares much in common with benzodiazepines as it is active at central benzodiazepine (sometimes called  $\omega$ ) receptors. The  $\omega$  receptor is a subunit of the GABA<sub>A</sub>

receptor. Benzodiazepines are thought to bind nonselectively and activate all  $\omega$  receptor subtypes; by contrast, zolpidem appears to bind preferentially to  $\omega_1$  receptors. Although this selective binding is not absolute, it may explain the relative absence of myorelaxant, anxiolytic and anticonvulsant effects of zolpidem at hypnotic dose, as well as the preservation of stages 3 and 4 sleep. Polysomnographic experience with zolpidem indicates that zolpidem induces a sleep pattern very similar to that of physiological sleep, and generally produces little effect on sleep architecture following abrupt discontinuation (Darcourt *et al.*, 1999).

Zolpidem is rapidly absorbed through the gastrointestinal tract and has a rapid onset of action. Peak concentration occurs from 30 minutes to 2 hours following administration. It is metabolized in the liver to several inactive metabolites and has an elimination half-life of approximately 2.5 hours. The elimination half-life is prolonged in the elderly and in patients with impaired hepatic or renal function. Zolpidem overdose can cause respiratory depression or coma, especially when combined with other CNS depressants. The benzodiazepine antagonist flumazenil can reverse the effects of an overdose of zolpidem, reflecting its benzodiazepine-like mechanism of action.

Although zolpidem is classified as a schedule IV drug by the FDA, it appears to cause tolerance and withdrawal syndromes somewhat less frequently than benzodiazepine hypnotics do. Withdrawal symptoms occur more frequently at doses higher than listed in the *Physician's Desk Reference* (PDR), which recommends a maximum dose of 10 mg. Cross tolerance with alcohol and benzodiazepines are found at higher doses, and the incidence of adverse effects is much higher. Anecdotal reports of hallucinations and confusion at standard hypnotic dosages have been reported (Toner *et al.*, 1999, Ansseau *et al.*, 1992), but further research is needed to determine the prevalence of such occurrences across a spectrum of dosages and age groups.

## Zaleplon

Zaleplon is a nonbenzodiazepine hypnotic of the pyrazolopyrimidine class. Like zolpidem, zaleplon binds preferentially to central benzodiazepine (or  $\omega$ ) receptors. Zaleplon binds to the  $\omega_1$ ,  $\omega_2$  and  $\omega_3$  subunits, while zolpidem bind only to the  $\omega_1$  subunit. Zaleplon is rapidly absorbed from the gastrointestinal tract, reaching peak serum concentrations within 1 hour. Absolute bioavailability is only 30% as it undergoes extensive hepatic first-pass metabolism. Its elimination half-life is approximately 1 hour. Since cimetidine inhibits aldehyde oxidase and CYP 3A4, and may increase zaleplon plasma concentrations by 85%, the initial starting dose of zaleplon should be halved in patients also taking cimetidine. Other potent inhibitors of the CYP 3A4 system such as ketoconazole and erythromycin also may increase zaleplon levels.

Because of the quick onset of action of zaleplon and its short elimination half-life, it can be used for patients who have a difficult time initiating sleep, but are able to remain asleep throughout the remainder of the night. In patients who have difficulty both in initiating and in maintaining sleep, zaleplon may permit the initiation of sleep, but be less effective in maintaining sleep due to its short elimination half-life. On the other hand, this same short half-life can be an advantage, as it can permit middle of the night dosing for those patients who awaken then. The short half-life permits such a dosing schedule without causing significant next-day sedation (Walsh *et al.*, 2000).

Zaleplon, like zolpidem, is classified as a schedule IV drug by the FDA. Higher than standard dosages have been associated with an abuse potential similar to that of triazolam. With dosages

of 20 mg or less, abuse and dependence appears to be significantly less than that of benzodiazepine hypnotic agents (Rush *et al.*, 1999). Rebound insomnia has been reported, but it appears to occur less frequently than in the short acting benzodiazepines such as triazolam.

## Other Prescription Hypnotics

Barbiturates are commonly prescribed outside the USA for insomnia. Butabarbital, phenobarbital and secobarbital are the most commonly prescribed barbiturates. The barbiturates are potentially lethal in overdose due to the risk of respiratory depression, and they commonly cause induction of hepatic oxidative metabolism. Their use has generally been replaced by other agents with better side-effect profiles such as the benzodiazepines, the imidazopyridines and the pyrazolopyrimidines.

Hydroxyzine hydrochloride and hydroxyzine pamoate are sedating  $H_1$  receptor antagonists that are used occasionally as hypnotic agents. Sedation occurs with these agents due to inhibition of histamine *N*-methyltransferase and blockage of central histaminergic receptors. Next-day sedation is a common problem with antihistamines as they have a relatively long elimination half-life. These agents are highly anticholinergic and may cause hypotension and are not usually recommended as first-line agents for the treatment of insomnia.

Trazodone, a triazolopyridine compound marketed as an antidepressant, is frequently used as a hypnotic. Hypnotic dosages vary markedly, from 25 to 300 mg, depending on individual susceptibility to its sedating effects. Trazodone increases slow wave sleep and total sleep time and does not appear to affect REM sleep, unlike other antidepressants (Yamadera *et al.*, 1998). Its elimination half-life of between 6 and 9 hours renders trazodone likely to cause daytime drowsiness. Using the lowest effective dosage can minimize this effect, as taking the medication in late evening rather than at bedtime. Trazodone is commonly used to counter the insomnia associated with SSRI use. It is rarely used as a sole antidepressant because of its strong sedating qualities and the need to take the medication more than once per day because of its half-life. Tolerance to its sedating effects develops only rarely with long-term use, making it an excellent option for those with chronic insomnia. Priapism is an exceedingly rare side effect, occurring in less than one in 40 000 cases. Since anticholinergic side effects and postural hypotension are not common, trazodone has some advantages over the tricyclic antidepressants.

## Suggested Guidelines for Prescribing Medications

It is often clinically useful to provide patients with information on good sleep hygiene practices. Certain elements are particularly important (e.g., going to another room and waiting until drowsy or looking for clues about waking life events, and issues that may be keeping one awake). Behavioral techniques such as stimulus control and progressive muscle relaxation are quite useful. When a hypnotic agent is prescribed, it is helpful to advise patients to take the medication on an empty stomach and with ample fluids (e.g., a full glass of water) to promote rapid dissolution and absorption, and onset of effect. For patients prone to nocturia the amount of fluids should be lessened substantially. One should always caution patients about potential impairments in memory, coordination, or driving skills and about unsteadiness if they are awakened after having taken a sleep aid. It is

also important to remind them that if they use the medication for more than a few nights, some pattern of tapering should be followed when they stop. It is reinforcing to work out a discontinuation schedule at the time of the first prescription. Patients should also be cautioned to avoid the use of alcohol when taking a hypnotic as the effects are additive in nature. Medications such as the benzodiazepines that have a propensity to be abused should be avoided in those patients with drug or alcohol problems.

Universally accepted guidelines for dosing and duration of use for hypnotics are not established. Both dose and duration must be individualized with the goal of finding the lowest dose and the shortest duration. Short-term treatment (i.e., from 1 or 2 nights to 1 or 2 weeks) is reasonable for most patients. However, some patients with chronic insomnia may benefit from longer-term use provided that there is careful monitoring by the prescribing physician. No criteria are presently available to identify this subpopulation. It seems reasonable to consider several short-term trials, with gradual tapering at the end of each period and a drug-free interval between each period, to establish the patient's need for and the appropriateness and value of continued therapy. The drug-free time interval between the initial periods should range from 1 to 3 weeks, depending on the half-life of the agent and its active metabolites and the rapidity of the taper schedule. Reevaluation of such a patient's continued need for hypnotic medication at 3- to 6-month intervals is also reasonable. Because the elderly are particularly susceptible to falls or confusion from hypnotic medication, use of the lowest available dosage strength is advisable. The elderly should also avoid the use of longer half-life agents or those with active metabolites with long half-lives because such medications tend to accumulate over time in older patients due to pharmacodynamic differences in drug metabolism in the elderly.

For those individuals who hope to benefit from behavioral and nonpharmacological approaches to their insomnia, prescribing hypnotics two or three times per week while they are working out such modifications may be beneficial. Because there are few predictable central tendencies that characterize patients with primary insomnia, individual variation is likely.

# Stimulants and Related Compounds

Psychostimulants are highly effective treatment agents that have been used for the treatment of depression, attention-deficit/hyperactivity disorder (ADHD), neurasthenia and acquired immunodeficiency syndrome dementia. However, the greatest clinical application for psychostimulants has been the treatment of childhood disorders, in particular, ADHD. More than 180 placebo-controlled investigations demonstrate that psychostimulants – methylphenidate and amphetamines are effective in reducing core symptoms of childhood ADHD. Approximately 70% of patients respond to stimulants compared with 13% to placebo. Short-term efficacy is more pronounced for behavioral rather than cognitive and learning abnormalities associated with ADHD. Although psychostimulants are clearly effective in the short term up through 14 months, concern remains that long-term benefits over years have not yet been adequately assessed.

## Psychostimulants: Efficacy and Utility

Two groups of stimulants are currently approved by the FDA for treatment of ADHD in children, and are available in both brand and generic. These include: the amphetamines (Adderall, Dextrostat, Dexedrine) and the methylphenidates (Concerta, Metadate-ER, Metadate-CD, methylphenidate, Methylin, Ritalin, Ritalin-SR, Ritalin-LA and Focalin). Characteristics of these stimulants can be found in Table 82.1. Dextroamphetamine (DEX) and methylphenidate (MPH) are structurally related to the catecholamines (DA and NE) (McCracken 1991). Signs of CNS stimulation, including blood pressure and heart rate increases, are more pronounced in adults. The term **psychostimulant** used for these compounds refers to their ability to increase CNS activity in some but not all brain regions. Stimulants ameliorate disruptive ADHD behaviors cross-situationally (classroom, lunchroom, playground and home) when repeatedly administered throughout the day.

## Mechanism of Action

The term psychostimulant refers to the ability of these compounds to increase CNS activity in some but not all brain regions. For example, while increasing the activity of striatum and connections between orbitofrontal and limbic regions, stimulants seem to have an inhibitory effect on the neocortex. The CNS psychostimulant effects of DEX and MPH may result in part from their lack of benzene ring substituents. Prominent central effects include activation of the medullary respiratory center and a lessening of central depression from barbiturates.

Psychostimulants have been described as noncatecholamine sympathomimetics. Sympathomimetics show potent agonist

**Table 82.1 Side Effects of Stimulants**

Common Side Effects	Uncommon Side Effects
Decreased appetite	Nail biting
Insomnia	Skin rash
Headaches	Psychosis
Stomachaches	Hepatitis and liver failure (pemoline)
Crying spells and irritability	
Tics and other nervous movements	
Dizziness	
Drowsiness	
Raised blood pressure	
Raised heart rate	
Transient weight loss	
Delayed growth	

effects at alpha- and beta-adrenergic receptors. Presynaptically, they cause a stoichiometric displacement of norepinephrine and dopamine from storage sites in the presynaptic terminal. Stimulants also block the reuptake of dopamine by the dopamine transporter (DAT). Postsynaptically, they function as direct agonists at the adrenergic receptor. They also block the action of a degradative enzyme, catechol-*o*-methyltransferase (COMT).

The putative action of psychostimulants in ADHD has been attributed to the release of DA and their ability to block its reuptake by the DAT at the presynaptic nerve terminal. Radioligand binding studies have demonstrated the direct action of psychostimulants, particularly MPH, on striatal DAT. The dopamine action of psychostimulants also explains the appearance of behavioral stereotypies, seen at high doses. Tritiated MPH binding in rat brain is highest in striatum and is highly dependent on sodium concentration, suggesting that MPH binding is associated with a neurotransmitter transport system.

Yet, no single theory explains the psychostimulant mechanism of action on the CNS which ameliorates ADHD symptoms.

Most hypotheses regarding the neurochemical basis of ADHD have focused on the catecholamines norepinephrine and dopamine. These hypotheses, which posit a dysregulation in

the norepinephrine or dopamine neurotransmitter systems, or both, are based primarily on the success of these dopaminergic medications in treating ADHD. All stimulant medications used for treating ADHD have their primary effects on these two neurotransmitter systems. Furthermore, the more selective norepinephrine-acting tricyclic medications, such as desipramine and imipramine, as well as the alpha-2-adrenergic agonist clonidine, have all been found to reduce symptoms of ADHD in children. Similarly, although much less commonly used, dopamine-blocking antipsychotic medications also have been found to be effective for treating children with ADHD (Zametkin and Rapoport, 1987).

### Pharmacokinetics: Absorption and Metabolism

Psychostimulants are rapidly absorbed from the gut and thus act quickly, often within the first 30 minutes after ingestion. Food enhances absorption. Due, in part, to MPH's low plasma binding rate (15%), it is highly available to cross the blood–brain barrier. Effects on behavior appear during absorption, beginning 30 minutes after ingestion and lasting 3 to 4 hours. Half-lives range between 3 hours for MPH and 6 to 9 hours for *d*-amphetamine. The concentration-enhancing and activity-reducing effects of MPH can disappear well before the medication leaves the plasma, a phenomenon termed **clockwise hysteresis**.

MPH's metabolism is rapid and complete because it is not highly bound to plasma protein and does not disappear into fat stores. MPH peaks in plasma in 2 to 2.5 hours and falls to half the peak (half-life) after 3 hours.

Because MPH's short half-life prevents it from reaching steady state in the plasma, the standard tablet must be given several times a day to maintain behavioral improvement throughout the school day. Although the Physicians' Desk Reference (PDR) suggests giving MPH before meals, standard administration times are after breakfast (8:00 AM), after lunch (noon), and before homework (about 3:30 pm). See Table 82.2 for review of some of the pharmacokinetics of the psychostimulants used to treat children with ADHD.

### Effects in Adults

Studies in adults taking *d*-amphetamine have shown a prolongation of performance at repetitive tasks before the onset of fatigue, a decreased sense of fatigue, mood elevation, euphoria, and

increased speech rate and initiative (Rapoport *et al.*, 1980). The psychostimulants increase CNS alertness, as shown on tasks requiring vigilance, both in laboratory tasks, such as the CPT, and on the job, such as maintaining the ability to notice new events on a radar screen for periods of hours. These changes have been described as the drug's ability to "increase capacity", although this phrase has been misinterpreted to mean an increase over the person's innate ability.

### Substance Abuse of Stimulants

Psychostimulants have been abused by adults, but the risk for addiction by children with ADHD is low. Klein (1980) found that the psychostimulants differ in their ability to induce euphoria, with "dextroamphetamine the most euphorogenic, methylphenidate, less so, and magnesium pemoline, hardly at all." Adolescents and young adults with ADHD do not list the psychostimulants among medications used recreationally, whether or not they had received treatment with psychostimulants. Adolescents previously diagnosed as having ADHD during their school-age years are at greater risk for substance abuse than control subjects, but those who do abuse medications tend not to pick stimulants.

Even though the evidence from the literature suggests that the abuse potential of psychostimulants by children with ADHD is low, DEX and MPH have been classified by the US Food and Drug Administration as potentially drugs of abuse (schedule II) and have warnings concerning abuse in the PDR. MPH was reclassified as a schedule II medication in 1971 because of a concern that the order by the Bureau of Narcotics and Dangerous Drugs to schedule methamphetamine and DEX would direct potential drug abusers to MPH. As a schedule II medication, the annual amount of stimulant medication manufactured must be approved or allocated.

## Formulation of Treatment

### What Is Being Treated

There are two main indications for the use of MPH: narcolepsy and ADHD. Other stimulants differ somewhat, with the indications for methamphetamine (Desoxyn Gradumets) including ADHD and obesity.

**Table 82.2 Drug Interactions**

Medication	Stimulant	Effect
Guanethidine	MPH	Decreased hypotensive effect of guanethidine
Coumarin	MPH	Decreased metabolism of coumarin
Antiepileptic medications (phenobarbital, diphenylhydantoin, primidone)	MPH	Decreased metabolism of antiepileptic agents
Phenylbutazone	MPH	Decreased metabolism of phenylbutazone
Tricyclic antidepressants	MPH	Decreased metabolism of antidepressant
Ammonium chloride	DEX	Increased elimination of DEX
Sodium phosphate	DEX	Increased elimination of DEX
Acetazolamide	DEX	Delayed elimination of DEX
Thiazide diuretics	DEX	Delayed elimination of DEX
Sympathomimetics	MPH, DEX	Increased sympathomimetic effects
Sympatholytic antihypertensives (beta-blockers, others)	MPH, DEX	Decreased antihypertensive effect of antihypertensives

## Diagnosis of the Stimulant-treatable Disorders

### Attention-deficit/Hyperactivity Disorder

ADHD is a heterogeneous behavioral disorder of unknown etiology. As its name suggests, ADHD is characterized by inattention, impulsivity and hyperactivity of varying severity. The disorder, which typically begins in early childhood and lasts into adulthood in a substantial minority, if not a majority, of cases, frequently leads to profound social and academic impairments. For a complete discussion of the ADHD diagnosis, see Chapter 28.

### Narcolepsy

Narcolepsy is a chronic neurological disorder that presents with excessive daytime sleepiness and various problems of rapid eye movement physiology, such as cataplexy (unexpected decreases in muscle tone), sleep paralysis and hypnagogic hallucinations, which are intense dream-like imagery before falling asleep (Dahl, 1992). For a more complete discussion of narcolepsy, see Chapter 59. The prevalence is estimated to be 90 in 100,000. Treatment can include a regular schedule of naps; counseling of family, school and patient; and use of medications, including stimulants and rapid eye movement-suppressant drugs such as protriptyline. Dahl recommended beginning with standard, short-acting stimulants, such as MPH, 5 mg b.i.d., and increasing the dose up to 30 mg b.i.d. if need be.

## Selection of a Stimulant Medication as a Treatment Modality

### Deciding to Use Medication

The decision to use stimulant medication in the treatment of ADHD employs different criteria for each developmental stage. The criteria for use of stimulants in school-age children and adolescents are well described in the DSM-IV-TR. More difficulty arises when deciding whether to use these medications in preschool children, adult patients, patients with mental retardation, or children with ADHD and comorbid disorders.

### Use of Psychostimulants in Children Younger than 6 Years

Unfortunately, there are only a handful of published treatment studies on preschoolers. No dose-ranging pharmacokinetic studies have been done in this age group to determine if younger children, with their larger liver-to-body size ratio, might show more accelerated metabolism of psychostimulants than seen in older children. Therefore, the optimal doses for this age group are not known. To date there are no studies that would validate or refute clinicians' concerns that preschoolers suffer more pronounced stimulant withdrawal effects.

### Adults

The prevalence of ADHD in adults, its severity and indications for treatment are issues that are not known. Although it had been assumed that children with ADHD outgrow their problems, prospective follow-up studies have shown that ADHD signs and symptoms continue into adult life for as many as 60% of children with ADHD (American Psychiatric Association, 1980). However, only a small percent of adults impaired by residual ADHD symptoms actually meet the full DSM-IV childhood criteria for ADHD (Hill and Schoener, 1996). Adults with concentration problems, impulsivity, poor anger control, job instability and marital difficulties sometimes seek help for problems they believe to be the

manifestation of ADHD in adult life. Parents may decide that they themselves are impaired by the same attentional and impulse control problems found during an evaluation of their ADHD children.

A variety of medications have been used to treat adults with ADHD. Physicians should be cautious in the use of these agents until proof of efficacy is available. Of particular concern is the danger of using psychostimulants in adults with comorbid substance abuse disorder. It would be wise to use MPH because of its relatively low abuse potential, and because it has been shown in controlled studies to significantly reduce the symptoms of ADHD in adults (see Table 82.3).

## Continuing Stimulant Treatment in Patients with Tic Disorders

Standard package instructions for using MPH warns against its use in patients with tics or in patients with a family history of tics. Patients with Tourette's syndrome often have comorbid ADHD. If the two conditions co-occur, concern arises that stimulant treatment – because of its dopamine agonist actions – might unmask, trigger, accelerate, or precipitate more severe tics.

Tics are unacceptably worsened for a minority of comorbid children, although reversibly, and the majority of such comorbid children can be treated cautiously with low-to-moderate doses of stimulants, particularly MPH (Comings and Comings, 1987).

## Patients with Mental Retardation

Many stimulant treatment studies for school-age children with ADHD exclude children with full-scale IQs below 70, who are considered to have mental retardation (MR). This is unfortunate, for the signs of ADHD are far more prevalent in children with IQs in the MR range (Aman *et al.*, 1991). Pharmacotherapy reviews involving patients with MR have reported that institutionalized subjects with severe or profound MR respond poorly to stimulants. However, studies involving community samples of children with MR, have shown that these children do respond to MPH. It appears that children with ADHD who have mild or moderate MR may be more vulnerable to certain stimulant-related adverse side effects.

## Does Comorbidity Affect the Indications for the Use of Stimulant Medication?

ADHD children that are referred from other physicians may have other Axis I psychiatric disorders. Extensive literature reviews report that ADHD co-occurs with conduct and oppositional defiant disorder in 30 to 50% of cases, with mood disorders in 15 to 75% of cases, with anxiety disorders in 25% of cases and with learning disabilities in 15 to 30% of cases. Clinicians should be aware that co-morbid ADHD/anxiety disorders may result in lesser response to treatment more side effects.

## Treatment with Stimulant Medications

An effective treatment strategy for this chronic disorder of ADHD requires a plan for follow-up and monitoring. Techniques involve regular follow-up visits, the use of rating forms from parent and teacher, and the monitoring of academic progress in the school. Seeing the patient and a family member regularly is essential, often on a once-monthly basis when the medication prescription must be renewed.

## Preparation of the Patient

Does the child's attitude about drug treatment influence its success? Concerns that medications may create negative attributions or

**Table 82.3** Drugs for ADHD: Doses, and Pharmacodynamics

Medication	Tablets/Dosages	Dose Range	Administration	Peak Effect	Duration of Action
<i>Amphetamines</i>					
Dexedrine®	5 mg	10–40 mg/d	b.i.d. or t.i.d.	1–3 h	5 h
(generic) Adderall	5, 7.5, 10, 12.5, 15, 20, 30 mg	10–40 mg/d	b.i.d. or t.i.d.	1–3 h	5 h

Medadate-CD®	20 mg	20–60 mg/d	q.d. in am	5 h	8 h
Concerta®	18, 36, 54 mg	18–54 mg/d	q.d. in am	8 h	12 h
Ritalin-LA®	20, 30, 40 mg	20–60 mg/d	q.d. in am	5 h	8 h
Modafinil	85 mg	1.25–4.5 mg/kg	b.i.d.	2 hours	8 hours

dysphoric effects in children with ADHD have not as a rule been confirmed in direct tests. Excellent studies show that there is considerable variability in children's attributions, as well as their mood response to pills. Pelham and colleagues (1992) found a subgroup of "depressogenic" children who gave external credit for positive events and internal blame for negative events. This group was above the median on attributions of success to their pills. Comorbidity and family history for anxiety and/or depression seemingly are relevant variables in prediction of such attributional effects. During treatment, a small percentage of stimulant-treated children do become dysphoric, weepy and mournful. Children who respond with depressogenic attributions or dysphoria may be children whose depressive diathesis is indistinguishable from ADHD and who are therefore mistakenly diagnosed as ADHD and treated with stimulants. Given the overlap of depression and ADHD, and the findings that depressogenic cognitive styles predict later depression, it could be important to identify those children who may be prone to attribute their success to pills rather than to their own effort, even though most patients do not do so.

Physicians can explain the reasons for taking pills and how the pills can prove helpful in school and at home. Children often have negative attitudes about treatment, thinking of treatment as a punishment. Pill taking can be socially stigmatizing to the child with ADHD if the daily trip to the nurse generates peer ridicule. Discussing the problem of in-school pill administration may be of great interest to the child, and he or she should be included in all discussions about dosing and changing of doses. At best, it may help with compliance.

### Consideration of Side Effects

Common side effects and their management are noted in Table 82.4. Stimulant side effects are dose dependent and range from mild to moderate in most children. The management of stimulant-related adverse effects generally involves a temporary

reduction of dose or a change in time of dosing. MPH has an excellent safety record, probably because the duration of action is so brief.

**Rebound** One adverse effect, commonly known as behavioral rebound, appears when children experience psychostimulant withdrawal at the end of the school day. Children present with afternoon irritability, overtalkativeness, noncompliance, excitability, motor hyperactivity and insomnia about 5 to 15 hours after the last dose. If rebound occurs, many physicians add a small afternoon MPH dose or add a small dose of a tricyclic antidepressant.

**Seizure Disorders** A commonly held notion is that stimulants lower the seizure threshold. The PDR warns against the use of stimulants in children with preexisting seizure disorders. Both ADHD and seizure disorders are quite prevalent and may occur in the same individual, so the question of the risk of stimulant treatment may frequently arise. Current practice is to give children with ADHD and epilepsy a combination of anticonvulsant and MPH. Plasma levels of the anticonvulsant should be monitored to avoid toxicity resulting from MPH's competitive inhibition of metabolic pathways. At the doses used to treat ADHD in children, the psychostimulants have variable but minimal effects on the seizure threshold.

### Long-term Stimulant Effects: Growth Velocity Reductions

Adults taking amphetamines routinely experience weight loss, which can be attributed to reduced appetite and decreased food intake. The drug's action on the lateral hypothalamic feeding center may explain this effect. Appetite suppression differs among different species, with humans showing only mild effects with rapid onset of tolerance. Children with ADHD taking psychostimulants routinely show appetite suppression when starting

**Table 82.4 Stimulant Pharmacokinetics and Pharmacodynamics**

Parameter	Dextroamphetamine	Methylphenidate	Adderall
Metabolism	Hepatic to inactive metabolites	Hepatic to inactive metabolites	Hepatic to inactive or weakly active metabolites
Excretion	Renal, of metabolites; rate accelerated by acidification	Renal, of metabolites	Renal; rate accelerated by acidification
$T_{\max}$	2–4 h	1–3 h	2–4 h
Half-life	6–8 h	2–4 h	5–7 h
Effect onset	30–60 min	30–60 min	30 min
Effect peak	1–3 h	1–3 h	1–3 h
Effect duration	3–5 h	2–4 h	3–5 h

treatment. For this reason, dosing should optimally occur after breakfast and lunch. Even though the daytime appetite is reduced, hunger rebounds in the evening. These effects on appetite often decrease within the first 6 weeks of treatment.

The growth effects of MPH appear to be minimal. Height and weight should be measured at 6-month intervals during stimulant treatment and recorded on age-adjusted growth forms to determine the presence of a drug-related reduction in height or weight velocity. If such a decrement is discovered during maintenance therapy with psychostimulants, a reduction in dosage or change to another class of medication can be carried out.

### Continuing Stimulant Treatment in Patients with Tic Disorders

The PDR suggests that the presence of tics is a contraindication to stimulant usage. With the comorbidity of ADHD in children with Tourette's disorder estimated to fall between 20 and 54%, there is a concern that a stimulant's dopamine agonist action will unmask, trigger, accelerate, or provoke irreversible Tourette's symptoms. This worry is enhanced by a number of papers, some of them retrospective, that reported onset of tics after stimulant treatment had begun.

### Drug Interactions

(See Table 82.5 for a listing of common drug interactions.)

Mixing psychostimulants with other psychotropic medications is generally not advisable. Most serious is the addition of a psychostimulant to a monoamine oxidase inhibitor antidepressant regimen, a potentially lethal combination that can elevate blood pressure to dangerous levels. Additive effects between psychostimulants and the systemic agents used to treat asthma can produce feelings of dizziness, tachycardia, palpitation, weakness and agitation. Theophylline, for example, when taken orally (Theo-Dur Sprinkle), can have this undesirable agitating effect. It is best to ask the pediatrician or allergist to switch from the orally ingested preparation to an inhalant to avoid such additive sympathomimetic effects.

Psychostimulants compete with other medications for the same metabolic pathway and have been thought to produce an increase in the plasma concentration of both drugs. The psychostimulants can also interfere with the action of other medications. MPH can block the antihypertensive action of guanethidine. DEX blocks the action of some beta-adrenergic

antagonists (e.g., propranolol) and slows the intestinal absorption of phenytoin and phenobarbital. The renal clearance of DEX is enhanced by urine acidifying agents, so that grapefruit juice will shorten the elimination half-life of the medication. Conversely, urine alkalinizing agents decrease clearance. This is also true for ritalinic acid, although this metabolite is not active in the CNS. MPH may elevate the plasma level of antidepressants, anticonvulsants, coumarin anticoagulants and phenylbutazone. MPH may increase the concentration of the serotonin reuptake blocker fluoxetine, potentially enhancing agitation, although no such side effect was seen in a single case report of the treatment of an 11-year-old boy with both ADHD and obsessive-compulsive disorder. Other medications have been combined successfully with MPH, such as clonazepam to reduce tics. Clonidine has been added to reduce sleep disturbances associated with ADHD and with stimulant medication. Bupropion may exacerbate tics when added to MPH given to children with ADHD.

### Initiation of Treatment

Medication treatment begins with a choice of medication. Although the MPH or DEX psychostimulant types have equal efficacy, MPH is often used first.

Titration serves two purposes: acclimatization of the child to the drug and determination of his or her best dose. School-age children should be started with low doses to minimize adverse effects. Psychostimulant medication should be taken at or just after mealtime to lessen the anorectic effects; studies have shown

**Table 82.5 Experimental Medication Therapies for Adults with Attention-deficit/Hyperactivity Disorder**

Possible Medication Treatments	Suggested Dose Range
Methylphenidate (Ritalin)	5 mg b.i.d.–20 mg t.i.d.
Amphetamine (Dexedrine)	5 mg b.i.d.–20 mg b.i.d.
Mixed amphetamine salts (Adderall)	5 mg b.i.d.–20 mg b.i.d.
Bupropion (Wellbutrin)	100 mg b.i.d.–100 mg t.i.d.
Selegiline (Eldepryl)	5 mg b.i.d. only

**Table 82.6 Stimulant Side Effects and Management**

Side Effect	Management
For all side effects	Unless severe, allow 7–10 d for tolerance to develop. Evaluate dose–response relationships. Evaluate time–action effects and then adjust dosing intervals or switch to sustained-release preparation. Evaluate for concurrent conditions, including comorbidities and environmental stressors. Consider switching stimulant drug.
Anorexia or dyspepsia	Administer before, during, or after meals.
Weight loss	Give drug after breakfast and after lunch. Implement calorie enhancement strategies. Give brief drug holidays.
Slowed growth	Apply weight loss remedies. Give weekend and vacation (longer) drug holidays. Consider another stimulant or nonstimulant drug.
Dizziness	Monitor blood pressure and pulse. Encourage adequate hydration. If associated with only $T_{max}$ , change to sustained-release preparation.
Insomnia or nightmares	Administer earlier in day. Omit or reduce last dose. If giving sustained preparation, switch to tablet drug. Consider adjunctive antihistamine or clonidine.
Dysphoric mood or emotional constriction	Reduce dose or switch to long-acting preparation. Switch stimulants. Consider comorbidity requiring alternative or adjunctive treatment.
Rebound	Switch to sustained-release preparation. Combined long- and short-acting preparations.
Tics	Firmly establish correlation between tics and pharmacotherapy by examining dose–response relationship, including no-medication condition. If tics are mild and abate after 7–10 d with medications, reconsider risks and benefits of continued stimulant treatment and renew informed consent. Switch stimulants. Consider nonstimulant treatment (e.g., clonidine or tricyclic antidepressant). If tic disorder and ADHD are severe, consider combining stimulant with a high-potency neuroleptic.
Psychosis	Discontinue stimulant treatment. Assess for comorbid thought disorder. Consider alternative treatments.

that food may enhance drug absorption. MPH treatment can be initiated with a single 5 mg dose at 8:00 am for 3 days; then a 5 mg dose at 8:00 am and at noon for the next 3 days; then 10 mg at 8:00 am and 5 mg at noon for 3 days; and finally 10 mg at 8:00 am and 10 mg at noon are given and maintained for at least 2 weeks. Preschoolers may start as low as 2.5 mg at 8:00 am but build to the same total 20 mg/day dose of MPH. The dosing instructions should be written down for the parent, with dates and times specified in detail. A photocopy of the instructions should be kept in the patient's chart.

Table 82.6 is an inventory of stimulant drugs and doses. DEX is usually started at 2.5 to 5 mg/day and gradually increased in 2.5- to 5-mg increments; MPH is usually started at 5 mg b.i.d. and then titrated in increments of 5 mg/dose every 4 to 7 days. Peak behavioral effects are noted 1 to 3 hours after ingestion and dissipate in 3 to 6 hours for both MPH and DEX.

The Conners Teacher Rating Scale is then repeated. Further dose adjustments up or down depend on the rating scale's scores,

teachers' verbal reports, parents' comments, and adverse effects experienced by the child. The minimal effective total daily dose and optimal timing of medication administration should be determined before switching to the sustained-release 20 mg formulation. Eventually, one dose of standard MPH may have to be mixed with one sustained-release 20 mg pill at 8:00 am (to give early- and late-morning coverage), just as one administers short- and long-acting insulin at the same time.

## Monitoring

**Maintenance** plans should include schedules for the regular collection of information that constitutes the child's therapeutic drug monitoring. Each child's response to psychostimulants is different. Likewise, each family's needs are different. Plans for medication vacations and weekend and after-school dosing must be individualized.

Medication **compliance** should be monitored at each visit. The parent is instructed to bring the medication bottle along so that

pill counts can be done monthly and compared with the prescription dates. Height and weight should be taken every 6 months, and the child's pediatrician can be requested yearly to perform a complete physical examination and blood work (complete blood count, liver function studies). The frequency of visits depends on the other therapies recommended. These may include once-monthly parental counseling, twice-monthly individual therapy, or weekly meetings for individual psychotherapy or behavioral modification management. A minimal frequency should be once monthly, particularly in the nine states requiring multiple-copy prescription forms, which limit the amount of psychostimulant ordered to a 30-day supply.

The next component of monitoring is the use of **structured rating scales**. These have been the backbone of psychostimulant treatment research but also have utility in clinical practice. Each physician should choose a scale that she or he finds easy to interpret and convenient to use. It should be available in both parent and teacher formats. These scales, however, should not be used as substitutes for an open discussion with the teacher.

These rating forms should be collected every 4 months and whenever the physician needs to make decisions about dosage adjustment, time of dosing, or even continuation of medication. Although the original 39-item Conners Teacher Rating Scale is ubiquitous in the field of child psychopharmacology, Satin and colleagues (1985) have shown the validity of the shorter, 10-item Abbreviated Rating Scale both as a repeated measure and as a screening tool for identifying school-age children with ADHD. This short form is good for tracking children in maintenance treatment. Like most scales, the Abbreviated Rating Scale assigns weights to each scale point. With a 10-item scale, and each point weighted between 0 ("not at all") and 3 ("very much"), 10 checks by a parent in the "very much" column yields a total score of 30.

Unlike the situation with anticonvulsants, it has not proved effective to monitor psychostimulants by maintaining plasma concentrations within a therapeutic range. Alternative medications such as desipramine, however, do lend themselves to regular plasma level monitoring every 3 months.

## Phases of Treatment

Medication therapy can be divided into baseline, titration and maintenance phases. Before the first pill is given, baseline data on height, weight, blood pressure and heart rate should be collected as well as a complete blood count. The Conners Teacher Rating Scale and Conners Parent Rating Scale can also be collected. Standardized scoring methods for the teacher rating scale can be used to generate a hyperactivity factor score.

The duration of treatment is an important step in the generation of a treatment plan for a child with ADHD. Although there is no clear-cut recommendation for the length of psychostimulant treatment, many parents have a reasonable expectation that it will not be open-ended. The onset of puberty is one possible stopping point for psychostimulant medication. School-age children were thought to respond "paradoxically", calming down on stimulant medication, an effect that was supposedly lost at puberty. Adolescents with ADHD, who may be at risk for substance abuse, were thought to be particularly vulnerable to psychostimulant euphoria and to abuse of their medications. In addition, more recent prospective follow-up studies suggest that the motor hyperactivity of ADHD disappears between ages 16 and 23 years.

## Integration with Other Modalities: Multimodal Treatment

Medication is only one component of a comprehensive therapeutic treatment plan. New standards have been promulgated for the treatment of ADHD recommending multimodal therapy including psychological, educational and social components. This was first reported by Satterfield and colleagues (1980) to be successful in maintaining the short-term stimulant gains for periods of 2 years or more.

## Treatment Failure

If a child fails to show improvement as the stimulant dose is being increased, how far should the dose be increased before turning to another medication? The physician is left with the dose range suggested in the PDR and to his or her own standards regarding what constitutes improvement and where to draw the line between a response and failure.

Do true nonresponders exist? Recent studies indicate that many apparent nonresponders to stimulants may simply have been treated with too low a dose. The treating physician is well advised to seek expert consultation with a child and adolescent psychopharmacologist before venturing beyond a total dose of 60 mg/day of MPH and 40 mg/day of DEX.

## Use of Long-acting Preparations

There are three reasons for the implementation of longer-acting stimulant preparations. First, children who take medications in school are subject to peer ridicule when they leave activities to go to the nurse. Secondly, some school officials refuse to allow school personnel involvement in the administration of medication. Thirdly, the time-action course of standard stimulant medications allows only a brief 1- to 3-hour window of effect, so some medicated children may experience trough periods of little or no drug action during important parts of the school day.

Sustained-release preparations have been marketed for DEX and MPH. MPH's sustained-release preparation (MPH-SR), which became available in 1984, is manufactured in brand (Ritalin-SR) and generic (MD Pharmaceuticals) versions but only in a single strength of 20 mg (MPH-SR20). DEX spansules are available in 5-, 10- and 15 mg strengths in the brand version (Dexedrine Spansules). The sustained-release preparations make it possible to give the psychostimulant once in the morning and avoid administration during the school day. Ritalin-SR uses a wax-matrix vehicle for slow release, whereas the DEX "spansule" is a capsule containing small medication particles.

## Conclusion

Psychostimulant medications are a mainstay in the US treatment of ADHD. This popularity has resulted from their proven efficacy during short-term controlled studies, as shown by improvements in global ratings by teachers and parents. In fact, the majority of children with ADHD respond to either MPH or DEX, so nonresponders are rare (Elia *et al.*, 1991). Yet, the long-term response of ADHD children to MPH and other psychostimulants is not known; published treatment studies have lasted months, not the years that children take stimulants to adapt to academics in school (Jacobvitz *et al.*, 1990). Optimal treatment involves the planning for a multimodal treatment program that combines

educational and psychosocial interventions with medication therapy.

Treatment plans that center on psychostimulant medication have flourished for a number of reasons. The effects of psychostimulants are rapid, dramatic and normalizing. The risk of long-term side effects remains low, and no substantial impairments have emerged to lessen the remarkable therapeutic benefit–risk ratio of these medications. More expensive and demanding treatments, including behavior modification and cognitive–behavioral therapies, have, at best, only equaled the treatment with psychostimulants. In a number of instances, the combination of behavioral and medication therapies is only slightly more effective than the medication alone (Gittelman-Klein, 1987). Current and future studies of multimodal therapies will test whether combined treatment results in better overall functioning in the long run and decreased appearance of comorbid conditions than does monomodal treatment with psychostimulants alone. It is essential to show that the continuation of stimulant medication during long-term maintenance benefits the patient with ADHD.

# Cognitive Enhancers and Treatments for Alzheimer's Disease

---

By the late 1980s the advent and general acceptance of research-based diagnostic criteria for the dementia of Alzheimer's disease (AD) (McKhann *et al.*, 1984), an understanding of its underlying pathology along with mechanism-based pharmacological therapeutics provided the framework for clinical trials to exploit a variety of new treatment strategies that might positively impact the illness.

Since AD is defined by the presence of dementia, attempts have been made to identify a predementia state of cognitive impairment, likely to lead to AD. This state of "mild cognitive impairment" (MCI) has now been the target of several clinical trials of medications previously used for AD. However, MCI is not merely a predementia stage of AD, since many people who fulfill criteria do not progress to dementia.

## Regulatory Issues

The Food and Drug Administration (FDA) utilizes *de facto* guidelines for establishing that a drug has "antidementia efficacy" (Leber, 2002). These require, in part, that: 1) clinical trials be double-blind and placebo-controlled; 2) patients fulfill the now-accepted criteria for a primary dementia such as AD (e.g., using either DSM-IV-TR or NINCDS-ADRDA (National Institute of Neurological and Communicative Disorders and Stroke-Alzheimer's Disease and Related Disorders Association) Work Group Criteria) (McKhann *et al.*, 1984); and 3) appropriate efficacy instruments be used. Although the *de facto* guidelines avoid specifying that only Alzheimer's dementia can be treated, allowing the possibility that any recognized or accepted conditions can receive approval, at present it is the only dementia for which FDA-approved medications are available. [Note that DSM-IV-TR criteria for Dementia of the Alzheimer's Type very closely reflect the NINCDS-ADRDA Work Group Criteria.]

Limitations to the current guidelines include the failure to recognize improvement in behavior or functional activities **alone** as legitimate therapeutic goals or indications in the prescribing information, despite the fact that behavioral symptoms occur in the majority of dementia patients, and that improvements in functional status may have a major effect on prolonging independence. In addition, these guidelines fail to provide for efficacy measures for severely impaired patients who are unable to perform standard cognitive tests.

## Therapeutic Implications of Pathophysiology

Advances in understanding of plaques and tangles over the last few years underscore the biological heterogeneity of the illness, and several clues about definitive therapeutic approaches have appeared. It is likely that there are several stimuli for these abnormal protein processes, genetically, biologically and environmentally determined. These processes need to be understood more fully in order to discover new drugs acting directly on the pathological processes responsible for the neurodegeneration. For example, the finding that amyloid precursor protein processing is in part controlled by a cholinergic mechanism suggests that cholinergically based therapeutic strategies may modify the progress of the disease as well as providing symptomatic relief (Giacobini, 1996).

Other potential interventions in development now include agents that interfere with beta-amyloid formation such as secretase inhibitors, modulators of APP expression,  $\beta$ -secretase and  $\beta$ -secretase inhibitors that prevent cleavage of APP into insoluble  $\beta$ -amyloid protein, inhibitors of  $\beta$ -amyloid protein aggregation or deposition, or the passive or active immunization with antibodies to  $\beta$ -amyloid.

The observed neurotransmitter perturbations in AD, however, provide more immediate and accessible targets for therapeutic interventions. For example, the observation of deficits in noradrenergic or serotonergic function provide rationales for the use of antidepressants in patients with AD and symptomatic behaviors. Although not the exclusive pathological change, the cholinergic deficits represent the most consistent transmitter depletion and appear to be one of the early events in the disease process (Francis *et al.*, 1985, 1999). Thus, it continues to remain a major focus of applied clinical pharmacological research.

## Treatment Paradigms

Approaches to the treatment of AD can be grouped into several conceptual categories (Table 83.1). One approach attempts to treat the behavioral symptoms such as agitation, aggression, psychosis, depression, anxiety, apathy, and sleep or appetite disturbances. A second approach attempts to treat the cognitive or neuropsychological signs symptoms of the illness such as memory, language, praxis, attention, orientation and knowledge. A third

**Table 83.1 Conceptualized Treatment Strategies for Patients with Cognitive Impairment**

Symptomatic and/or Restorative
<p><b>Targets:</b> impaired cognition, depression, psychosis, agitation, aggression, anxiety, insomnia</p> <p><b>Examples:</b> cholinesterase inhibitors, various cholinergic agonists, antidepressants, antipsychotics, mood stabilizers, anti-anxiety agents, hypnotics, NMDA and AMPA receptor modulators, angiotensin converting enzyme inhibitors</p> <p><b>Neurotrophic factors:</b> nerve growth factor, brain-derived neurotrophic factors, estrogens</p> <p><b>Notes:</b> some substances may have symptomatic or restorative effects but are unproven. These may include Hydergine and neotropics such as piracetam.</p>
Pathophysiologically-directed
<p><b>Targets:</b> underlying pathophysiology of neurodegeneration, including inflammation, production of oxidizing free radicals, excitatory amino acids.</p> <p><b>Examples:</b> anti-inflammatory agents, calcium channel blockers, NMDA and AMPA receptor modulators. Transplantation of hormonally active tissues, or NGF (nerve growth factor) gene therapy using viral vectors have been undertaken experimentally.</p>
Etiologically-directed
<p><b>Targets:</b> <math>\beta</math>-amyloid formation or hyperphosphorylated tau protein.</p> <p><b>Examples:</b> modulators of APP expression, <math>\beta</math>- and <math>\gamma</math>-secretase inhibitors, inhibitors of beta-amyloid protein aggregation or deposition, immunization with antibodies to beta-amyloid.</p> <p><b>Note:</b> The interventions listed above include some that are available and marketed, as well as some that have not been demonstrated effective or safe, and some conceptual treatments not yet developed.</p>

approach attempts to slow the rate of progression of the illness, preserving patients' quality of life or autonomy. (Slowing the rate of decline might also be related to treating symptoms.) A fourth conceptual treatment approach is primary prevention, to delay the time to onset of illness. Success at this approach could have considerable impact.

### Cholinergic Agents

The primary implication of the cholinergic hypothesis is that potentiation of central cholinergic function should improve the cognitive and behavioral impairment associated with AD. This simple "neurotransmitter replacement" rationale has been made most compelling by the consistent effects of cholinesterase inhibitors as a class of drugs across trials.

While agents with several kinds of procholinergic action have been evaluated for efficacy in AD, the ChIs (cholinesterase inhibitors) are the only agents to have consistently demonstrated efficacy in numerous multicenter, placebo-controlled trials, and thus have been approved by many national regulatory authorities.

Thus ChIs represent the first **class** of efficacious pharmacological approaches for AD, and an approach that is likely to be clinically useful for the indefinite future, especially since research on drugs with other mechanisms has not advanced as rapidly as had been hoped for.

The well-established cholinergic defects in AD include: decline of cholinergic baso-cortical projections; reduced activity of ChAT, the key acetylcholine (ACh) synthesis enzyme, and cholinergic cell body loss in the nucleus basalis. Additionally, there are correlations between cortical ChAT reduction or nucleus basalis cell reduction and cortical plaque density. Such cholinergic deficits correlate with cognitive decline as measured by the Blessed-Roth Dementia Rating Scale (Blessed *et al.*, 1968). The cholinergic hypothesis proposes that cognitive deficits of AD are related to decreases in central acetylcholinergic activity, and that increasing intrasynaptic ACh will enhance cognitive function and clinical well-being. (See Figure 83.1.)

### Cholinergic Treatment Approaches

Cholinergic treatment approaches include precursor loading, cholinesterase inhibition, direct cholinergic receptor stimulation and indirect cholinergic stimulation. Unfortunately, most of these cholinergic strategies have thus far proven ineffective, effective but too toxic, or have not been completely developed.

### Cholinesterase Inhibitors

ChIs have shown generally consistent symptomatic efficacy in standardized, well-controlled multicenter trials lasting from 6 months to occasionally 12 months. Cholinesterase inhibitors (Table 83.2) have been the most frequently used experimental treatment for AD and the major group of medications to yield consistently positive results in clinical trials. Current marketed ChIs include tacrine, donepezil, rivastigmine and galantamine, although tacrine is now used much less commonly due to the risk of hepatotoxicity.

### Mechanisms of Cholinesterase Inhibition

Acetylcholine is inactivated when it is hydrolyzed to choline and acetate by acetylcholinesterase (AChE). By inhibiting the actions of AChE, ChIs effectively increase the amount of ACh available for intrasynaptic cholinergic receptor stimulation. A summary of pharmacokinetics and pharmacodynamics is in Table 83.3.

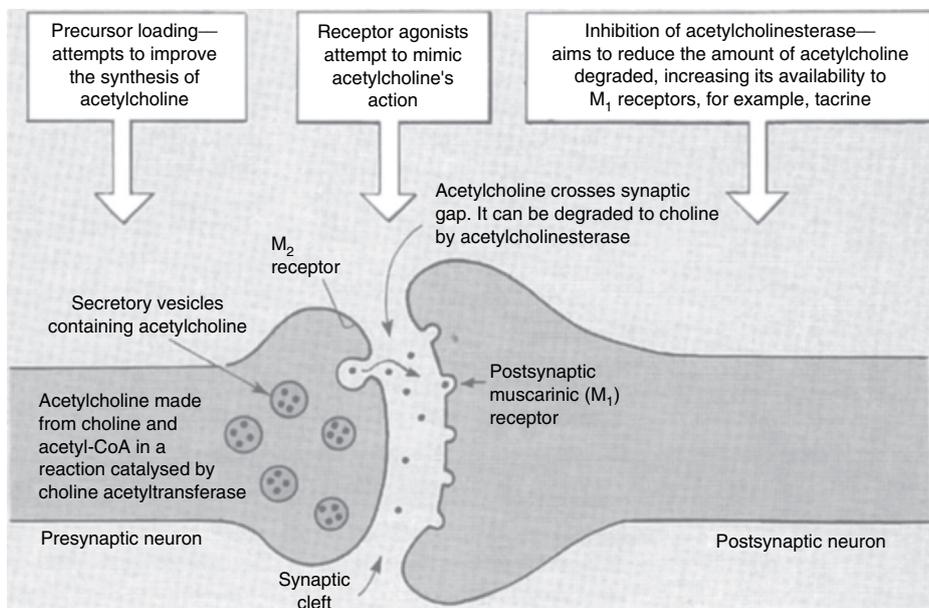

### Individual Cholinesterase Inhibitors – Dosing and Adverse Effects

#### Tacrine

Tacrine is a noncompetitive reversible inhibitor of ChE. It binds near the catalytically active site of the AChE molecule to inhibit enzyme activity. It has other actions as well including blocking sodium and potassium channels, and direct activity at muscarinic receptors (Adem *et al.*, 1990).

#### Dosing

Tacrine's FDA-approved dosing regimen is based on the clinical trials. The recommended starting dose is 10 mg q.i.d. to be

**Figure 83.1** Possible areas of action for therapy in AD. Reprinted with permission from Tariot P, Schneider L, and Coleman PD [1993a] *Treatment of Alzheimer's disease: Glimmers of hope?* *Chem Ind* 20, 801–807.

maintained for 6 weeks, while serum transaminase levels are monitored every other week. If the drug is tolerated and transaminase levels do not increase above three times the upper limit of normal, the dose is then increased to 20 mg q.i.d. After 6 weeks, dosage should be increased to 30 mg q.i.d., again with biweekly monitoring and then, if tolerated, to 40 mg q.i.d. for the next 6

weeks. Due to hepatotoxicity concerns, Tacrine's use greatly decreased.

### Donepezil

Donepezil (Aricept™) is a long-acting piperidine-based highly selective and reversible acetylcholinesterase inhibitor.

### Dosing

Donepezil is initiated at 5 mg/day and then increased to 10 mg/day after 4 to 6 weeks. Raising the dose earlier increases the risk for cholinergic adverse events. Five or 10 mg/day are effective doses; 10 mg tends to be somewhat more effective than 5 mg when the various trials as a group are evaluated.

### Rivastigmine

Rivastigmine (Exelon™) is a pseudo-irreversible, selective AChE subtype inhibitor.

### Dosing

The recommended starting dose of rivastigmine is 1.5 mg b.i.d., taken with meals. If this dose is well tolerated after a minimum of 2 weeks of treatment, it may be increased to 3 mg b.i.d. Subsequent increases to 4.5 mg and then 6 mg b.i.d. should be based on good tolerability of the current dose and may be considered after a minimum of 2 weeks of treatment. Higher daily doses, averaging about 9 to 10 mg were associated with better efficacy than lower doses.

### Galantamine

Galantamine (Reminyl™), an alkaloid originally extracted from Amaryllidaceae (*Galanthus woronowi*, the Caucasian snowdrop), but now synthesized, is a reversible, competitive inhibitor of AChE with relatively less butyrylcholinesterase activity (Harvey, 1995).

**Table 83.2** FDA-Approved Drugs to Improve Cognitive Function in Alzheimer's Disease

Drug	How Supplied	Initial Dosage	Maintenance Dosage
Tacrine	10, 20, 30 and 40 mg capsules	10 mg q.i.d.	30 or 40 mg q.i.d.
Donepezil	5 and 10 mg tablets	5 mg q.i.d.	5–10 mg q.i.d.
Rivastigmine	1.5, 3, 4.5 and 6 mg capsules	1.5 mg b.i.d.	3, 4.5, or 6 mg b.i.d.
Galantamine	4, 8 and 12 mg tablets Solution 4 mg/mL	4 mg b.i.d.	8 or 12 mg b.i.d.
Memantine	5 and 10 mg tablets, oral solution 2 mg/mL	5 mg q.d.	10 mg b.i.d.

Initial dosages should be maintained for at least 2 and preferably 4–6 weeks before increasing. For Memantine, dose may be increased weekly in 5 mg increments. Adverse events may occur with dosage titration.

**Table 83.3 Pharmacodynamic and Pharmacokinetics of Marketed Cholinesterase Inhibitors**

Drug	Pharmacodynamics	Absorption	Bioavailability	Peak Plasma (h)	Elimination Half-life (h)	Protein Binding	Metabolism/Comments
Tacrine (Cognex)	Noncompetitive, reversible ChI, both butyryl and acetyl ChI, also multiple other actions	Delayed by food	17%	1–2	2–4	55%	Via 1A2, nonlinear pharmacokinetics; hepatotoxicity requires regular monitoring of serum alanine aminotransferases.
Donepezil (Aricept)	Noncompetitive, reversible acetyl-ChI.	Not affected by food	100%	3–4	70	96%	Via 2D6, 3A4. Nonlinear pharmacokinetics at 10 mg/d
Rivastigmine (Exelon)	Noncompetitive ChI, both butyryl and acetyl ChI, may differentially effect different acetyl ChEs	Delayed by food	40%	1.4–2.6	< 5	40%	Hydrolysis by esterases and excreted in urine (nonhepatic). Duration of cholinesterase inhibition longer than plasma half-life. Nonlinear pharmacokinetics
Galantamine (Reminyl)	Competitive, reversible ChI, modulates nicotine receptors	Delayed by food	90%	1	7	18%	Via 2D6, 3A4

*Note:* Pharmacodynamic effects of some ChIs are longer than their elimination half-lives. Drugs that inhibit or induce the cytochrome enzymes above might be expected to increase or decrease blood levels. For the most part, clinically however, drug interactions with donepezil, rivastigmine and galantamine have not been clinical problems.

## Dosing

Initial dosing is 4 mg b.i.d., and should be raised to 8 mg b.i.d. after 2 to 4 weeks. For patients who are tolerating medication but not responding the dose can be raised to 12 mg b.i.d. after another 4 weeks.

## Adverse Effects of Cholinesterase Inhibitors

Most adverse events from ChIs are cholinergically mediated, and are characteristically mild in severity and short-lived, lasting only a few days. Adverse events of the marketed ChIs are summarized in Table 83.4. Significant cholinergic side effects can occur in up to about 25% of patients receiving higher doses. Often they are related to the initial titration of medication. Patients tend rapidly to become tolerant to the adverse events when they occur. Hepatotoxicity with tacrine is a significant concern requiring very close monitoring if the drug is used.

Because of the actions of ChIs, these drugs require caution when used in patients with significant asthma, significant chronic obstructive pulmonary disease, cardiac conduction defects, or clinically significant bradycardia. Appropriate considerations are involved in general anesthesia as well since they may prolong the effects of succinylcholine-type drugs.

Drug interactions with medications which inhibit cytochrome P450 types 3A4 or 2D6 may occur with this class of medications.

## Infrequent Adverse Events Worth Noting

A number of infrequent adverse events that may be of particular concern to patients, caregivers and physicians, and are common among the class of ChIs include fatigue, anorexia, weight loss and bradycardia. Myasthenia and respiratory depression occurred in a few patients treated with the higher doses of the organophosphate drug metrifonate leading to its therapeutic demise for AD. Although myasthenia might not be expected to occur with the reversible ChI, physicians should be vigilant for complaints of fatigue and weakness.

An increased but modest incidence of anorexia appears to be a consistent finding across clinical trials and appears to be dose related. The absolute reported incidence varies across trials from approximately 8 to 25% at the highest dose of ChI compared with 3 to 10% in comparable placebo patients. Similarly, there is an increased rate of significant weight loss with higher doses of ChIs compared with placebo patients. The proportion of patients losing greater than 7% of

**Table 83.4 Adverse Effects of Cholinesterase Inhibitors**

Summary of adverse event data in placebo-controlled, randomized clinical trials. The method of obtaining adverse events and their reporting vary among trials

Drug	Adverse Events
<b>Tacrine</b>	Nausea, vomiting, diarrhea, dyspepsia, myalgia, anorexia, dizziness, confusion, insomnia, rare agranulocytosis  Many patients will develop direct, reversible hepatotoxicity manifested by elevated transaminases  Drug interactions may include increased cholinergic effects with bethanacol; increased plasma tacrine levels with cimetidine or fluvoxamine. This may occur by inhibition of P450 1A2. The association of tacrine with haloperidol may increase parkinsonism and tacrine increases theophylline concentration.
<b>Donepezil</b>	Nausea, diarrhea, insomnia, vomiting, muscle cramps, fatigue, anorexia, dizziness, abdominal pain, myasthenia, rhinitis, weight loss, anxiety, syncope (2 vs. 1%)
<b>Rivastigmine</b>	Nausea, vomiting, anorexia, dizziness, abdominal pain, diarrhea, malaise, fatigue, asthenia, headache, sweating, weight loss, somnolence, syncope (3 vs. 2%). Rarely, severe vomiting with esophageal rupture
<b>Galantamine</b>	Nausea, vomiting, diarrhea, anorexia, weight loss, abdominal pain, dizziness, tremor, syncope (2 vs. 1%)

Adverse event estimates vary widely among the cholinesterase inhibitors from study to study and thus relative adverse event rates among drugs are difficult to estimate. Cholinergic side effects generally occur early and are related to initiating or increasing medication. They tend to be mild and self-limited. Medications should be restarted at lowest doses after temporarily stopping. See prescribing information referenced in Table 83.2.

**General precautions with cholinesterase inhibitors** (as indicated in the prescribing information)

By increasing central and peripheral cholinergic stimulation cholinesterase inhibitors may:

1. increase gastric acid secretion, increasing the risk for GI bleeding especially in patients with ulcer disease or those taking anti-inflammatories
2. produce bradycardia, especially in patients with sick sinus or other supraventricular conduction delay, leading to syncope, falls, and possible injury
3. exacerbate obstructive pulmonary disease
4. cause urinary outflow obstruction
5. increase risk for seizures
6. prolong the effects of succinylcholine-type muscle relaxants

their baseline weight varies from approximately 10 to 24% in the higher doses and from 2 to 10% of the placebo-treated patients in those trials reporting the statistic. Anorexia and weight loss are significant clinical problems for many elderly patients independent of medication effects, and whether or not demented.

### Treatment Approach with Cholinesterase Inhibitors

The typical candidates for ChIs are outpatients with AD of mild to moderate cognitive severity. They usually live at home or in an assisted living facility. Dementia is their main clinical problem; concurrent illnesses are not severe or dominating the clinical picture. Nor do behavioral syndromes such as psychosis, agitation, or significant insomnia, apathy, or depression dominate.

As indicated above, dosing should be initiated with 5 mg/day donepezil, 1.5 mg b.i.d. rivastigmine or 4 mg b.i.d. galantamine. Tacrine should be reserved as a second-line medication since it requires q.i.d. dosing and biweekly blood monitoring for elevated transaminase. After a minimum of 2 weeks, but preferably 4 to 6 weeks, the dosages should be doubled although 5 mg of donepezil is an effective dose.

Optimal duration of treatment with continuing efficacy is unknown but overall efficacy extends at least 9 to 12 months based on the clinical trials and open-label extension phases.

Maintenance treatment can be continued as long as a therapeutic benefit for the patient seems apparent. Therefore, the potential clinical benefit of ChIs should be reassessed on a regular basis. Discontinuation should be considered when evidence of a therapeutic effect is no longer present. Because of the great interpatient variability of response, it is not possible to predict individual patient responses to ChIs.

It is difficult to assess individual patient response because of the variability of the deteriorating course of AD, and because most of the effect of medication is due to a stabilization or lack of worsening of symptoms or cognitive function while placebo-treated patients continue to decline. Therefore, the clinical observations of minimal or no clinical worsening may be sufficient reasons to continue medication treatment if patients are tolerating therapy.

### Monitoring Side Effects

Cholinergic side effects such as diarrhea, nausea and vomiting, when they occur, tend to occur at initiation of treatment and when titrating to higher doses. They are often transient or self-limited and can often be managed with encouragement and maintenance of the present dose level, by omitting one or more doses, or by temporarily decreasing dosage. Most cholinergic side effects are related to the dose escalation phase of treatment, just after starting or increasing. Patients on maintenance doses should have few and very mild cholinergic side effects if any.

However, anorexia and weight loss may be clinically significant problems over the longer term, especially in older, more medically ill and nursing home patients, so these parameters should be monitored and medication reduced or discontinued if anorexia or weight loss become clinically significant to assess if appetite returns.

Uncommonly, the vagotonic effects of ChIs may cause significant bradycardia, and this can be a particular concern to patients with supraventricular conduction impairments or sick sinus syndrome.

Because gastric acid secretion may be increased with cholinesterase inhibitors, there may be an increased risk for developing ulcers or gastrointestinal bleeding. Patients receiving nonsteroidal anti-inflammatory drugs may be at a particularly additive risk. It is possible that ChIs may cause bladder outflow obstruction, seizures and exacerbate asthma or obstructive pulmonary disease, and interfere with succinylcholinergic anesthetics.

### Effect on Behavior

The evidence that ChIs may improve behavior is based on case series and secondary analyses of efficacy trials (Kaufer *et al.*, 1996; Raskind *et al.*, 1997). Nevertheless, clinical experience suggests that they may be effective at least for mildly disturbed behavior, and in delaying the onset of troublesome behaviors, perhaps by maintaining cognitive function or perhaps through enhancing attentional processes and activation.

### Neuroprotection

Cholinergic therapies may have effects beyond the short-term symptomatic improvement of cognition and may modify the pathogenetic processes of the illness (Radebaugh *et al.*, 1996; Thal *et al.*, 1997). For example, activation of  $M_1$  muscarinic receptors can stimulate secretion of amyloid precursor proteins via the  $\alpha$ -secretase pathway such that there is a decrease in the production of toxic and insoluble  $\beta$ -amyloid, thus theoretically decreasing the formation of amyloid plaques and promoting the normal processing of APP (Inestrosa *et al.*, 1996; Muller *et al.*, 1997; Nitsch *et al.*, 1992). These effects remain to be proven in clinical trials (Buxbaum *et al.*, 1992; Haroutunian *et al.*, 1997; Lahiri *et al.*, 2000).

### Memantine

L-glutamate is the main excitatory neurotransmitter in the central nervous system. Enhancement of its activity at the N-methyl-D-aspartate (NMDA) receptor may contribute to the pathogenesis of Alzheimer's disease, a phenomenon known as excitotoxicity. Memantine is a low affinity antagonist that is believed to reduce NMDA receptor overstimulation and restore receptor signalling function to more normal levels. It is also possible that reducing excitotoxicity may be neuroprotective by preventing neuronal calcium overload though there is no evidence that memantine modifies neurodegeneration in patients with Alzheimer's disease.

Unlike the cholinesterase inhibitors, memantine is approved by the FDA for the treatment of moderate to severe Alzheimer's disease (defined as an MMSE score of less than 15).

### Dosing

Treatment should be initiated at a dose of 5 mg/day and increased in increments of 5 mg at intervals of one week to a target dose of 20 mg/day; doses of 10 mg/day or more should be divided into two given 12 hours apart. Memantine is well tolerated and is not associated with an increase in treatment discontinuation compared with placebo.

### Restorative Approaches: Other Agents

The structural and functional disturbances of central catecholaminergic systems in AD and their important role in brain-related functions provide the rationale for pharmacological enhancement of these systems. The general strategies employed are analogous to those used with cholinergic agents: precursor loading, inhibition of degradative enzymes and use of agonists. Studies of dopamine precursors (e.g., with tyrosine, l-dopa) and agonists (e.g., clonidine, guanefacine, amantadine, bromocriptine) have largely been negative (Schneider and Tariot, 1997).

There have been some positive effects reported with selegiline (l-deprenyl, Eldepryl<sup>®</sup>, Somerset), a monoamine oxidase (MAO) inhibitor that relatively selectively inhibits MAO type B at a 5 to 10 mg daily dose (Tariot *et al.*, 1993). The overall effect of selegiline at this dose may be to increase CNS levels of dopamine and some trace neurotransmitters such as phenylethylamine without affecting norepinephrine levels. Selegiline is currently marketed for the treatment of Parkinson's disease for which it has demonstrated effects in maintaining motor function (Parkinson Study Group, 1993). However, an adequate efficacy trial has yet to be completed in AD.

Selegiline, 5 mg b.i.d., along with and separately from vitamin E, 1000 IU b.i.d., has been associated with prolonged maintenance of ADLs and survival in the community in moderately to severely impaired AD patients but with no improvement in function (Sano *et al.*, 1997).

### Metabolic Enhancement

In view of regional decreases in glucose utilization and abnormal oxidative metabolism, drugs have been employed with the aim of correcting these abnormalities, including ergot alkaloids and nootropics. A discussion of the ergot alkaloids, Hydergine<sup>®</sup>, can be found in a Cochrane systematic review (Olin *et al.*, 2002). Although once one of the most frequently prescribed medications in the world, it is now uncommonly prescribed. Numerous clinical trials in various elderly patient groups have not clarified its efficacy or clinical role. Another ergoloid derivative available in Europe, nicergoline (Sermion, Pharmacia), was associated with significant improvement on some areas such as orientation and attention and has been undergoing clinical testing (Fioravanti and Flicker, 2002; Winblad *et al.*, 2001).

### Nootropics

Piracetam, oxiracetam, pramiracetam, aniracetam, CI 933, and BMY 21502 are pyrrolidone derivatives of  $\gamma$ -aminobutyric acid (GABA), although they do not appear to have GABA-like effects, and are postulated to have a neuroprotective effect on the CNS against hypoxia, electroconvulsive treatment and drug intoxication. These types of drugs may also enhance the CNS microcirculation by reducing platelet activity and by reducing adherence of red blood cells to vessel walls and may stimulate central cholinergic activity. These diverse effects are termed nootropic to indicate the class of drugs that are structurally related to piracetam and may improve learning and memory (Nicholson, 1990). However, a specific mechanism of action relevant for dementia has not been established. Double-blind, multicenter, controlled studies have shown mixed results with piracetam in the treatment of dementia in the elderly (Flicker and Evans, 2002; Vernon and Sorkin, 1991). Pramiracetam and

oxiracetam have been evaluated in large scale multicenter studies with no sufficiently significant clinical effects in dementia. Piracetam is undergoing a clinical trial for mild cognitive impairment.

## Estrogens

Estrogens may have cholinergic neurotrophic and neuroprotective effects and may enhance cognitive function (Simpkins *et al.*, 1994).

A beneficial role for estrogen in AD, cognitive function, mood and aging is suggested by observations of an inverse relationship of ERT (Estrogen Replacement Therapy) dose and duration with dementia diagnoses on death certificates (Paganini-Hill and Henderson, 1994); by preliminary trials suggesting a cognitive enhancing effect of estradiol, estrone, and conjugated estrogens in AD (Asthana *et al.*, 2001; Fillit *et al.*, 1986; Honjo *et al.*, 1989; Ohkura *et al.*, 1994).

Unfortunately, clinical trials of conjugated equine estrogens (Premarin®) to improve cognition in both hysterectomized and nonhysterectomized women with AD have not led to success, and indeed women treated with Premarin fared somewhat worse both in cognition and safety including 5% developing deep vein thrombosis (Henderson *et al.*, 2000; Mulnard *et al.*, 2000). Thus currently estrogen replacement cannot be recommended as a treatment for women with Alzheimer's dementia.

## Etiologically-directed Approaches in AD

### Immune and Inflammatory Processes

Inflammatory processes may be seen in various neurodegenerative disorders. Emerging evidence indicates overactivity of aspects of immune function in AD (Aisen and Davis, 1994). Immune/inflammatory reactions may be established by reactive microglia surrounding senile plaques and astrocyte proliferation; and inflammatory cytokines are produced such as tumor necrosis factor alpha, interleukin-1 (IL-1),  $\alpha$ -2-macroglobulin and  $\alpha$ -1-antichymotrypsin. IL-1 and IL-6 promote the synthesis of  $\beta$ -amyloid precursor protein.

### Anti-inflammatory medications

Epidemiological evidence supports the use of nonsteroidal anti-inflammatories as preventative of AD. However, clinical trials data is less encouraging. Thus, overall efficacy of anti-inflammatory agents in AD has yet to be demonstrated.

### Antioxidants

There are both theoretical reasons, and empirical findings, to suggest that free radical damage may be one of the mechanisms causing neuronal degeneration in a range of conditions including aging and Alzheimer's disease. Many studies have found evidence of increased level of oxidative damage to neurons in Alzheimer's disease, but neither Vitamin E nor ginkgo biloba can be recommended based on research results to date.

### Calcium Channel Blockers

The process of neuronal death in aging and in AD may be mediated by an increase in intracellular free calcium, which activates

various destructive enzymes (such as proteases, endonucleases and phospholipases) and disrupts intracellular processes. In principle, blocking the increase in intracellular free calcium may retard these mechanisms of neuronal death and thus slow progression of disease.

Based on this hypothesis, two calcium channel blockers that have been tested in AD patients are nimodipine and a Bristol-Myers Squibb investigational compound. In one trial, the low-dose nimodipine group (30 mg t.i.d.) showed less deterioration on several memory tests over a 10- to 12-week treatment period than the placebo or high-dose nimodipine (60 mg t.i.d.) group (Tollefson, 1990). A larger study showed significant cognitive effects for nimodipine compared with Hydergine® and placebo (Kanowski *et al.*, 1988). It is not clear, however, whether study subjects fulfilled criteria for possible AD. Nimodipine is marketed to reduce the severity of neurological deficits resulting from vasospasm in patients who have had a recent subarachnoid hemorrhage. It is also used off-label as a cognitive enhancer. A continuing interest in calcium blockers is also spurred by results from a French hypertension trial that found that patients taking calcium blockers were less likely to develop dementia.

## Combined Therapies

The combination of drugs with different mechanisms of action may be more effective than individual medications alone. The most relevant clinical questions are whether the available ChIs can or should be combined with other drugs. As a past example, choline precursors were combined with ChIs, but with no evident augmenting effect. Most practicing clinicians would take a dim view of combining two ChIs since their actions are additive. Physicians should be skeptical also of combining available anti-inflammatories or hormones with ChIs: first because of the lack of demonstrated efficacy of these drugs, and second because of the additive adverse events, especially gastrointestinal events. Some clinicians are combining memantine with of the ChIs. Clinical experience appears positive but there is no data from controlled trials.

## Summary

The prospects for both treatments with greater efficacy for AD, and for cognitive enhancement in elderly patients are encouraging. ChIs are the best proven efficacious symptomatic treatments for AD. They provide consistent effects in many patients with mild to moderate dementia, and have become the current pharmacological standard of treatment. Other therapeutic approaches are not as well tested or as clearly efficacious. Therefore, ChIs are likely to be actively used clinically for at least the next several years.

However, therapeutic results are usually modest, affecting a minority of patients. Patients assessed were usually outpatients with mild to moderately severe dementia and few concomitant medical illnesses. Duration of effect beyond 1 year and long-term safety are not known, except for the uncontrolled observations of patients who continue on these drugs after the controlled trial. It is essential to understand the broad magnitudes of effects and the range of clinical utility. It often takes time, experience and further studies for clinicians to appreciate the overall

effectiveness and utility of new drugs. Long-term trials of the cholinesterase inhibitors in patients with mild cognitive impairment will help define the extent and limits of their efficacy, as will trials in vascular dementia. Memantine demonstrates efficacy with very mild adverse events, at least in more severely impaired patients.

Many of the putative cognitive enhancers described in this chapter would not likely be specific for AD and might be expected to be effective in other dementias. The area of cognitive enhancers for people without clinical illness remains to be explored.

# Pharmacotherapies for Substance Abuse

This chapter describes the pharmacologic tools that physicians need to manage syndromes related to intoxication and overdose; syndromes related to withdrawal; relapse prevention once detoxification is complete; and the pharmacotherapy of comorbid psychopathology in substance abusers.

## Syndromes Related to Intoxication

An accurate diagnosis is of fundamental importance in the assessment of a patient who may be intoxicated. A full history must be obtained in the awareness that progression to potentially fatal overdose or withdrawal syndromes may occur. The focus of physical examination should be the acute effects of intoxication (such as vital and neurologic signs) and chronic signs and symptoms associated with drug dependence (size of liver, evidence of venipuncture). Drug use within the previous 4–12 hours can be determined by analysis of blood and breath samples whereas urinalysis is useful for assessing substance use within the preceding 24–72 hours. With the exception of alcohol testing, urine is generally the body fluid of choice for toxicologic analysis. Urine testing systems for drugs of abuse providing immediate results (e.g. dipsticks) are increasingly available and are handy for rapid office or clinic-based assessment. Saliva testing is also increasingly available.

## Alcohol Intoxication

The rate at which blood alcohol levels decline averages 15 mg/dL/hour. Overall, nonpharmacological management is preferred because it avoids the risk of interactions between drugs and alcohol. Lorazepam 1–2 mg orally may be effective in belligerent patients who cannot be managed by supportive limit setting. If, despite these measures, the patient's condition worsens over the next 1–2 hours, an intramuscular injection of haloperidol 5 mg can be safely given.

In patients with significant mental status changes or alterations in sensorium, clinicians should be alert to the possibility of other causes such as head trauma or metabolic disturbance (e.g. thiamine deficiency). Further, intoxicated patients with a recent history of regular heavy use and likely physiologic dependence on alcohol, may be at risk for serious alcohol withdrawal (seizures or delirium) as the blood level clears, particularly if there is a past history of such complications. In that case, clinicians should consider starting tapering doses of a long-acting benzodiazepine (e.g. chlordiazepoxide) as acute intoxication begins to clear (see section on alcohol withdrawal below).

## Sedative-hypnotic Intoxication

Suspected benzodiazepine overdose can be reversed with the benzodiazepine antagonist flumazenil, which should be administered intravenously, beginning with 0.2 mg slow push over 30 seconds, followed by increments of 0.3 mg or 0.5 mg if no response, with total dose not to exceed 3 mg to 5 mg. If no response is obtained at those total doses, then another cause of stupor or coma should be considered.

As with alcohol, clinicians should be alert to other causes of mental status changes, and for patients with recent regular use and physiologic dependence on sedative-hypnotics, particularly short-acting agents (e.g. alprazolam, lorazepam), serious withdrawal can ensue, and prophylactic treatment with taper of a long-acting agent considered (see section on sedative-hypnotic withdrawal below).

## Opiate Intoxication

Severe opiate intoxication is a life-threatening condition because of the high likelihood of respiratory depression or arrest. Opiate overdose is a common cause of death, especially among teenagers and young adults, and is particularly likely among individuals with low levels of tolerance, including inexperienced users, or patients who have recently detoxified or been abstinent for a period of time. Death from opiate overdose is an underappreciated risk, and just as one would assess risk of suicide in depressed patients, clinicians evaluating a patient presenting with opiate intoxication should evaluate the risk of overdose, including level of tolerance and past history of overdose episodes.

The presence of miosis and respiratory depression at presentation is an indication for immediate treatment. An intravenous dose of the pure opiate antagonist naloxone HCl 0.4–0.8 mg usually reverses opiate-induced respiratory and CNS depression in 2 minutes. The dose may be repeated every 2–3 min if the previous dose was not effective.

Cocaine and other stimulant use may be associated with serious physical consequences so the cardiac and neurologic status of patients with this type of intoxication must always be evaluated. A management plan for medical emergencies including arrhythmias, hypertension and seizures should be prepared.

The adverse behavioral and psychological effects of stimulant intoxication should be treated in a quiet environment and in a straightforward and reassuring way. If drug treatment is indicated, lorazepam 2 mg is usually effective. Benzodiazepines are also preferable for treating psychosis because antipsychotic drugs may worsen cardiovascular complications such as tachycardia or neurologic effects such as seizures and hyperthermia. However, a

high-potency antipsychotic such as haloperidol 5 mg may be used with caution if treatment with a benzodiazepine does not control behavioral escalation. The clearance of amphetamine may be increased by urinary acidification but this is not recommended in cases of cocaine intoxication.

### Intoxication by Hallucinogens such as LSD, Mescaline, MDMA (“Ecstasy”) and Psilocybin

The usual treatment option is the oral administration of 20 mg of diazepam; this should attenuate the LSD experience and alleviate any associated panic to a halt within 20 minutes and is considered a superior treatment option than the once-common “talking down” method.

### Phencyclidine Intoxication

Phencyclidine undergoes enterohepatic recirculation and this is associated with inter-individual variability in the time over which symptoms resolve. As a result, symptoms may re-emerge after a period of apparent quiescence and patients with phencyclidine intoxication should therefore be observed for 12 hours before being discharged.

There is no specific antagonist for the effects of phencyclidine and the aim of drug treatment for phencyclidine intoxication is to produce sedation or relieve psychosis. A benzodiazepine like lorazepam (orally or by intramuscular injection) may be administered for general sedation; if this does not control psychotic agitation, haloperidol is a reasonable choice of antipsychotic agent. Antipsychotics with anticholinergic properties may exacerbate the anticholinergic effects of phencyclidine and others may additively enhance phencyclidine-induced muscle rigidity and dystonias. Although urinary acidification has been suggested as a means to promote the clearance of phencyclidine, there is a risk that it may exacerbate incipient metabolic acidosis and increase the risk of renal failure secondary to rhabdomyolysis.

### Drug Treatment of Withdrawal Syndromes

Some general principles apply to drug treatments for specific withdrawal syndromes:

When monitoring treatment:

- Set clear targets.
- Make serial assessments and modify based on these assessments.

Psychosocial factors:

- Prepare the patient.
- Emphasis on detoxification as a beginning to treatment.

From a pharmacologic standpoint, an ideal agent for the treatment of withdrawal should have the following characteristics:

- Efficacy in relieving the complete range of abstinence signs and symptoms for a given type of withdrawal.
- A relatively long duration of action and gradual offset of effects.
- A high degree of safety in the dosage needed to suppress withdrawal (i.e., high therapeutic index).
- It should be available by a variety of routes of administration and have little abuse potential in itself.

Other general but important aspects of detoxification are also frequently overlooked:

- Clear treatment targets should be kept in mind.
- Structured rating scales should be used to measure symptom severity: serial assessment of the clinical response is the best strategy for guiding treatment and detoxification should not be conducted “on autopilot”.
- While protocols may offer useful guidance, orders should be rewritten with thought and often daily.

Patients must understand that detoxification is not a treatment for addiction but the beginning of treatment for the chronic problems associated with substance dependence. They should know what they will experience and they should if at all possible be engaged in the effort to relieve their symptoms as safely as possible and with greatest effectiveness. They need to understand, however, that they are likely to experience some distress. Detoxification can be carried out on an outpatient basis for patients who are in relatively good health and have sufficiently stable social support.

### Alcohol Withdrawal

Alcohol withdrawal is a medical emergency and can be life-threatening without appropriate supportive medical treatment.

The risk of progressing from uncomplicated withdrawal to seizures or delirium should be greatly reduced by proper management. Patients should be assessed systematically when entering the detoxification protocol and during the process. A widely used but simple tool is the Clinical Institute Withdrawal Assessment – Alcohol Scale (Table 84.1). Starting 6–24 hours after the last drink, this scale should be used to assess the patient initially every 1–2 hours and at regular intervals until two consecutive scores below 8–10 are achieved. It is then safe to end structured assessment. Scores greater than 15 are an indication for monitoring the patient even more closely. Scores in between these limits should be interpreted according to clinical judgment according to the degree of discomfort reported by the patient and their history of withdrawal syndromes.

Undertreatment with doses that are too low or dose intervals that are too long is the commonest error in the drug treatment of withdrawal syndromes. However, striking the balance between withdrawal and intoxication is not complicated provided serial assessments are made.

Benzodiazepines are the drugs of choice for treating alcohol withdrawal because:

- There is cross-tolerance with alcohol (therefore higher than normal doses may be needed).
- They are relatively safe compared with other sedative-hypnotics.
- They have been shown to reduce the frequency of seizures and delirium.

The benzodiazepines can be divided into two major classes according their duration of action. Longer-acting agents, including chlordiazepoxide and diazepam, undergo metabolic oxidation and glucuronidation. Their advantage is that blood levels decline more slowly during the tapering process, increasing patient comfort and reducing the risk of seizures. The disadvantage is that, in older patients and patients with impaired hepatic or pulmonary function, decreased elimination may result in accumulation and toxicity. Chlordiazepoxide may be preferred to diazepam because it may have a lower abuse potential.

**Table 84.1** Clinical Institute Withdrawal Assessment – Alcohol Scale

Patient: \_\_\_\_\_

Time: \_\_\_\_\_:\_\_\_\_\_

(24 hour clock, midnight = 00: 00)

Date: \_\_\_\_\_ / \_\_\_\_\_ / \_\_\_\_\_  
y mo d**NAUSEA AND VOMITING:** Ask, “Do you feel sick to your stomach? Have you vomited?” Observation.

- 0—no nausea and no vomiting
- 1—mild nausea with no vomiting
- 2
- 3
- 4—intermittent nausea with dry heaves
- 5
- 6
- 7—constant nausea, frequent dry heaves and vomiting

**TREMOR:** Arms extended and fingers spread apart. Observation.

- 0—no tremor
- 1—not visible, but can be felt fingertip to fingertip
- 2
- 3
- 4—moderate, with patient’s arms extended
- 5
- 6
- 7—severe, even with arms not extended

**PAROXYSMAL SWEATS:** Observation.

- 0—no sweat visible
- 1—barely perceptible sweating, palms moist
- 2
- 3
- 4—beads of sweat obvious on forehead
- 5
- 6
- 7—drenching sweats

Pulse or heart rate, taken for

1 minute: \_\_\_\_\_

Blood pressure: \_\_\_\_\_ / \_\_\_\_\_

**TACTILE DISTURBANCES:** Ask, “Have you any itching, pins-and-needles sensations, any burning, any numbness, or do you feel bugs crawling on or under your skin?” Observation.

- 0—none
- 1—very mild itching, pins and needles, burning, or numbness
- 2—mild itching, pins and needles, burning, or numbness
- 3—moderate itching, pins and needles, burning, or numbness
- 4—moderately severe hallucinations
- 5—severe hallucinations
- 6—extremely severe hallucinations
- 7—continuous hallucinations

**AUDITORY DISTURBANCES:** Ask, “Are you more aware of sounds around you? Are they harsh? Do they frighten you? Are you hearing anything that is disturbing to you? Are you hearing things that you know aren’t there?” Observation.

- 0—not present
- 1—very mild harshness or ability to frighten
- 2—mild harshness or ability to frighten
- 3—moderate harshness or ability to frighten
- 4—moderately severe hallucinations
- 5—severe hallucinations
- 6—extremely severe hallucinations
- 7—continuous hallucinations

**Table 84.1** Clinical Institute Withdrawal Assessment – Alcohol Scale *continued*

**VISUAL DISTURBANCES:** Ask, “Does the light appear to be too bright? Is its color different? Does it hurt your eyes? Are you seeing anything that is disturbing you? Are you seeing things that you know aren’t there?” Observation.

- 0—not present
- 1—very mild sensitivity
- 2—mild sensitivity
- 3—moderate sensitivity
- 4—moderately severe hallucinations
- 5—severe hallucinations
- 6—extremely severe hallucinations
- 7—continuous hallucinations

**ANXIETY:** Ask, “Do you feel nervous?” Observation.

- 0—no anxiety, at ease
- 1—mildly anxious
- 2
- 3
- 4—moderately anxious, or guarded, so anxiety is inferred
- 5
- 6
- 7—equivalent to acute panic states as seen in severe delirium or acute schizophrenic reactions

**AGITATION:** Observation.

- 0—normal activity
- 1—somewhat more than normal activity
- 2
- 3
- 4—moderately fidgety and restless
- 5
- 6
- 7—paces back and forth during most of the interview, or constantly thrashes about

**HEADACHE, FULLNESS IN HEAD:** Ask, “Does your head feel different? Does it feel like there is a band around your head?” Do not rate dizziness or lightheadedness. Otherwise, rate severity.

- 0—not present
- 1—very mild
- 2—mild
- 3—moderate
- 4—moderately severe
- 5—severe
- 6—very severe
- 7—extremely severe

**ORIENTATION AND CLOUDING OF SENSORIUM:** Ask, “What day is this? Where are you? Who am I?”

- 0—oriented and can do serial additions
- 1—cannot do serial additions or is certain about date
- 2—disoriented for date by no more than 2 calendar days
- 3—disoriented for date by more than 2 calendar days
- 4—disoriented for place and/or person

Total CIWA-A score \_\_\_\_\_

See Sullivan JT, Sykora K, Schneiderman J, Narango CA, and Sellers EM (1989) Assessment of alcohol withdrawal: the revised Clinical Institute Withdrawal Instrument for Alcohol Scale (CIWA-AR). *Br J Addiction* 84, 1353–1357.

Shorter-acting agents, such as oxazepam and lorazepam, are metabolized only by glucuronidation. Both drugs are available in oral and intravenous forms though only lorazepam may also be administered by intramuscular injection. These agents are more readily metabolized and eliminated by older patients and they are

less likely to accumulate and cause toxicity in patients with liver disease. However, blood levels decline more rapidly and this may cause breakthrough symptoms and seizures between doses.

The treatment response should be assessed serially. Medication should be adjusted according to clinical need: if signs of

**Figure 84.1** Medication recommendations for treating alcohol withdrawal. Reprinted from *Psychiatric Drugs*, p. 224. Lieberman JA and Tasman MD (2000). Copyright 2000, Elsevier.

withdrawal are apparent, the dose should be increased or the dose interval reduced. Some degree of sedation is desirable but medication should be withheld if the patient becomes over-sedated and recommenced when clinically indicated. Recommendations for medication are summarized in Figure 84.1.

Hallucinations that develop as a feature of delirium are relatively refractory to treatment with a benzodiazepine alone. Patients who develop hallucinations despite sedative-hypnotic substitution may be treated with adjunctive haloperidol, 2 to 5 mg.

In the event of persistent tachycardia or hypertension, the possibility of inadequately treated withdrawal should first be excluded. This problem has been managed successfully with beta-blockers and clonidine but while these agents may decrease vital signs and tremor they do not prevent seizures.

An alternative strategy is to “frontload” the patient, achieving sedation by administering diazepam or chlordiazepoxide every 1 to 2 hours. Because these agents have a long elimination half-life, their effects diminish slowly and smoothly over the withdrawal period. However, careful serial assessment remains essential while the patient is vulnerable to the complications of withdrawal.

Thiamine is indicated for every patient with alcoholism to prevent Wernicke’s encephalopathy and Korsakoff’s amnesic syndrome. It should be administered immediately (typical dose 100 mg daily), before intravenous glucose. Less urgently, nutritional support should include supplementation with folate 1 mg and multivitamins. It has been suggested that magnesium supplementation may prevent withdrawal seizures but there is no consensus on its use in the absence of documented magnesium deficiency.

There are promising reports on the use of carbamazepine and valproate in alcohol withdrawal and they may be helpful in special circumstances. However, the safety and efficacy of benzodiazepines are currently unsurpassed.

### Sedative-hypnotic Withdrawal

Similar to the treatment for alcohol withdrawal, benzodiazepine taper (as described above) is a good choice, particularly if the

patients is dependent on benzodiazepines. Another excellent choice for substitution therapy is phenobarbital: it has low potential for abuse, there is a wide margin between therapeutic and lethal blood levels, and it has a long duration of action with relatively little variation in between-dose blood levels. The symptoms of intoxication with phenobarbital (ataxia, slurred speech, nystagmus) are readily observed easy and managed within a detoxification protocol.

For patients dependent on sedative-hypnotics, the first step in management is to take a history. Information about the level of drug consumption can be converted to “phenobarbital equivalents” to provide a guide to the required dose of phenobarbital, as specified in Table 84.2.

The number of phenobarbital equivalents is summed and administered as a thrice-daily dose regimen. The total daily requirement of phenobarbital rarely exceeds 500 mg even in patients with extreme dependency. The first dose of phenobarbital may be administered as an intramuscular injection if signs of withdrawal occur before substitution therapy begins. Symptoms of withdrawal and intoxication should be reassessed after 1 to 2 hours to determine the next dose of phenobarbital.

**Table 84.2** Phenobarbital Withdrawal Equivalents of Sedative-Hypnotics

Class/Generic Name	Dose (mg)*
<b>BENZODIAZEPINES</b>

\*Dose equivalent to 30 mg of phenobarbital for withdrawal  
Adapted from Wesson DR, Smith DE, Ling W and Seymour RB: Chapter 17: Sedative-Hypnotics, in *Substance Abuse: A Comprehensive Textbook*, 4th ed. (eds Lowinson JH, Ruiz P, Millman RB, Langrod JG). Philadelphia: Lippincott Williams and Wilkins; 2005.

The degree of dependence can also be assessed by serial challenge with pentobarbital at doses of 200 mg but it is not clear that this method offers any advantage over direct substitution with phenobarbital, which is safe, rapid and simple.

There should be no signs of sedative-hypnotic withdrawal or phenobarbital toxicity after 24 to 48 hours; dose reduction of phenobarbital can then be started. Maintaining the thrice-daily dose regimen, the dose of phenobarbital should be reduced in increments of 30 mg/day. If there is evidence of phenobarbital toxicity (slurred speech, nystagmus, ataxia), the next dose should be withheld and the total daily dose reduced. Conversely, if there are objective signs of withdrawal, the total daily dose of phenobarbital should be increased and dose reduction delayed until the patient is once again stable.

## Opiate Withdrawal

Withdrawal from opiates may be intensely uncomfortable but, by contrast with sedative-hypnotic withdrawal, it is not usually life-threatening for adults; important exceptions include adults with little reserve – for example, due to advanced AIDS – and newborn infants. Nevertheless, reducing withdrawal symptoms may help to engage an addict in a treatment program or facilitate the management of another medical condition.

Methadone is approved by the FDA for treating opiate withdrawal but states may have different regulations governing its use and clinicians need to be aware of local requirements. Methadone use is typically permitted for inpatient detoxification or maintenance treatment but it cannot be prescribed to treat opiate withdrawal in outpatients except as part of a licensed methadone maintenance treatment program.

Methadone is administered orally and has a long duration of action. An initial dose of 15 to 20 mg may be given when signs of opiate withdrawal are seen (not merely when craving is reported). An additional 5 to 10 mg may be given in 1 to 2 hours if symptoms persist or worsen. A dose of 40 mg/day usually controls signs of withdrawal well (note that this is often insufficient for the different indication of long-term maintenance). If oral administration is impossible due to withdrawal symptoms, doses of 5 mg may be administered by intramuscular injection. Having reached a dose at which withdrawal symptoms are alleviated, the dose can be tapered by 5 to 10% per day until full detoxification is achieved.

A newly available option for treatment of opioid withdrawal is the Schedule III opioid partial agonist buprenorphine, which is now available for use in the office based practice by any physician who has taken a brief training and certification. While the use of Schedule II drugs such as methadone for the treatment for opiate dependence is restricted to hospitals or specially licensed clinics (leading to a shortage of facilities where opiate-dependent individuals could receive appropriate treatment), the Drug Addiction Treatment Act of 2000 introduced less stringent regulations, allowing the use of narcotic drugs for the treatment of addiction in the office or any other health care setting by any licensed physician who has taken a brief training course and obtained registration, thereby increasing access to treatment. Two new formulations of the buprenorphine (Subutex and Suboxone sublingual tablets) were the first products to be approved by the FDA under this Act for the treatment of opioid dependence. Subutex contains only buprenorphine in doses of 2 or 8 mg; Suboxone also contains the opioid antagonist naloxone (0.5 and 2 mg respectively); the purpose of the naloxone is to discourage diversion of the medication for abuse intravenously (crushing the

pills and injecting them), since naloxone is poorly absorbed after oral or sublingual administration, but if injected would produce precipitated withdrawal.

Buprenorphine is an excellent detoxification agent because of its long duration of action, due to very high affinity for and very slow dissociation from opioid receptors. Starting buprenorphine must be done carefully, because of the partial agonism. If administered too close in time to the last dose of a full agonist such as heroin, buprenorphine will precipitate withdrawal, and the withdrawal produced can be atypical and in rare cases has been observed to include delirium. Precipitated withdrawal is more likely among patients dependent on long-acting agonists (e.g. methadone), or high daily doses of a shorter-acting agonist such as heroin. Thus, when starting buprenorphine, the clinician should wait for symptoms of opioid withdrawal to begin to appear before giving the first dose of buprenorphine, which should be a test dose of 2 mg (Subutex 2 mg, or Suboxone (2 mg buprenorphine/0.5 mg naloxone)). If this dose is well tolerated, administer another 2 mg one hour later, and up to 8 mg total on the first day, and up to 16 mg on the second day. After this buprenorphine can be tapered slowly to zero over 10 days to 2 weeks. Considerable flexibility in the taper schedule is possible, including a much faster taper, since the slow dissociation from receptors in itself effectively produces a taper. However, clinicians should also be alert for the emergence of low-grade withdrawal symptoms (fatigue, anxiety, mild flu-like physical symptoms) in the weeks after discontinuing buprenorphine. This subacute or protracted withdrawal can be observed after withdrawal from any opioid drug, but can seem surprisingly with buprenorphine because the taper phase of a buprenorphine detoxification is usually comfortable and uneventful.

If one of the first few doses of buprenorphine administered is followed by a rapid worsening of withdrawal symptoms, this is precipitated withdrawal, and no further buprenorphine should be given; at this point it is probably best to treat with a full agonist (methadone), although one could also wait for precipitated withdrawal to clear and full-blown opiate withdrawal (from whatever the patient was addicted to) to emerge, after which one can try again beginning with a test dose of 2 mg buprenorphine.

A number of nonnarcotic medications are useful in treating the symptoms of opiate withdrawal. These include the  $\alpha$ -adrenergic receptor agonist and antihypertensive clonidine, which is particularly helpful with the autonomic symptoms of withdrawal as well as the anxiety, benzodiazepines (clonazepam is typically used), which are particularly helpful for the anxiety and insomnia, antiemetics and NSAIDs for muscle aches (oral agents such as ibuprofen, or Toradol which can be given parenterally). Autonomic symptoms may be well controlled with clonidine alone but patients frequently report greater subjective distress than with methadone or buprenorphine. The role of clonidine is for detoxification from illegal opiates, for example in settings where methadone is not allowed, or to alleviate abstinence symptoms when a patient comes to the end of a methadone maintenance program. Its major side effects are hypotension (which may require dose reduction or discontinuation) and sedation. Hypotension may be worsened by diarrhea, or vomiting, which are common in opiate withdrawal. Patients should be encouraged to take plenty of fluids, and sports drinks such as gatorade are particularly helpful because they also supply electrolytes. Clonidine does not address all aspects of withdrawal and it should therefore be used in combination with the alternatives detailed above. A protocol for clonidine-assisted detoxification is given in Table 84.3.

**Table 84.3 Clonidine Detoxification**

Day	Short-acting Opiate*	Long-acting Opiate†
Day 1	0.1 mg q4h	0.1 mg q4h
Days 2–4	0.1–0.2 mg q4h (depending on symptoms)	0.1–0.2 mg q4h (depending on symptoms)
Days 5–10	Reduce daily dose by 0.2–0.4 mg/d	Maintain on 0.4–1.2 mg/d
Day 11		Reduce daily dose by 0.2–0.4 mg/d

Adjunctive medication: oxazepam (in limited supplies) for sleep or agitation; ibuprofen or toradol for muscle or bone pain; bismuth subsalicylate for diarrhea; prochlorperazine or ondansetron for nausea.

\*For example, heroin.

†For example, methadone.

A combination of clonidine with naltrexone has been used to achieve a more rapid withdrawal, followed by maintenance treatment with naltrexone. However, clinical experience and close monitoring of the patient is necessary to titrate the dose of clonidine against withdrawal symptoms induced by naltrexone. The acceptability of maintenance treatment with naltrexone to opiate addicts is disappointing.

With opiate detoxification, it is particularly important to consider the indications for it, and to establish an adequate treatment plan after detoxification is completed. Chronic opioid use induces tolerance, and detoxification reduces or eliminates tolerance. Because of the loss of tolerance, detoxified opiate addicts are at increased risk for death from opiate overdose; doses that they routinely self-administered previously when tolerant, could now be lethal, a problem exacerbated by the variable and sometimes high potency of illicit heroin. In general, the risk of relapse following opioid detoxification is high. Therefore, patients should be assessed for overdose risk, and those with a history of past overdoses, or with multiple past relapses, should be encouraged to take agonist maintenance treatment, with methadone or buprenorphine, rather than undergoing detoxification. For those not entering agonist maintenance, a strong plan for psychosocial treatment is important, for example long-term residential treatment or Therapeutic Community, a good outpatient treatment program, supplemented by self-help group (Alcoholics Anonymous, or Narcotics Anonymous).

## Management of Withdrawal in Patients with Drug Dependencies

### Medications for Alcohol Dependence

Three medications are now FDA approved for treatment of alcohol dependence, disulfiram, naltrexone and acamprosate.

Disulfiram is an irreversible inhibitor of aldehyde dehydrogenase, the enzyme that catalyzes the conversion of alcohol to acetic acid. Inhibiting aldehyde dehydrogenase alters the body's response to alcohol, leading to an accumulation of acetaldehyde. The resulting reaction is extremely dysphoric but self-limiting and not life-threatening. However, it is associated with hypotension, palpitations, nausea and vomiting, and diaphoresis, which

can produce substantial stress to the cardiovascular system, particularly with high doses both of alcohol and of disulfiram. This is generally not dangerous in young, healthy individuals, but could lead to cardiovascular collapse and death in patients with significant cardiovascular or renal disease. Disulfiram has also been associated with liver toxicity, and education of the patient about signs of liver failure, and periodic monitoring of liver functions, are advisable.

Disulfiram was approved by the FDA for treatment of alcoholism in an era that required efficacy studies that would not meet today's standards. The best work to date suggests that disulfiram may reduce the number of drinking days in those alcoholics who drink while taking it. Placebo-controlled studies suggest that compliance with medication taking, rather than the disulfiram itself, is the critical factor in producing a better outcome in persons with alcoholism.

For patients who are well-motivated, disulfiram provides an important disincentive to drink alcohol. It is particularly effective as part of a contract with a spouse, in which the spouse agrees not to comment on the patient's drinking and the patient agrees to allow the spouse to witness disulfiram ingestion. If disulfiram is taken regularly, it will prevent drinking, since even a small amount of intake will make the patient sick.

The usual dose of disulfiram is 250 mg/day. This minimizes side effects such as lethargy while maintaining inhibition of aldehyde dehydrogenase. Some patients will report being able to drink without consequence on 250 mg per day. This may simply mean the patient is not actually taking the medication regularly, and should prompt gentle inquiry into compliance. However, some patients do need higher doses, up to 500 mg per day. Disulfiram inhibits dopamine  $\alpha$ -hydroxylase and may rarely cause psychosis. It may affect the blood levels of other drugs (for example, levels of antidepressants and phenytoin are increased). Patients should be made aware that products other than alcoholic beverages contain alcohol (e.g. shaving lotions) and that the risk of an acetaldehyde reaction persists for up to 2 weeks after the last dose of disulfiram.

The rationale for prescribing naltrexone to prevent alcohol relapse is based on the hypothesis that the reinforcing effects of alcohol may be mediated via endogenous opiate mechanisms. Naltrexone combined with structured psychosocial treatment has been associated with improvements in complete abstinence, less craving for alcohol when the patient was abstinent, and less drinking once drinking began. Psychosocial treatments that have proven particularly effective in combination with naltrexone are those, such as cognitive-behavioral relapse prevention, that emphasize coping skills for handling various sources of relapse risk. The recommended dose is 50 mg per day. This agent differs from disulfiram in that there is no added ill effect once drinking begins. It may limit the severity of binges, and diminish preoccupation with alcohol in abstinent alcoholics. Nausea has been a common side effect early in naltrexone treatment for alcoholism, but is generally mild and clears with continued use. Naltrexone can produce liver toxicity, which is dose dependent, has mainly been observed at much higher doses (200 or 300 mg per day), and resolves with dose reduction. Elevated liver enzymes which do not resolve with dose reduction or discontinuation likely represent another cause of hepatitis (e.g. viral, alcoholic).

Acamprosate has been approved for a number of years in Europe, and recently received FDA approval. Its mechanism is not well understood, but is thought to involve interference with excitatory amino acid mechanisms that may be involved in

relapse. Clinical trials have shown a modest effect in reducing relapse risk, and studies are underway to determine if it may have complementary effects to those of naltrexone and whether the combination of the two may be increase effectiveness. Acamprosate is supplied in 333 mg tablets, and the recommended dosage is two tablets, three times daily. Blister packs, organized according to the daily schedule of dosing, can be helpful to patients in maintaining compliance. Acamprosate is a generally safe and well tolerated. Diarrhea is the most common side effect.

In the same way that any given antidepressant medication will be helpful to some depressed patients, but not others, naltrexone and acamprosate may similarly have little effect in some patients, but work well in others. As of yet, there are no reliable predictors of which alcohol-dependent patient will benefit from these medications, but clinicians should be encouraged to attempt adequate trials (effective dose, for at least a month) of these medications for patients with problem drinking, and not be discouraged by the fact that some patients will not benefit.

### Medications for Cocaine Dependence

Given the high relapse rates with psychosocial treatment alone, there has been considerable interest in the development of pharmacotherapies for cocaine dependence. Although case reports and small studies have suggested that a variety of agents may be effective, these findings have not been consistently repeated in double-blind studies and no drug has met the criteria for FDA approval. Nevertheless, survey show that many specialists in the management of addiction prescribe drug treatment for cocaine dependence.

The drugs most frequently prescribed for cocaine dependence are antidepressants. This is based on the observation that depression is relatively frequent among cocaine addicts and the hypothesis that antidepressants may correct underlying abnormalities of neurotransmitter function associated with cocaine use. Although desipramine is the most widely studied, initially encouraging reports of its efficacy in relapse prevention have been followed by studies either challenging its efficacy or suggesting its benefits may not continue beyond 6 to 12 weeks. Typical doses are the same as those used to treat depression. Concurrent use of cocaine and an antidepressant increases the risk of cardiotoxicity; patients who relapse during treatment should be investigated for additive cardiac effects.

It has been suggested that dopamine receptor blockade may attenuate the euphoric response to cocaine and that treatment with an antipsychotic drug may therefore be an appropriate treatment for cocaine dependence. However, experience treating patients with schizophrenia and cocaine dependence do not support this hypothesis. Further cocaine use may increase the risk of extrapyramidal side effects due to dopamine depletion.

Psychomotor stimulants have been suggested as an agonist maintenance treatment strategy. Although early clinical reports suggested stimulants might exacerbate cocaine dependence, more recent placebo controlled trials suggest oral dextroamphetamine may have promise. Patients with attention deficit disorder, which commonly co-occurs with cocaine dependence, may benefit from stimulants. Lithium has only been effective in reducing cocaine use in patients with bipolar disorder and, despite promising early trials, controlled trials have shown that carbamazepine has disappointing efficacy. However, more recently, some of the newer anticonvulsants with GABA-enhancing or excitatory amino acid inhibiting effects (e.g. topiramate, gabapentin) have shown promise in small placebo controlled trials.

Interestingly, perhaps the most consistent data so far regarding disulfiram, which has shown promise in a series of small placebo-controlled trials for cocaine dependence, and the effect does not seem to depend on concurrent alcohol use. Since disulfiram inhibits dopamine  $\beta$ -hydroxylase, which catalyzes the conversion of dopamine to norepinephrine in the brain, it may promote increased levels of brain dopamine, and combat the dopamine depletion engendered by cocaine.

Another pharmacotherapeutic strategy for cocaine dependence is to treat comorbid psychopathology, most commonly unipolar depression, bipolar disorder, attention deficit hyperactivity disorder and anxiety disorders. Such treatment is most likely to have a direct impact on the psychopathology, followed by indirect effects of improved functioning and reduced drug use; the benefits of pharmacotherapy for patients without comorbid psychopathology remain unclear. The development of an effective pharmacotherapy for cocaine dependence is a research priority of the highest order.

### Medications for Opiate Dependence

Agonist maintenance treatment for opiate dependence is a powerful treatment with a large effect size. When properly prescribed, methadone will rapidly induce a dramatic remission in 50% or more of patients. It prevents or reduces illicit opiate use, craving for illicit opiates, criminal behavior associated with acquisition of illicit opiates, and diseases associated with illicit opiate use (such as illness related to infection with human immunodeficiency virus), and improves employment and other aspects of social functioning. Methadone has also been shown to reduce mortality rates among opioid dependent patients, in part by protecting against overdose. Methadone is also sometimes misunderstood as “substituting one drug for another”. In fact, methadone works by inducing marked tolerance such that effects of other opiates are blocked, and no euphoric effects of the methadone itself are experienced. When prescribed with careful titration, methadone is neither intoxicating nor sedating, and it does not interfere with performance of functions that are important for responsible adult roles (e.g., studies have shown that methadone does not impair driving ability).

Methadone is a good choice for maintenance treatment:

- it is orally active
- its half-life exceeds 24 hours
- it suppresses opiate withdrawal syndrome for up to 36 hours
- it blocks the euphoriant effects of other opiates
- side effects are minimal during chronic use; the commonest are constipation, excess sweating and decreased sexual interest but they rarely cause discontinuation

Doses of methadone in the early phase of a maintenance program are in the 20 to 40 mg range, primarily to relieve abstinence symptoms. The dose is increased in increments of 5 to 10 mg during the “induction period” over a period of days to weeks until a dose is achieved that prevents opiate craving and blocks the euphoric effects of illicit opiates. Urine toxicology analysis should be carried out regularly and frequently to support subjective reports and interval history. A dose of 40 mg/day is adequate for some patients but there is evidence that most require a dose of 80 mg/day. Under Federal regulations, doses greater than 120 mg/day require permission, though lower ceilings can be specified in individual states. As with many psychopharmacologic treatments, the most common reason for treatment failure in

methadone maintenance is inadequate dose, and continued opiate use should prompt consideration of a dosage increase. There is evidence that trough methadone blood levels should be in the range 200 to 400 ng/ml for optimal treatment response, and blood level monitoring may be useful in nonresponders. Some patients are rapid metabolizers, which can be assessed by comparing peak and trough blood levels. Rapid metabolizers may benefit from a divided, twice daily dose schedule.

A pragmatic drawback of methadone maintenance is regulations require that it can only be administered at specially licensed clinics which require frequent attendance (daily at the outset), and are not even available in many geographic regions. This can be a practical constraint or a disincentive for many patients. On the other hand, it has been shown that the effectiveness of methadone maintenance depends upon regular counseling in conjunction with the medication, which is a requirement of methadone clinics, and more severely dysfunctional patients probably benefit from the structure imposed by clinic rules. Further, many of the better methadone clinics offer primary medical and psychiatric care, which is important since chronic opiate dependent patients often have multiple medical (e.g. hepatitis B and C, HIV) and psychiatric (e.g. depression, PTSD) problems.

A recent development is the approval and marketing of the long-acting opiate partial agonist buprenorphine (see also section above on opiate detoxification), which has been shown in clinical trials to have effectiveness equivalent to that of methadone for maintenance treatment. A major difference is that buprenorphine can be prescribed by any physician who has taken a brief training course and received certification, making it more widely available than methadone maintenance. The main regulatory restriction is that individual physicians practicing in an office-based setting are restricted to treating no more than 30 patients with maintenance buprenorphine at any one time.

Buprenorphine has interesting pharmacologic properties. It is a partial agonist, meaning that it binds opiate receptors but only partially activates them. This may translate into lower abuse potential compared with full agonists, although buprenorphine has been abused by intravenous injections in other countries where it was widely available. The sublingual formulations marketed for treatment of opioid dependence do appear to have limited abuse potential by themselves, and the Suboxone formulation, which includes naloxone, discourages attempts to extract and inject the contents, since intravenous naloxone will precipitate withdrawal; the naloxone is poorly absorbed by the sublingual or oral routes. Buprenorphine binds almost irreversibly to opiate receptors, and dissociates very slowly, accounting in part for its long duration of action. When properly dosed, similar to methadone, it induces tolerance, blocks the effects of other opiates, and produces little or no sedating or intoxicating effects.

The buprenorphine/naloxone combination (Suboxone) if preferred for both detoxification and maintenance treatment, although some patients may be more sensitive to the presence of the antagonist (naloxone) and tolerate straight buprenorphine (Subutex) better. Because it is a partial agonist, buprenorphine will precipitate withdrawal in individuals who have recently used any opioid drug; treatment should therefore begin when there are clear signs of withdrawal (or at least 4 hours after last use of a short-acting opioid) (see also section above on buprenorphine for detoxification). There is less experience of induction with buprenorphine in individuals using long-acting agents such as methadone, but the risk of precipitated withdrawal is greater. The daily methadone dose should be below 40 mg per day before

buprenorphine induction is attempted, and a delay of around 48 hours or more is advisable to allow withdrawal symptoms from methadone to clearly manifest. Induction is completed over 2 to 4 days, depending on the target dose. The recommended dose on day 1 is 16 mg, increasing to 16 mg on day 2 and thereafter and more gradual induction may be associated with a higher risk of drop-out. The dose should be adjusted in increments of 2 to 4 mg to that which keeps the individual in the treatment program and suppresses withdrawal symptoms; the target maintenance dose is 16 mg/day but may range from 4 to 32 mg/day. Buprenorphine should be administered as part of a psychosocial treatment program. The relative ease of withdrawing from buprenorphine may result in a greater tendency to leave the treatment program compared with methadone.

Due to its long duration of action, buprenorphine can be administered every other day (e.g. 32 mg every other day), or even twice per week; this property can be useful for patients where there are concerns about compliance, since the medication can be held at a clinic or by a significant other and administered under observation on a less than daily basis.

Buprenorphine can produce sedation. However, emergence of sedation should also raise suspicion of use of other drugs or alcohol. Unlike full opiate agonists (heroin, methadone, other narcotic analgesics) where respiratory depression is a serious risk, buprenorphine by itself produce less respiratory depression. The rate of deaths from drug overdose dropped substantially in France after buprenorphine was introduced for treatment of drug dependence. The one exception was overdoses of buprenorphine in combination with benzodiazepines where deaths were observed. This has led to an exaggerated concern that buprenorphine is contraindicated in patients who use benzodiazepines. For patients using benzodiazepines at regular, modest doses, which is the most common pattern even among opiate addicts, buprenorphine is safe. Patients who take large doses or binges of benzodiazepines are at risk for overdose in combination with a variety of other drugs, including buprenorphine, and alcohol. It is likely that the risk of overdose in such patients would be the same on either methadone maintenance or buprenorphine maintenance.

Naltrexone is a long-acting (24 to 48 hour duration) opioid antagonist available in 50 mg tablets. It is effective in blocking the effects of opioids and can be used as a maintenance treatment, but its effectiveness has been limited by poor compliance. Compliance can be improved with behavioral therapy, but rates of retention in treatment still remain well below what can be expected from agonist maintenance with methadone or buprenorphine. Further, naltrexone does not protect against opiate overdose; patients who stop naltrexone are not tolerant and are therefore vulnerable to overdose. Naltrexone is also complicated to manage. It cannot be started until a patient has been fully detoxified, in order not to precipitate withdrawal. Rapid induction methods using buprenorphine, clonidine and clonazepam, have been described, but generally require 5 to 7 days to carry out. Anesthesia assisted rapid detoxification and induction onto naltrexone has been shown to involve the same level of discomfort, with increased risk of serious adverse events, and is not recommended. Once a patient is inducted onto naltrexone, if they stop taking the naltrexone and relapse, naltrexone cannot be resumed without precipitating withdrawal, and repeat detoxification is needed. In summary, while some patients benefit from naltrexone, it is considered a second-line agent, for patients who have failed or refuse agonist treatment. Patients maintained on

naltrexone should be warned about the risk of fatal drug overdose if naltrexone is discontinued.

### Special Considerations

Methadone-maintained patients on medical-surgical units and pregnant patients merit special comment. After admission to general hospital, the dose of methadone should be verified with the patient's maintenance program. The dose should be maintained during the stress of an illness and its treatment. Maintenance methadone will suppress opiate withdrawal but it will not provide analgesia. Patients taking methadone who have severe pain should therefore be treated with nonopiate analgesics or short-acting opiates as needed, noting that higher doses and shorter dose intervals may be needed. Drugs with mixed antagonist-agonist activity, such as pentazocine and buprenorphine, may provoke opiate withdrawal and should be avoided.

Women who become pregnant should be encouraged to continue their methadone maintenance programme. The dose may need to be reduced during the third trimester and neonatal symptoms due to abstinence should be planned for. Longitudinal studies show that infants exposed to methadone in utero develop normally and parents should be reassured.

### Medications for Nicotine Dependence

By contrast with methadone, nicotine replacement therapy is not intended as an indefinite maintenance therapy. Instead, the aim is to provide a medically safe source of nicotine while gradually reducing the dose. Nevertheless, it is reasonable to speculate whether, in terms of harm reduction, nicotine replacement is superior to cigarette smoking. Two forms of nicotine are available without prescription: nicotine polacrilex (gum) and a transdermal patch. Both are effective in promoting abstinence.

The FDA has recently approved a sustained-release formulation of bupropion for the treatment of nicotine dependence; efficacy is similar to that of nicotine replacement therapy. The recommended dose is 150 mg twice daily; treatment should begin 2 weeks before the date on which smoking will cease. Combining nicotine replacement and bupropion offers greater efficacy and safety than either agent alone for patients who have not succeeded with monotherapy.

Many patients who succeed in initiating abstinence from cigarettes will relapse within 3 to 6 months. Clinicians and patients should not be discouraged by this. The data suggest that most patients who make repeated quit attempts eventually succeed in achieving sustained abstinence.

### Pharmacotherapies for Substance Abusers with Additional Types of Psychiatric Illness

Rates of substance abuse are higher than expected among patients with psychiatric disorders, and psychiatric disorders are higher than expected among people with substance abuse disorders.

Clinical experience shows that:

- treatment should be administered by professionals with considerable experience in both general psychiatry and chemical dependence;
- it is unrealistic to insist on abstinence as a precondition for treatment;
- some symptom stability may be necessary before reductions in substance use are evident;

- abstinence is not a prerequisite for safe and effective treatment with most psychotropic agents;
- unless treated as a disorder in itself, a substance abuse tends to persist after comorbid psychopathology is effectively treated.

This section summarises the management of particular psychiatric illnesses complicated by substance use and some relevant drug interactions.

### Drug Treatment for Specific Psychiatric Disorders

There is controversy about the stage at which a mood disorder induced by substance abuse becomes a major depressive episode. Most specialists will diagnose a second disorder in a patient who presents with a depressive syndrome only after a 2 week period of sobriety. However, evidence from clinical trials shows that antidepressants may be effective in patients who are not initially abstinent. Clinical judgment is therefore important and, if a nonabstinent patient has persistent depression, a trial of antidepressant therapy may be carried out. Concurrent use of an antidepressant and a substance of abuse may increase the risk of cardiotoxicity (arrhythmias), neurologic effects (seizures) or death from intentional overdose. These risks are greatest with the tricyclic antidepressants whereas the selective serotonin reuptake inhibitors have a safer pharmacologic profile. Patients should always be discouraged from substance abuse but significant numbers of those taking antidepressants also use alcohol and other potential drugs of abuse in moderation without harm. Antidepressants seem to have a low risk of abuse, though abuse of amitriptyline (for its sedative effects) and fluoxetine (for stimulant effects) has been reported.

Substance abuse or dependence is a common complication of schizophrenia and psychotic symptoms occurring during drug intoxication or withdrawal also complicate the diagnosis of schizophrenia. An especially high degree of psychiatric sophistication and patience is necessary for this group of patients. Long-term studies (>one year) show that patients with schizophrenia and substance abuse need an energetic treatment strategy to engage them in treatment for psychosis, with an emphasis on compliance with antipsychotic medication and the maladaptive effects of substance abuse. For most patients, the problem of substance abuse diminishes after a year of compliance with medication and treatment for addiction. In this setting, the use of long-acting depot antipsychotic preparations is rational. Medication may also be combined with contingency contracting for patients with schizophrenia, making the unsupervised use of disability benefits contingent on negative urine toxicology analysis.

Substance-induced disorders (particularly stimulant intoxication and alcohol or sedative-hypnotic withdrawal) can resemble generalized anxiety disorder or panic attacks, and thus, as with depression, at least a two week period of abstinence is preferable prior to initiating pharmacotherapy, although again there is room for judgment. Other anxiety disorders, such as social phobia, agoraphobia, PTSD or OCD have distinctive symptoms that do not overlap with symptoms of toxicity or withdrawal. Behavioral approaches are effective for many anxiety disorders, and should be considered, first alone and then as a supplement to pharmacotherapy. Antidepressants are effective in the treatment of panic disorder or generalized anxiety disorder and have less abuse potential than the benzodiazepines. Buspirone may be effective in generalized anxiety disorder,

especially at a dose of at least 45 mg/day. If a benzodiazepine is prescribed, clinical opinion supported by experimental evidence suggests that oxazepam and chlordiazepoxide are the safest alternatives because of their gradual onset of action and a lower risk of euphoria. In general, benzodiazepines should be avoided due to their abuse potential.

Substance abuse occurs frequently in patients with bipolar disorder but there is a lack of evidence of the effects of its treatment on substance abuse. Lithium does not appear to have significant interactions with alcohol and cocaine but there is little information about the safety of carbamazepine or valproic acid in patients with bipolar disorder and substance abuse.

Attention deficit/hyperactivity disorder (ADHD) occurs more frequently than expected among patients with substance abuse disorders, and high rates of substance abuse occur in children with both ADHD and conduct disorder. It is possible that such patients may preferentially seek stimulants as self-medication of their behavior disorder. The diagnosis of ADHD should be confirmed by evidence of childhood illness and if possible verified by another informant. There is some evidence that methylphenidate may be helpful in such cases and desipramine and bupropion, both of which are used to treat ADHD in children, have also been suggested. Studies are under way to improve our understanding of substance abusers with ADHD.

### Drug Interactions in Chemical Dependency

Drug interactions in patients with chemical dependency may be pharmacodynamic or pharmacokinetic, and may occur between drugs of abuse or between drugs of abuse and prescribed medications.

#### Alcohol

The combination of alcohol and cocaine has been associated with increased hepatotoxicity and fatal cardiotoxicity. Alcohol together with opiates or cannabis causes greater sedation and neurologic impairment than any of these agents alone. Acute alcohol intoxication inhibits hepatic enzymes, increasing blood levels of drugs metabolized by this system. By contrast, chronic alcohol use induces hepatic enzymes and lowers blood levels of antipsychotic drugs, tricyclic antidepressants, valproic acid, carbamazepine and certain benzodiazepines. Griseofulvin, metronidazole, chloramphenicol and oral hypoglycemic agents cause a mild disulfiram-like reaction in combination with alcohol. Chloral hydrate and alcohol are both metabolized by a pathway dependent on alcohol dehydrogenase; taken simultaneously, competition for this enzyme results in higher blood levels of both agents (this combination is known as a “Mickey Finn”).

### Cocaine and Other Stimulants

The combination of cocaine and cannabis is associated with more tachycardia than with either agent alone. Combining heroin and cocaine in a “speedball” more readily produces respiratory depression than either alone. The use of cocaine or amphetamine by someone taking a monoamine oxidase inhibitor may result in hypertensive reactions.

#### Opiates

Methadone increases blood levels of tricyclic antidepressants and zidovudine. Conversely, methadone levels may be reduced to the point where abstinence occurs by rifampin, phenytoin, barbiturates and carbamazepine. Meperidine taken during treatment with a monoamine oxidase inhibitor may cause extreme reactions ranging from collapse (hypotension and coma) to excitation (hypertension and convulsions).

#### Nicotine

Smoking cigarettes smoking lowers blood levels of caffeine; caffeine toxicity may be therefore be misinterpreted as nicotine withdrawal in patients who stop smoking. Smoking also lowers blood levels of antipsychotic drugs, tricyclic antidepressants, theophylline and propranolol.

#### Hallucinogens

Hallucinogens may act partly via serotonergic mechanisms and it is therefore unsurprising that a serotonin reuptake inhibitor reportedly exacerbated hallucinogen-persisting perception disorder (flashbacks) in adolescent LSD users.

# Therapeutic Management of the Suicidal Patient

---

According to 1999 data from the Center for Disease Control and Prevention, suicide kills more people than homicide. Suicide was the eleventh leading cause of death (homicide was fourteenth), and the third leading cause of death between ages 15 and 24 years. In the year 1999, 29 199 Americans took their own lives (Hoyert *et al.*, 2001). Suicide and the suicidal patient represent a significant public health problem. The vast majority of people with suicidal intent have a major psychiatric diagnosis. It has been estimated that 90% or more of them can be shown to have a major psychiatric illness (Henriksson *et al.*, 1993; Mann, 2002). Some patients become suicidal, or commit suicide with relatively little warning. Others have communicated their intent to a caregiver or significant other. A significant proportion, estimated as high as 70%, saw a physician within 30 days prior to their death, and nearly 50% had seen a physician in the preceding week (Barraclough *et al.*, 1974). It was noted in the classic studies of Robins and colleagues (1959) that only 18% of suicidal patients communicated their intent to helping professionals, while 69% communicated their intent to an average of three close relatives or associates, 73% within 12 months of their suicide (Robins *et al.*, 1959).

Some patients become acutely suicidal while others are chronically at risk. Suicide leaves in its wake intense suffering among the victim's family and friends, including feelings of grief, anger, shame and frequently guilt. There are relatively limited data on the frequency of suicide attempts. Management of the chronically suicidal is frequently a source of frustration and fear for caregivers. Identifying the risk factors, understanding the suicidal patient and intervening appropriately are key elements in the prevention of suicide. There is a role for parents, families, friends, schools, workplaces and physicians in this task. The suicide rates have fallen since 1993 (Hoyert *et al.*, 2001). However, it remains a given that even with due diligence, not all suicides can be predicted or prevented.

Mann and colleagues (1999) have proposed a stress-diathesis model of suicidal behavior, as "a psychiatric disorder is generally a necessary but insufficient condition for suicide". The model posits that suicidal behavior is a function of an individual's threshold for suicidal acts and the stressors that can lead to vulnerability. The authors believe that the threshold for suicidal acts is trait-dependent (diathesis), and is mediated by factors such as aggression, impulsivity, substance abuse, family history and low brain serotonin function. Stressors include psychiatric illness and interpersonal problems. In this model, intervention should consider the diathesis as well as the stressors (Mann *et al.*, 1999). Low serotonin levels may be the underlying feature of suicidal behavior, aggression and substance abuse (Mann *et al.*, 1999).

## Hypotheses

### Dynamic

Dynamic theories facilitate the attempt to understand patients and their difficulties. Gabbard (2000) presents an overview to these approaches to understanding the suicidal patient. As he discusses, Freud postulated that suicide could be the result of displaced murderous impulses toward an internalized object, and later in the structural model, the aggression of a sadistic superego against the ego. Menninger believed that suicide was a function of wishes to kill (e.g. an angry act designed to devastate survivors), be killed, and to die. A familiar theme in object relations of the suicidal patient is the conflict between the internalized tormentor and the anguished victim. Patients may either identify with the internalized aggressor and lash out at others or submit to the tormentor through suicide. Fenichel noted the less aggressive reunion fantasy, in which death abates object loss by the imagined joining with a departed loved one, frequently a maternal superego figure. When identity and self-esteem are tied to a lost object, suicide can be viewed as restorative. Pathological grief and anniversaries of losses may be vulnerable times for such patients (Gabbard, 2000).

Cognitive rigidity, especially the inability to revise expectations of the self, can lead to hopelessness and suicidality. Suicidal ideation that is egosyntonic is especially concerning. Four patterns of ego functioning and object relations that differentiate between serious attempters and manipulative gestures are: "(1) an inability to give up infantile wishes for nurturance, associated with a conflict about being overly dependent; (2) a sober but ambivalent view toward death; (3) excessively high self-expectations; and (4) overcontrol of affect, particularly aggression" (Gabbard, 2000).

In contrast to those who are intent on dying, most patients are ambivalent about death, and can come to choose life. Psychotherapy can be an important avenue to understanding why a patient wants to die and what they expect in the aftermath. Gabbard sees this effort as treatment, while providing safety may only be management (Gabbard, 2000).

### Neurobiology

There are genetic and biologic correlates of suicidality as well as the underlying psychiatric illnesses that are often associated with suicidal behavior. For example, Ahearn and colleagues (2001) compared MRI studies in 20 pairs of unipolar depressed patients with and without suicide attempts. Subjects were matched on cardiovascular history, ECT treatment and psychosis. There were no

statistical differences in age of onset of illness, number of episodes, or depression ratings. It was found that the patients with suicide attempts had more subcortical gray matter intensities. There was a trend toward more periventricular white matter hyperintensities in the patients with suicide attempts. The authors concluded that patients with abnormal MRI, especially gray matter hyperintensities in the basal ganglia, may be at higher risk for mood disorders and suicide attempts secondary to interference in neuroanatomic pathways. These pathways may be crucial to mood regulation (Ahearn *et al.*, 2001). These and other neurobiologic correlates may improve our ability to predict suicide and suicidal behavior. Promising mechanisms include the serotonin system, although adrenergic and dopaminergic systems have also been implicated. Abnormalities in the hypothalamic–pituitary–adrenal (HPA) axis have long been associated with mood disorders.

For example, dysregulation in the serotonin system has been linked to major depression, suicide and violence (see Table 85.1). Disparate findings are a function of the inherent difficulties with association studies. A number of these studies have found an association between reduced serotonin function, including low levels of the serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) in cerebrospinal fluid (CSF), with impulsivity, violence and suicide (Mann, 1998; Placidi *et al.*, 2001). Low CSF 5-HIAA levels may also predict future suicide attempts (Roy *et al.*, 1989). Aggressive behavior and, independently, suicidal behavior, may have impulsivity as a common denominator, which may be mediated by serotonergic dysfunction (Placidi *et al.*, 2001).

Small sample sizes, heterogeneous diagnostic groups, retrospective analyses, uncertain impact of psychotropic agents, the continuum of suicidal behaviors (manipulative gestures to self-mutilation without the intent to die to completed suicide), and the “cross talk” between many of the neurobiologic systems targeted for study can all undermine consistency of findings.

Suicide is a multiply determined act, including genetic vulnerabilities, mental illness, environmental and social stressors, impulsivity, and aggressive tendencies.

### Psychiatric Diagnoses

A number of psychiatric diagnoses are linked with suicidality. While patients with mood disorders (major depression and bipolar disorder) are commonly assessed for suicidality, anxiety disorders are also associated with significant suicide risk. Psychosis, in both mood disorders and schizophrenia, can heighten risk. Although borderline personality disorder has a high prevalence of suicidal ideation, impulsivity and self-injurious behavior, these patients are at risk for unexpected intentional and accidental death.

### Bipolar Disorder

Oquendo and colleagues (2000) evaluated the applicability of their stress-diathesis model to a sample of bipolar patients. As with their other sample of psychiatric patients (Mann *et al.*, 1999), objective illness severity was not a differentiating factor between bipolar attempters and nonattempters, although the symptoms were more severe at the index hospitalization via self-report and research clinician depression ratings. Similarly, bipolar attempters had increased suicidal ideation, hopelessness and decreased reasons for living. In contrast, there were no differences in impulsivity, although bipolar attempters had higher lifetime aggression. Oquendo and Mann (2001) include gender (men more likely to attempt than women, in contrast with other studies); white race; age (no difference in their study); suicidal ideation, hopelessness, fewer reasons for living; life time aggression and impulsivity; smoking, alcoholism and substance abuse, and family history of suicide as possible diathesis-related suicide risk factors for bipolar patients. Stress-related risk factors in

**Table 85.1 Summary of Serotonin Mechanisms**

Serotonin Mechanisms	Suicide Attempts	Postmortem Studies
5-HIAA	↓ CSF (Placidi <i>et al.</i> 2001, Cremniter <i>et al.</i> 1999) ↓ plasma (Spreaux-Varoquaux <i>et al.</i> , 2001) ↓ urine (Brunner <i>et al.</i> , 1993)

bipolar patients may include depressed or mixed state (Oquendo and Mann, 2001).

### Anxiety Disorders

A frequently overlooked risk factor for suicidal behavior is anxiety. The clinical history features that are most predictive of serious suicide attempt in a study of patients with suicide attempts (Hall *et al.*, 1999) are severe anxiety (92%) and panic attacks (80%), partial insomnia (difficulty falling asleep, middle insomnia, early morning awakening) (92%), depressed mood (80%), relationship disruption (78%), substance abuse (68%), pessimism (hopelessness 64%, helplessness 62% and worthlessness 29%), global insomnia (46%) and anhedonia (43%). Severe anxiety and agitation may be an important risk factor for an acute suicide attempt. These “modifiable risk factors” may be responsive to early intervention. Evidence accumulated argues for the assessment of severe anxiety/agitation and aggressive anxiolytic treatment in the management of suicide risk.

### Psychosis

Grunebaum and colleagues (2001) reported that about half of the reviewed articles published since 1982 reported a positive association between delusions and suicidal ideation or behavior and about half found a negative association. Approximately half of the subset of studies of delusional depression and suicide risk were negative. Half of the studies of delusions and suicide risk in schizophrenia were negative. A study of delusions and suicidal ideation in bipolar patients was negative.

Although the best predictors of suicidal behavior are past history of suicide attempts, substance abuse, and chronic and/or deteriorating clinical course, clinicians should consider new onset psychosis as a significant risk factor (Verdoux *et al.*, 2001).

### Borderline Personality Disorder

Suicidal behavior is frequently associated with affective lability, anger, impulsivity and disruption in interpersonal relationships. Suicidal ideation and suicide attempts are part of the diagnostic criteria for borderline personality disorder. The recurrence and/or chronicity of suicidal ideation, combined with multiple low lethality attempts, have assigned some of these episodes to communicative idioms of distress or suicidal gestures. However, there is evidence (Soloff *et al.*, 2000) that suggests borderline personality disorder may be predictive of the number of attempts, but does not differentiate attempt characteristics, for example intent to die, planning, or lethality. Assumptions about the seriousness of suicidal behavior based on diagnosis alone may be flawed. Comorbid substance abuse and interpersonal disruption/abandonment issues heighten the risk (Soloff *et al.*, 2000).

### Risk Factors

Since there are no reliable and specific tests for suicidal behavior, the clinician must rely on clinical, demographic, historical and patient self-report information to guide their judgment and to tailor their intervention. However, the clinician should not be lulled into a false sense of security because of their assessment. The positive predictive value of individual or group of risk factors is low. Stepwise multiple regression was used to develop a statistical model that would predict suicide in 1906 inpatients (admitted between 1970 and 1981). There were 46 suicides at the

**Table 85.2 Risk Factors**

Irresponsible media coverage of suicides

end of the follow-up period (1983). Medical illness, substance abuse, personality disorder, marital status were among characteristics that failed to reach significance for the final model. Variables that met significance level criteria (number of prior suicide attempts, suicidal ideation, bipolar disorder, gender, outcome at discharge, unipolar depression with bipolar first-degree relative) were included in the model. The model did not identify any patient who committed suicide. Limitations include the low suicide rate and possible underestimation of suicides (Goldstein *et al.*, 1991). There may be differences in people who attempt suicide versus those who complete it. In 1999, it was estimated that there were 730 000 annual attempts, with an attempt and completion ratio of 25 : 1. It was estimated that 5 million had a history of a suicide attempt (Hoyert *et al.*, 2001). Differential risk factors include gender, ethnicity, age, substance abuse, past suicide attempts, means, family history, hopelessness, comorbid medical conditions, relationship/esteem losses resulting in murder–suicide and media coverage (see Table 85.2).

### Assessment of Suicidal Patients

Common presentations include acute, chronic, contingent, and/or potentially manipulative suicidal patient. All are associated with anxiety for the care provider doing the assessment. Careful assessment, use of collateral information and acceptance of predictive limitations can be helpful (see Table 85.3).

As reviewed by Nicholas and Golden (2001), factors to be considered in the assessment of the acutely suicidal patient include the current mental status, with special attention to direct inquiry about suicidal ideation, intent (may be ascertained from family and friends, for example, saying good-byes or putting affairs in order), and plans (well thought out with available means). Sadness, hopelessness, social withdrawal/isolation, anxiety, agitation, impulsivity, insomnia, psychosis (especially command hallucinations or distressing persecutory delusions) are additional concerning symptoms. These factors, coupled with prior high lethality attempts, uncommunicative presentation, recent major loss, active substance abuse, or untreated mood, psychotic, or personality disorder, might indicate that hospitalization is warranted to ensure safety prior to treating the underlying psychiatric disorder (Nicholas and Golden, 2001).

Sachs and colleagues (2001) reviewed suicide prevention strategies for bipolar outpatients, but they can easily be adapted to any potentially suicidal patient. The reader is reminded that “care providers can, however, be fooled by the deceptions of a

clever patient intent on carrying out a lethal act". Individualized treatment plans should be developed after eliciting current symptoms, including suicidal ideation; review of risk factors, stressors, comorbid states like substance use; and past history of suicide attempts. Acute efforts are directed toward safety and treating the underlying disorder, with follow-up monitoring. Adjunctive medications like antipsychotics and anxiolytics can be beneficial. Clinicians must monitor the amounts of medications prescribed and continue to be vigilant during early recovery. Harm reduction strategies can include minimizing access to lethal means, decreasing social isolation, close follow-up and informing of emergency contact procedures. Hospitalization may be warranted if suicide is considered as a solution for problems, for active suicidal ideation, or if there has been a recent attempt. With the caveat that while admission may provide safety, current knowledge of risk factors do not wholly inform when to admit or discharge, overreliance on hospitalization may deter honest reporting, and many acutely depressed patients can be managed as outpatients with sufficient safeguards. Involuntary admission, while not therapy in and of itself, may be lifesaving. ECT remains a safe, typically quick onset, effective option for those at high risk of suicide (Sachs *et al.*, 2001).

There is no evidence that denial of suicidal intent predicts nonsuicide. Review of standard risk factors, additional risk factors (e.g. acute relationship and employment changes), acute versus chronic suicidal ideation, and treatment of readily reversible factors should be undertaken. High risk diagnoses include major depression, bipolar disorder, schizophrenia, alcoholism and substance abuse, and borderline personality disorder. Comorbid alcoholism increases the risk in every diagnostic category. A history of past attempts, hopelessness, previous hospitalizations and recent discharge, while not individually predictive, do heighten concern. Acute risk factors include severe anxiety, panic attacks, global insomnia and agitation. These symptoms should be carefully assessed, with aggressive intervention. Benzodiazepines and antipsychotics can be employed to address anxiety and agitation. Caution must be taken with benzodiazepines to avoid disinhibition and combination with alcohol. Mixed states may require mood stabilizers. Serial assessments should be performed with acute changes as well as chronic suicidal states.

Chronically suicidal patients also require aggressive treatment of anxiety and agitation. DBT and cognitive behavioral therapy (CBT) can be helpful in addressing parasuicidal and suicidal behavior.

A significant number of psychiatrists utilize the no-suicide contract, or the contract for safety. Over half of a sample of psychiatrists acknowledged using them in recent survey, and 41% of them had patients make suicide attempts after entering into one (Kroll, 2000). Sixty-four percent of 14 psychiatric hospital inpatient suicides denied suicidal ideation and half had some form of no-suicide agreement in place in the week before their deaths (Busch *et al.*, 1993). These have not been systematically studied as to whether they have any protective effect (Gray and Otto, 2001). Resnick (2002) cautions that psychiatrists tend to view the patient as a collaborator in treatment. However, the psychiatrist can be less viewed as an "ally" and become an "adversary" when the patient has determined to die by suicide. He notes that failure to recognize this shift in the doctor-patient relationship can have devastating results. Objective evidence, as opposed to patient subjective reports, may be telling. Alliances with family and other caregivers should be maintained, as they can become crucial sources of information. Resnick believes that no-suicide contracts have little credence, especially in an adversarial relationship, cause a false sense of security for the therapist, and have no research literature to suggest efficacy (Resnick, 2002).

Gutheil and Schetky (1998) wrote of a most difficult assessment: the patient who expresses suicidal ideation in terms of a future eventuality. The "if [event or outcome does or does not happen], I will kill myself" contingency poses different challenges from acute suicidality, manipulative suicidal threats and chronic suicidality. Suicidality typically engenders anxiety in the therapist. Contingency suicidality frequently lacks verbalized imminence, may make involuntary commitment difficult, and invites countertransferences which can lead to exaggerated or inappropriately muted responses. For some patients, the contingency is a defense against suicide. For others, it represents the ultimate control. Gutheil and Schetky (1998) make several important points: 1) Some patients almost have an object relationship with death, with death personified as a benevolent bringer of relief. The therapist should approach that tie with caution, as it may be the only one in which the patient has any confidence; 2) Future deadlines should not be accepted literally; 3) Even when the contingency is met positively, the suicidal ideation may not resolve; 4) Some patients view themselves as already dead, cannot conceive of life without depression, and challenge the therapist to resurrect them. This stance undermines any potential relationship; and 5) It is of benefit to negotiate a halt to suicidal acts until depression can be separated from decision-making. Gutheil and Schetky assert "... psychiatrists should never support suicide, but should acknowledge the human impossibility of preventing it". The authors note that in these circumstances, the patient is at least communicating their suicidal ideation. The rationale can be explored and an effort made to maintain the therapeutic relationship. Helplessness should be discussed, as suicidal ideation can be a defense against lack of control or an expression of pain. The countertransference of the therapist should be considered, as it can cloud clinical judgment. Consultation with colleagues can be very helpful. The competency of the patient may be called into question, and has been used as a defense in suicide malpractice cases. The clinician can frequently be justified in involuntary commitment as critical dates or junctures approach. Finally, Gutheil and Schetky state that "accepting the patient's pain and

sense of hopelessness is not the same as acceding to his or her wish to commit suicide; the psychiatrist must always hold out hope. At the same time, it may be therapeutic and realistic to let patients know that one can not ultimately prevent their suicides” (Gutheil and Schetky, 1998).

### Intervention

Successful suicide prevention strategies include educating the public and primary care providers about mental illness, its common presentations, the availability of treatment and how to access it. Underdiagnosis and undertreatment remain significant problems. Antidepressants, lithium, mood stabilizers and ECT, as well as adjunctive benzodiazepines and antipsychotics, can significantly ameliorate underlying psychiatric diagnoses associated with suicide. Psychosocial interventions have much to add, especially for chronic suicidal ideation, but more intensive outpatient strategies may be limited by resources available.

### Education

Educating the public and clinicians about the prevalence, symptoms and available treatment for mood disorders is of crucial importance. It is estimated that half to a quarter of mood disorders go undiagnosed and untreated (Grandin *et al.*, 2001; Nierenberg *et al.*, 2001). Many patients will have spoken to significant others about their distress or have recently seen a health care professional. The US Surgeon General issued a call to action in 1999 to prevent suicide. The linchpins of the strategy include awareness, intervention and methodology. Recommendations include improving public awareness of suicide, including their preventability, enhancing access to prevention resources, and decreasing the stigma of mental illness. Interventions include improved ability of primary care physicians to recognize, treat, or refer the mentally ill; remove barriers; create incentives to treatment; train other professionals, community members and family to recognize or assess risk; develop programs for at risk adolescents; enhance community access to care and support for suicide survivors; and partnering with the media for educated reporting and depictions of mental illness and suicide deaths. Methodology involves researching effective prevention programs, clinical and culture specific interventions; developing evaluation tools to measure efficacy of interventions; and the reduction of access to lethal means of suicide (US Public Health Service, 1999).

Oquendo and colleagues (1999) examined the aggressiveness of antidepressant treatment on patients with major depression, with and without suicide attempts. They included 171 inpatients with major depression, 80 “remote” (defined by the authors as an attempt more than 90 days prior to admission) suicide attempters and 91 nonattempters, in their data analysis. Subjectively and objectively, degrees of major depression were not significantly different. Only 15% of the entire sample was taking antidepressants on admission, and of those who were, 35% were deemed adequately dosed. Almost inexplicably, the patients with a history of suicide attempts, and therefore more likely to have future attempts, were less likely to receive adequate antidepressant therapy. The failure to diagnose and adequately treat major depression warrants ongoing education of all physicians (Oquendo *et al.*, 1999).

Two reports from the NIMH Collaborative Depression Study, 1978–1980 (Keller *et al.*, 1982, 1986), also note undertreatment. Keller and colleagues (1982) described 217 patients

entering the naturalistic study. Only 3% with moderate to severe unipolar depression of a month’s duration had been treated with the most intensive dose of tricyclic antidepressants. A quarter of those with psychotic depression received the most intensive therapy and another quarter with psychotic depression received no antipsychotics or antidepressant therapy of any category. The follow-up report (Keller *et al.*, 1986) described treatment of 338 patients in the 2 months after enrollment. Of inpatients, 31% received no or inadequate antidepressant somatotherapy, and only 49% received the equivalent of at 200 mg of imipramine. Of outpatients, 51% received no or inadequate somatotherapy, and 19% received the equivalent of 200 mg of imipramine. As reviewed by Hirshfeld and colleagues (1997), there is “overwhelming evidence” that depression is being undertreated, both before and during the widespread use of SSRIs.

### Lithium

Lithium shows consistent antisuicidal effects (Tondo *et al.*, 2001a). Tondo and colleagues (2001b) performed a meta-analysis of the suicide risk with long-term lithium treatment. They included 22 studies, 13 of which provided data on suicide rates with and without lithium ( $N = 5647$  patients), and analyzed suicide completions, not attempts. Suicide rates were higher without lithium in all of the studies except one. Four of the studies were exclusive to patients with bipolar disorder. Suicide rates were significantly lower (81.8%) during lithium treatment. Notably, suicide rates in this population were significantly higher than in international general populations. This is probably reflective of differences between clinical and general populations, inclusion of highly suicidal individuals in the study samples, partial or failed treatment, and possible noncompliance (Tondo *et al.*, 2001b).

As reviewed by Goodwin (1999), there has been increasing use of anticonvulsants in the management of bipolar disorder. Anticonvulsants may have an advantage in rapid cycling, mixed states, comorbid substance abuse, or history of poor response to lithium. There is little data about the suicide preventive impact of the anticonvulsants, although a comparison of lithium and carbamazepine was more favorable to lithium (Thies-Flechtner *et al.*, 1996). Both lithium and anticonvulsants can have a positive impact on suicide risk factors of impulsivity and aggression (Goodwin, 1999).

### ECT

Electroconvulsive therapy (ECT) has long played a role in the treatment of severe, and treatment refractory depression. Thus, ECT is indicated for illnesses frequently associated with suicidal symptoms, and is noted for relatively quick efficacy. It can have a profound impact on acute suicidal symptoms, in both responders and nonresponders. The authors conclude that although an acute treatment, ECT’s long-term impact on mortality may be a function of repeated use in treating or preventing (via continuation and maintenance ECT) relapse and recurrence (Prudic and Sackeim, 1999).

### Psychosocial Interventions

Sachs and colleagues (2001) note that psychotherapy is not a cure for suicidal ideation, but may strengthen protective factors and decrease inclination. Gray and Otto (2001) reviewed psychosocial approaches to suicide prevention and their applicability to

bipolar patients. An approach tailored toward psychosocial risk factors, for example, hopelessness, poor problem-solving, negative cognitions and dysfunctional coping strategies, may be particularly helpful. Gainful employment and increasing social supports are also appropriate goals. Gray and Otto (2001) reviewed 17 randomized, controlled studies of efforts to decrease suicidal and self-injurious behavior. The studies could be categorized as brief hospitalization, efforts to enhance treatment utilization, problem-solving interventions and intensive treatments. Brief hospitalization was associated with negative to small effect size, while facilitated/rapid hospital reentry was more promising for subjects with initial episodes of self-harm. Studies of some outreach services found no benefits, while those that included home visits had modest to no reductions in suicidal behavior. One in this latter category with noteworthy results (threefold difference compared with treatment as usual) involved 4 months of weekly or biweekly home-based interventions combining psychotherapy, crisis intervention and family therapy (Welu, 1977). This represents a significant commitment of resources. Problem-solving interventions, for example, around interpersonal conflicts or cognitive behavioral therapy, had moderate effect size, and were largely brief, structured and problem-focused. Intensive treatments (1 year) like dialectical behavior therapy (DBT) reflected a large effect size (Gray and Otto, 2001).

Clinicians should consider three effective strategies: lowering barriers to care during times of distress, brief training in problem-solving strategies, and comprehensive strategies that combine problem-solving with intensive rehearsal of cognitive, social, emotional-labeling and tolerance, and coping skills. Patients and families should be educated on procedures for accessing after-hours and emergency care. Cognitive restructuring can address hopelessness, pessimism, cognitive distortions and enhance reasons for living. The development of distress-tolerance skills may be particularly beneficial for patients who feel unable to resist urges to harm themselves or have chronically maladaptive responses to stress (Gray and Otto, 2001).

### Aftermath: Clinicians Coping with Patient Suicide

A suicide has repercussions for all parties involved. Primary care providers can be as, or more, vulnerable to patient suicides than psychiatrists. As reviewed by Luoma and colleagues (2002), they are more likely to have been in recent contact with a suicide victim than mental health professionals. In their review of 40 studies, last contacts with mental health services compared with primary care providers within 1 month and 1 year of death were 19% versus 45%, and 32% versus 77%, respectively. The lifetime rate of contact with mental health services averaged 53%.

Kaye and Soreff (1991) had a number of recommendations in the aftermath of a patient suicide, with the caveat that a patient suicide is a very personal event, and the approach has to be individualized in recognition of nuances. They believe that families should be contacted and met with, told realistically of all the efforts on the decedent's behalf, and contact maintained through the funeral and autopsy report. Hospital staff should be contacted and, if possible, informed as a group. Attendance at the funeral can be beneficial. They advocate the psychological autopsy as an opportunity to vent as well as facilitate learning and any policy reform. In some instances, inpatients or surviving group members should meet with staff, with a concern toward patients' devaluing staff and increased suicidal risk to surviving patients.

The treating psychiatrist should seek support, solicit formal or informal consultation with colleagues, consider attending the funeral or sending forms of condolence, and offer expressions of sympathy. The latter is not felt to represent an admission of guilt. A psychological autopsy should be conducted, and attending the autopsy is not verboten in their opinion. Billing for past services, although difficult, is typically appropriate. If affiliated with an institution, cooperation with its risk management is advised, with due caution. Medical records should be accurately completed, with those submitted after the patient's death clearly reflecting so. Although the suicide of a patient reminds the psychiatrist of powerlessness, the psychiatrist should function as team leader in the aftermath (Kaye and Soreff, 1991).

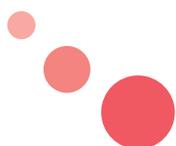

### Conclusion

Suicide is a multiple-determined phenomenon, with psychological, dynamic and biologic substrates. Future sophistication in neurobiology and genetics may add greatly to our very limited predictive power as to who is at risk and improve our interventions. Even so, there remains a significant failure appropriately to utilize the knowledge base that we currently have. Too many patients commit suicide because they were undiagnosed, undertreated, or too stigmatized to seek mental health treatment. Those patients who are identified and treated continue to have risk. They require a therapeutic alliance, and frequently our ability to bind anxiety, psychosocial interventions and judicious hospitalization, in addition to our biologic armamentarium.

## Introduction

Violent behavior in patients with psychiatric disorders is a frequent reason for presentation to an emergency room and subsequent admission to an inpatient unit, and is often an obstacle to discharge and reintegration back into the community. Aggressive behavior places other patients, mental health workers and family members or other caregivers at risk for harm. Fortunately, within the past 10 years, new treatment approaches have emerged enabling greater opportunities for the successful management of these behaviors.

Some patients are violent only when acutely psychotic, while others may have persistent aggressive behavior unrelated to psychosis. Co-occurring substance use disorders increase the risk of violent behavior. Neuropsychiatric deficits and poor impulse control, underlying character pathology, or a chaotic environment may also be contributing factors.

The management of violent behavior can be divided into short-term and long-term strategies. First, there is a need to manage acute episodes of agitation. Secondly, there is a need to decrease the frequency and intensity of these episodes. The pharmacological treatment of acute agitation requires the use of sedating agents, but long-term use of these same agents would interfere with a patient's level of functioning. Consequently, long-term approaches require the use of medications that target aggressive behavior, without causing undue sedation.

## Definitions

Aggression, violence, and hostility are used in the psychiatric literature to denote behaviors that are particularly noxious and a considerable source of concern for those in the field. These terms are used with varying precision and interpretation of research data can be a challenge when different studies use different definitions. Published rating scales may contain their own definitions and these scales may be further modified or adapted to the specific needs of the study in question. In general, "aggression", a term used for both human and animal research, is defined as overt behavior involving intent to deliver noxious stimulation to another organism or to behave destructively toward inanimate objects. Humans demonstrate three main subtypes of aggression: verbal aggression, physical aggression against other people and physical aggression against objects. "Violence" is an exclusively human term, and usually denotes physical aggression against other people and thus can be seen as a subtype of aggression. On the other hand, "hostility" is a loosely defined term in the psychiatric literature. Hostility may include agitation, aggression, irritability, suspicion, uncooperativeness and jealousy, depending on the context in which the word is used.

Agitation can be defined as excessive verbal and/or motor behavior. Mild agitation can escalate to include behaviors such as aggression and violence.

## Pathophysiology of Aggressive Behavior

Several principal pathways leading to a predisposition to aggressive behavior are schematically displayed in Figure 86.1. The parents may contribute to the offspring's predisposition via transmitted genes, fetal environment, obstetric complications and rearing environment. Several polymorphisms of genes that control the activity of various neurotransmitters (particularly serotonin and catecholamines) are apparently associated with persistent aggressive behavior. Maternal use of alcohol, smoking and malnutrition during pregnancy were all reported to explain statistically significant (but clinically modest) proportions of the variance of aggressive behavior in adult offspring. Obstetric complications, particularly in interaction with other factors such as early maternal rejection, may lead to elevated rates of violent crime in the offspring. Rearing environment not just limited to overt child abuse is one of the most important factors in the development of predisposition to violence. Detailed explanation of Figure 86.1, as well as the bibliography supporting it, are presented elsewhere (Volavka, 2002).

Mechanisms displayed in Figure 86.2 may operate in persons with or without a diagnosable mental disorder. We will now focus on aggressive behavior in persons with mental disorders.

## Substance Use Disorders

Acute effects of alcohol and illicit drugs are involved, perhaps causally, in a large proportion of aggressive incidents. For example, 51.6% of women injured during a physical assault by a male partner reported that the assaulter had been drinking just before the incident (Kyriacou *et al.*, 1999). Positive urine tests for illicit drugs were obtained in a majority of arrested males in the USA (Pastore and Maguire, 2000, p. 380). Epidemiological studies indicate that substance use disorders elevate substantially the prevalence of overt physical aggression (Swanson, 1994).

## Psychoses

Most persons diagnosed with a psychosis are not violent. Nevertheless, psychoses are associated with an elevated risk for aggression. It is clear that comorbidity of psychosis and substance use disorder contributes to this risk very substantially. Furthermore, persons with psychoses are more likely to have substance use disorders than other people (Regier *et al.*, 1990). Combination of substance abuse and nonadherence to treatment is the typical prelude to the development of aggressive behavior in persons with severe mental illness living in the community (Swartz *et al.*, 1998).

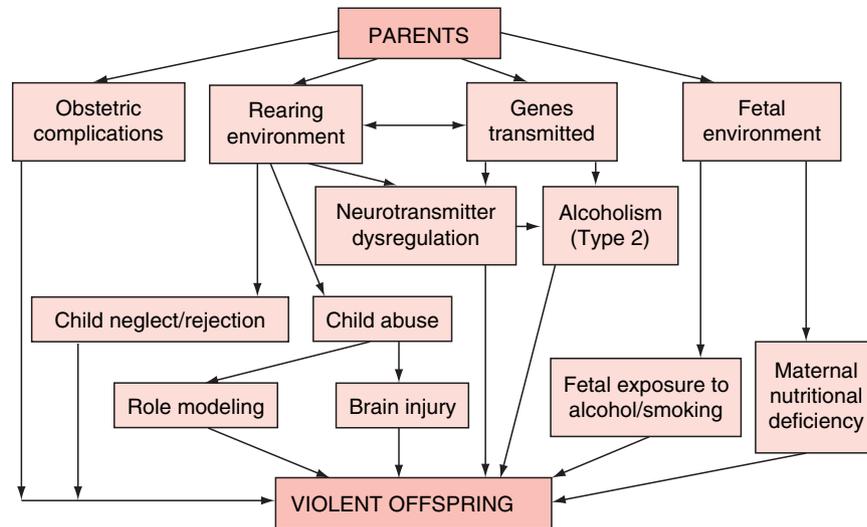

Figure 86.1 Transmission of violence.

As every hospital psychiatrist knows, there are many psychotic inpatients who are aggressive without access to alcohol and drugs, and in spite of supervised antipsychotic treatment. Thus, factors other than substance use and nonadherence to treatment must be involved in the pathophysiology of aggression in these patients.

From the standpoint of practical management of aggressive patients with major mental disorders, it seems that it could be fruitful to study in detail individual assaults in order to assess underlying pathophysiology. This is a promising avenue of research since it is generally agreed that aggressive behavior has multiple causes that differ among patients, and perhaps among different incidents in individual patients. Our experience, based on interviews of assailants, victims and witnesses, as well as on observations of videotapes, suggests that most assaults among psychiatric inpatients diagnosed with psychoses are not driven

by psychotic symptoms. It appears that many of these assaults are attributable to comorbid personality disorders.

### Personality Disorders

Antisocial personality disorder (APD) is partly defined by aggressive behavior and therefore it is not surprising that many violent psychotic patients meet its diagnostic criteria. This circularity of definition makes the use of this diagnosis somewhat unhelpful. The concept of “psychopathy”, introduced to modern psychiatry by Cleckley (1976), is less circular since it relies primarily on personality and psychological processes rather than on criminal or aggressive behavior. Psychopathy is assessed by a valid and reliable checklist constructed by Hare and his coworkers (Hart *et al.*, 1992). Table 86.1 shows the screening version of the checklist intended for use in persons with serious mental illness (Hare, 1996; Hart *et al.*, 1995). The first six items in Factor-1 measure the severity of interpersonal and affective symptoms of psychop-

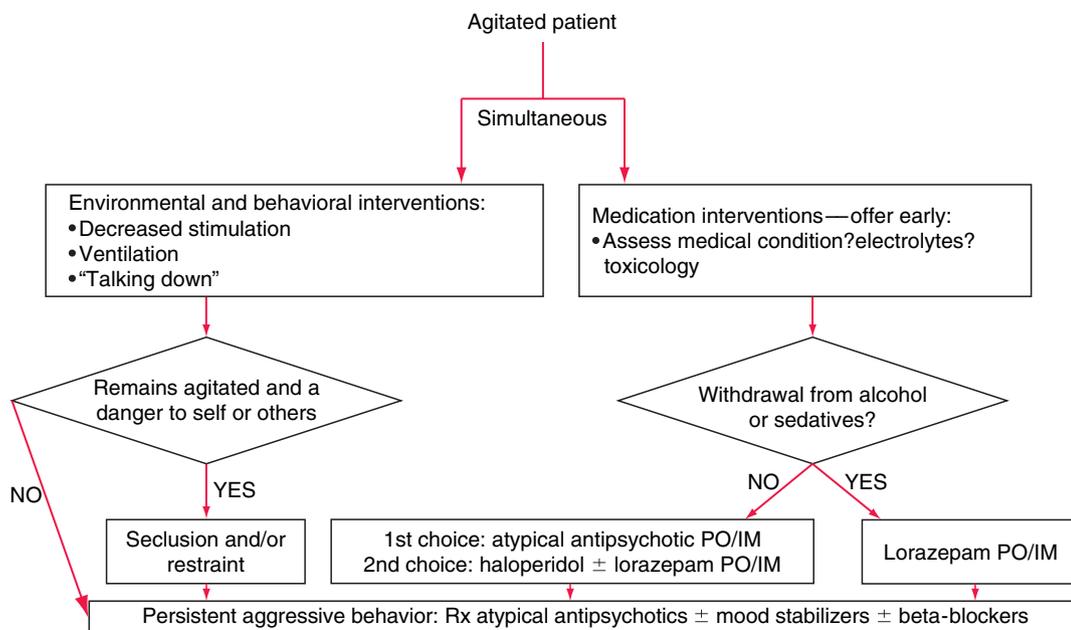

Figure 86.2 Management of agitation: overview.

**Table 86.1** Hare Psychopathy Checklist (Screening Version)

Factor 1: Interpersonal/ Affective	Factor 2: Social Deviance
1. Superficial	7. Impulsive
2. Grandiose	8. Poor behavior controls
3. Manipulative	9. Lacks goals
4. Lacks remorse	10. Irresponsible
5. Lacks empathy	11. Adolescent antisocial behavior
6. Does not accept responsibility	12. Adult antisocial behavior

athy. The next six items in Factor-2 reflect the social deviance symptoms. Psychopathy is a narrower concept than APD. Most psychopaths meet the criteria for APD, but subjects diagnosed as APD do not necessarily meet the criteria for psychopathy. Psychopathy predicts violent behavior in nonpsychotic individuals (Hare and Hart, 1993), as well as in persons with major mental disorders (Hart *et al.*, 1994). The rates of comorbidity of psychopathy and schizophrenia are elevated among violent patients (Nolan *et al.*, 1999).

Differentiating aggressive behavior based on psychopathy from that based on psychotic symptoms has consequences for treatment. It is unlikely that psychopathy will respond to antipsychotics.

## Acute Agitation

Agitation can be defined as excessive motor or verbal activity. Common examples include hyperactivity, verbal abuse, and threatening gestures and language. Unmanaged acute agitation can lead to violence. As such, acute agitation is a psychiatric emergency that requires rapid intervention. Oral medication treatment may be impractical or impossible. This section will focus on intramuscular medications within the context of a behavioral management plan.

## Assessment

Key points in assessment are outlined in Table 86.2. The time available for patient assessment will be dependent on the acuity of the presentation. For someone who is acutely agitated and an immediate danger to self or others, emergency measures must be taken to avoid harm. Somatic conditions must be ruled out prior to initiating additional treatment, as an underlying metabolic, toxic, infectious, or other nonpsychiatric cause may need to be treated. In these cases the agitation is a symptom to be treated alongside the underlying condition. This is not as great a concern for the physically healthy psychiatric patient whose history is well known to the staff than for the relatively unknown patient presenting to the emergency room. In addition, in the nursing home environment, new-onset agitation may indicate a newly emerging somatic condition. Once the patient is under behavioral control further medical and psychiatric work-ups can be done. Mechanical restraints may be necessary to prevent the agitated patient from injuring himself/herself, or others, while the medical work-up is being conducted.

**Table 86.2** Key Issues in Assessment of Acute Agitation/Aggression/Violence

1. Somatic conditions
2. Previous history of violence
3. Access to weapons
4. Current ideation, including content of delusions
5. Active substance abuse, including alcohol
6. Comorbid antisocial personality disorder/traits or psychopathy
7. Verbal threats
8. Premonitory physical signs (clenched fist, pacing)

Care must be taken not to miss comorbid conditions of alcohol or sedative abuse or dependence that may present with acute intoxication or withdrawal. Such conditions will drive the treatment choice towards the use of a benzodiazepine (see later).

Assessment should also include the context of the agitation. Patients may be purposefully using aggressive behavior to intimidate others. Antisocial personality traits may be the most important factor in some instances of patient violence where goal-directed behavior such as extortion of money or cigarettes is present. These antisocial behaviors may not always be evident to staff, as they can occur in unsupervised areas such as hallways, bedrooms and bathrooms. Such predatory behavior may involve victims who are unable to articulate what is happening to them, while the aggressor appears to have an abundance of material goods or undue influence on others.

Where aggressive behavior may appear to be impulsive or random, environmental factors may be a significant factor. Some patients are transiently violent when in a chaotic environment, others are persistently violent no matter the milieu (Krakowski and Czobor, 1997). In contrast to the persistently violent patient, those who were transiently violent were more likely to respond to a new structured environment (Krakowski *et al.*, 1988). Environmental factors leading to increased aggressive behavior on a psychiatric ward include crowding (Palmstierna *et al.*, 1991; Ng *et al.*, 2001). It appears that the transiently violent are more responsive to typical antipsychotic medication and have less neurological impairment than the persistently violent patient (Volavka and Krakowski 1989).

It is generally agreed that it is impossible to predict with absolute certainty if a violent act will occur, but it is possible to assess risks. Past history of violence may be the best predictor of future violent behavior (Blomhoff *et al.*, 1990; Convit *et al.*, 1988; Karson and Bigelow, 1987), and obtaining a history of this, access to weapons, and current ideation are essential elements in risk assessment.

## Treatment

Behavioral, psychological, and pharmacological interventions are used simultaneously (Citrome and Green, 1990). Clinicians are urged to survey the environment for potential weapons, not to turn their back on the patient, and to have other staff available. Taking verbal threats seriously and being aware of physical premonitory signs such as a clenched fist and pacing are important. Initially, an agitated patient should be isolated from other patients and from distractions because extraneous stimulation can intensify psychosis in a patient who may be hallucinating, paranoid and agitated. Moreover, other patients may intentionally or inadvertently interfere with treatment. Generally

it is easier to clear the area of many calm patients than to move one dangerous individual. Restraint or seclusion may be necessary, and this is the time where the risk for injury for both staff and patients is highest. The technique of the calming blanket, a soft comforter with canvas reinforcements, may be helpful in subduing the patient who is punching, scratching, or kicking.

### Psychotherapeutic Approaches

Nonspecific sedation is often used in the management of an acutely agitated patient. In general, intramuscular injection of a sedative has a faster onset of action than oral administration but it has been observed that a patient may calm down readily after an oral dose, knowing that action has been taken and help is being provided. Previously, choice of intramuscular medication for these behavioral emergencies has been limited to typical antipsychotics (such as haloperidol or chlorpromazine) versus benzodiazepines (principally lorazepam) (Table 86.3). The availability of intramuscular formulations of novel atypical antipsychotics provides additional treatment options for the management of acute agitation in patients with psychosis (Citrome, 2002). Lorazepam, the only benzodiazepine that is reliably absorbed when administered intramuscularly, appears to be a good rational choice when treating an acute episode of agitation, especially where the etiology is not clear such as when a patient with a history of schizophrenia may actually be withdrawing from alcohol (Salzman, 1988; Greenblatt *et al.*, 1979, 1982). Caution is required when respiratory depression is a possibility. There may be increased risk of this in patients with sleep apnea (associated with being morbidly obese, history of snoring and daytime drowsiness). Lorazepam is not recommended for long-term daily use because of the problems associated with tolerance, dependence and withdrawal. Paradoxical reactions to benzodiazepines, as exhibited by hostility or violence has been an area of concern (Bond and Lader, 1979), but the evidence is not convincing and, in any event, such reactions are uncommon (Dietch and Jennings, 1988). The possibility of alcohol or sedative withdrawal as a cause of agitation is another point in favor of using lorazepam.

The typical antipsychotics cause sedation, given in a high enough dose. Haloperidol, a high potency butyrophenone, has been frequently used as an intramuscular prn medication for

agitation and aggressive behavior in an emergency department setting for a wide variety of patients (Clinton *et al.*, 1987). Depending on the clinical response, subsequent doses may be administered as often as every hour if necessary. However, 4- to 8-hour intervals may be satisfactory. Haloperidol's advantage over the low potency typical antipsychotics (e.g., chlorpromazine) is that it causes less hypotension, fewer anticholinergic side effects, and causes less of a decrease in the seizure threshold. In addition to this nonspecific sedation, a benefit would be its antipsychotic effect (in responsive patients), but this would be evident only after the acute episode of agitation has subsided. High doses of typical antipsychotics may lead to more adverse effects, including akathisia, which may itself provoke violent behavior (Keckich, 1978; Siris, 1985).

The new atypical antipsychotics may emerge as important options in the management of acute agitation in schizophrenia. Although sedation or "calming" remains the primary mode of action when used emergently in the acutely agitated patient, the atypical antipsychotics have several advantages over typical antipsychotics (Citrome, 1997), in particular a lower propensity for extrapyramidal side effects, including akathisia.

### Long-term Treatment

The treatment goal is to decrease the frequency and intensity of aggressive behavior. Specialized units such as secure or psychiatric intensive care units (Musisi *et al.*, 1989; Goldney *et al.*, 1985; Warneke, 1986; Citrome *et al.*, 1995) provide a structured environment that optimizes staff and patient safety. In general these specialized units are staffed with persons trained in interacting with volatile and difficult to manage patients (Maier *et al.*, 1987). When available, these units can be a valuable resource for education, training, consultation and referral.

Although pharmacotherapy remains a mainstay of treatment for the persistently aggressive patient, behavioral plans need to be used in tandem. Providing structure, including the use of behavioral contracts, can be useful. Preventive aggression devices (PADS) are a form of ambulatory restraints, which can be used as an alternative to seclusion (Van Rybroek *et al.*, 1987). The technique was first developed for a specialized inpatient unit

**Table 86.3 Pharmacological Options for Acute Agitation—Intramuscular Agents**

Agent	Dose (mg)	Half-life (h)	Comments
Lorazepam	0.5–2	10–20	There are no active metabolites. Can be administered orally, sublingually, intramuscularly, or intravenously.
Haloperidol	0.5–7.5	12–36	Can combine with lorazepam in the same syringe (combination of haloperidol 5 mg and lorazepam 2 mg is commonly used).
Droperidol	2.5–5	2	QTc prolongation. Withdrawn in UK.
Olanzapine	10 (2.5 for patients with dementia)	34–38	Superiority over haloperidol (schizophrenia) and lorazepam (bipolar disorder) in clinical trials.
Ziprasidone	10–20	2.2–3.4	Superiority over haloperidol (schizophrenia) in clinical trials. QTc prolongation.

with repetitively aggressive patients. Patients in these wrist-to-belt and/or ankle–ankle restraints can remain with their peers on the ward, eat their meals and interact, yet are prevented from striking out and injuring others. In combination with a comprehensive behavior modification program, these patients can be weaned off the use of the ambulatory restraints.

Although pharmacotherapy for the longer-term management of aggressive behavior is somewhat dependent on the patient's underlying diagnosis, clinical management is often complicated and can entail the use of several coprescribed medications. At the core of impulsive aggressive behavior may be a dysregulation of the serotonergic neurotransmitter system and this may explain the possible ameliorative effects of atypical antipsychotics and the selective serotonin reuptake inhibitors (SSRIs). In addition, beta-blockers and moodstabilizers have been used with some success. Table 86.4 outlines the medication strategies useful in patients with aggressive behavior and schizophrenia. Nonadherence to a treatment regimen may require the use of outpatient commitment, now available in many jurisdictions.

### Atypical Antipsychotics

The availability of atypical antipsychotics has led to the observation that these agents may act differently from the older antipsychotics in that they may specifically target aggressive behavior. Several retrospective studies have demonstrated a decrease in the number of violent episodes and/or a decrease in the use of seclusion or restraint among inpatients after they began clozapine treatment (Wilson and Claussen, 1995; Ratey *et al.*, 1993; Chiles *et al.*, 1994; Mallya *et al.*, 1992; Spivak *et al.*, 1997; Maier, 1992; Ebrahim *et al.*, 1994). At this time, the weight of the evidence favors clozapine as specific antiaggressive treatment for schizophrenia patients (Glazer and Dickson, 1998), with demonstrated superiority to haloperidol and risperidone (Citrome *et al.*, 2001). More research is needed to compare the other atypical antipsychotics with clozapine for this indication. Ideally, such studies

need to be done double-blind with subjects specially selected because of their aggressive behavior. This is operationally quite difficult because of a number of logistical factors, including the relative rarity of aggressive events and consequent need for a large sample size and lengthy baseline and trial periods, as well as selection/consent bias (Volavka and Citrome, 1999).

### Mood Stabilizers

There is an expectation that adjunctive mood stabilizers can reduce aggressive and impulsive behavior (Citrome, 1995). This is understandable when the primary diagnosis is bipolar or schizoaffective disorder where the mood stabilizer is treating the core symptoms of the disorder, but these agents, notably valproate, lithium and carbamazepine, are also used, though less frequently, in patients with schizophrenia.

### Beta-blockers

Beta-adrenergic blockers, in particular propranolol, have been used in the treatment of aggressive behavior in brain injured patients (Yudofsky *et al.*, 1981, 1984). Propranolol has also been used as an adjunctive treatment for schizophrenia, and a reduction in symptoms, including aggression, was found (Sheppard, 1979). Nadolol may also be helpful (Ratey *et al.*, 1992; Alpert *et al.*, 1990; Allan *et al.*, 1996). Beta-blockers may exert some of their effects by decreasing akathisia, which in turn may decrease agitation.

### Benzodiazepines

Clonazepam, a high potency benzodiazepine, had been reported useful in patients with bipolar disorder. This result is in contrast to a double-blind placebo-controlled trial of adjunctive clonazepam in 13 schizophrenic patients receiving antipsychotics (Karson *et al.*, 1982). In that study no additional therapeutic benefit was observed and, in fact, four patients demonstrated violent behavior during the course of clonazepam treatment.

**Table 86.4 Pharmacological Options for Persistent Aggressive Behavior in Schizophrenia**

Class of Agent	Basis of Evidence	Comments
Atypical antipsychotics	Case reports, retrospective record reviews, secondary analyses of randomized clinical trials	Best evidence exists for clozapine, some evidence for olanzapine and quetiapine, and conflicting evidence for risperidone. Insufficient information for ziprasidone.
Mood stabilizers	Case reports, retrospective record reviews, few randomized clinical trials	Although mood stabilizers are helpful in bipolar disorder, evidence in schizophrenia is not as strong. Best evidence exists for valproate, some for carbamazepine, and conflicting evidence for lithium. Insufficient information for gabapentin, topiramate, oxcarbazepine.
β-blockers	Case reports, retrospective record reviews, few randomized clinical trials	Best studied in patients with brain injuries. Some evidence demonstrating usefulness in schizophrenia for propranolol and nadolol.
SSRIs	Case reports, one randomized clinical trial	Adjunctive citalopram found helpful in a randomized double-blind study (Vartiainen <i>et al.</i> , 1995).
Benzodiazepines	Case reports, one randomized clinical trial	Negative outcomes (patients worsened) in a randomized double-blind study of adjunctive clonazepam (Karson <i>et al.</i> , 1982).

Using lorazepam for long-term management (in contrast to acute use as a “prn”) can be problematic because of physiological tolerance. Missing scheduled doses of lorazepam may result in withdrawal symptoms that can lead to agitation or excitement, as well as irritability and a greater risk for aggressive behavior.

### Antidepressants

The current interest in certain antidepressants’ role in aggression is based on the crucial role of serotonergic regulation of impulsive aggression against self and others. A number of reports have emerged that posit a role for fluoxetine (Goldman and Janecek, 1990), citalopram (Vartiainen *et al.*, 1995) and fluvoxamine (Silver and Kushnir, 1998) in the treatment of persistent aggressive behavior.

### Adjunctive Electroconvulsive Therapy

Although not often considered as a first-line treatment, adjunctive electroconvulsive therapy (ECT) may be helpful in patients who have inadequately-responsive psychotic symptoms (Fink and Sackeim, 1996). An open trial of ECT in combination with risperidone in male patients with schizophrenia and aggression resulted in a reduction in aggressive behavior for nine of the 10 patients (Hirose *et al.*, 2001). The combination of ECT and clozapine may also be helpful. A review of 36 reported cases treated with this combination, all of whom with a history of treatment-resistance, revealed that approximately two-thirds benefited from this treatment (Kupchik *et al.*, 2000).

### Conclusion

The effective management of aggression is a priority for clinicians. Strategies to control acute agitation include the use of mechanical restraints and the administration of parenteral medication. Early intervention is important to avoid further escalation to violence. An overview is presented in Figure 86.2. The new intramuscular formulations of atypical antipsychotics hold promise quickly and efficaciously to control acute agitation, without the side-effect burdens of the older typical antipsychotics. Lorazepam remains a first choice for patients withdrawing from alcohol or sedatives and presenting with agitation. Longer-term management may include the use of a specialized hospital unit, if available. Treatment of the underlying disorder is key, but this may be complicated by a history of poor response to standard treatments. Lorazepam for long-term daily use is not recommended because of problems associated with tolerance, dependence and withdrawal. Clozapine appears to be the most effective antipsychotic in reducing aggressivity in patients with schizophrenia and schizoaffective disorder. Valproate and carbamazepine can be used with antipsychotics to decrease the intensity and frequency of agitation and poor impulse control, but they have not been extensively studied under double-blind placebo-controlled conditions for this indication. Beta-blockers and SSRIs may also be helpful. Adjunctive ECT, together with atypical antipsychotics, may be considered for patients who have failed other approaches.

# Combined Therapies: Psychotherapy and Pharmacotherapy

The rationale for combining treatment modalities is based on the idea that the strengths of each modality are promoted while the weaknesses are minimized, producing results that are better than with either modality alone (Hollon and Fawcett, 1995). Although intuitively this rings true, psychiatrists have a duty to incorporate evidence-based approaches into their clinical practice. While most evidence-based mental health research in the literature is based on efficacy studies, there has been a recent move towards conducting effectiveness studies that are hoped to be of increased relevance to general outpatient clinical practice (Nathan *et al.*, 2000). Table 87.1 highlights the differences between efficacy and effectiveness research (Barlow, 1996; Nathan *et al.*, 2000). Recent literature examining the efficacies of combined treatment (not necessarily integrated treatment by a psychiatrist) vary by disorder, timing of treatments and whether administered during the acute or maintenance phase. Recent literature has also examined the sequential application of combined treatment (Fava *et al.*, 2001; Frank *et al.*, 2000). Effectiveness studies are far fewer, as mentioned, and do not always demonstrate superiority of combined approaches over either medication or therapy alone.

Hollon and Fawcett (1995) have outlined four ways in which combined treatment may prove advantageous over either treatment alone: increase the magnitude, probability, or breadth of clinical response, and increase the acceptability to the patient of either modality. In general, they feel that there is literature to support the statement that combined treatment enhances the breadth of clinical response. It is within this context that clinical practice guidelines published by the Agency for Health Care Policy and Research support the use of combined treatment in depressive disorders (Depression Guideline Panel, 1993).

Various authors discuss the potential benefits of employing pharmacotherapy within a psychotherapeutic context (Klerman, 1991; Kay, 2001). Pharmacotherapy has been noted to have a quicker onset of action on acute symptoms than most psychotherapies, perhaps with the exclusion of cognitive therapy (Hollon and Fawcett, 2001). It is felt that this rapid dampening of symptoms may enhance the patient's ability to more productively participate in therapy by a variety of mechanisms. These have been described cogently by Klerman (1985, 1991) and include enhancing the patient's self-esteem, creating a safe environment in which emotions are more freely discussed, reducing the stigma of

seeking mental health care through a positive placebo effect, improving cognition (verbalization and abreaction), and functioning as a transitional object during breaks in therapy, among others.

The benefits of employing psychotherapy within a primarily psychopharmacologic relationship have also been described. Empirical evidence exists across the spectrum of mental health disorders to support the following suggested benefits of adding psychotherapy to medications. It decreases the incidence of illness relapse (Hogarty *et al.*, 1986), as well as symptom relapse upon medication discontinuation (Wiborg and Dahl, 1996; Spiegel *et al.*, 1994). It fosters the patient's ability to utilize healthy coping strategies, addresses issues that are not typically targeted by psychopharmacologic treatment such as dysfunctional relationship patterns or negative self-appraisals due to traumatic past events, and enhances psychotropic compliance (Paykel, 1995; Cochran, 1984).

## Clinical Applications: Treatment Adherence

Adherence may be enhanced in part through discussion of the patient's metaphor for the medication, either positive or negative (Kay, 2001). Clinical vignettes 1 and 2 illustrate a patient's frequently held conceptions regarding medication use.

The above case highlights one of the beliefs that patients may have regarding medications, that is, they indicate their provider's level of interest in them as a person and the provider truly appreciates the level of their distress. In certain contexts these beliefs may be regarded as a "positive metaphor"; however in others, as demonstrated above, it may hinder the patient's response to treatment, their compliance with the treatment regimen, and their level of trust in their provider.

## Clinical Applications: Sequential Treatment

Fava (1999) highlights that sequential treatments may be applied in four ways: 1) using a second type of psychotherapy when the first orientation has not fully achieved treatment goals; 2) introducing a second type of pharmacotherapy when the first medication has not achieved adequate symptom relief; 3) introducing psychotherapy when initial pharmacotherapy has not been fully effective; and 4) introducing pharmacotherapy when initial psychotherapy has not been fully effective. The latter two may include use of combined treatments in a sequential fashion. Clinical Vignette 1 was an example of the third method; Clinical Vignette 2 highlights the fourth method.

**Table 87.1 Efficacy and Effectiveness Research – Comparison**

	Efficacy	Effectiveness
Definition	The methodical assessment of an intervention in a controlled clinical trial setting	The assessment of an intervention for pertinence and practicality in a routine clinical practice setting
Type of intervention assessed	Any; may be experimental	Only those with established efficacy
Study population	Homogeneous	Those in need of treatment
Diagnosis	Exclude comorbidity	Comorbidity common
Illness severity, length of illness	Narrow range	Broad range
Inclusion/exclusion criteria	Strict	Few
Need for randomization/control group	Yes	No
Provision of psychotherapy intervention	Strict adherence to intervention, use of treatment manuals common	No requirement for use of/adherence to treatment manuals
Emphasis	Internal validity Replicability	External validity Generalizability

### Clinical Vignette 1

Ms E, a married 38-year-old with a diagnosis of major depressive disorder, recurrent and severe, and dependent personality disorder presents as a referral to Dr A for continued care due to the retirement of the psychiatrist whom she had been seeing in 15-minute medication management appointments over the past year. Ms E's symptoms included poor energy, anhedonia, lack of libido, intermittent suicidal ideation without a prior history of attempts, trouble concentrating and complaints of "memory loss". Ms E's current stressors include her father's terminal illness and longstanding marital conflicts. Ms E's father, sister and brother all suffer from an affective disorder. A review of the patient's records reveals a complex medication regimen, with frequent medication changes and poor symptom control. Ms E seemed to do well initially on new medications, often responding within a day or two, but then would have her spouse call the psychiatrist on her behalf to report that the effects of the medication had "worn off". Dr A and Ms E agreed to initiate brief psychotherapy, in addition to medication management, due to the persistence of her symptoms despite trials of various psychotropics. During the course of her first session, she revealed a distant relationship with her father, who had been a physician. She found him aloof and unnurturing, except for those times in which she was ill, during which he often directed her medical care. Dr A made no changes to Ms E's medication regimen at the first visit. At her next visit, Ms E commented to Dr A that she greatly missed her former psychiatrist whom she described as "really knew what he was doing with my meds, and understood the depth of my suffering". She asked for a referral to a new psychiatrist as she felt Dr A and herself were "just not a good fit".

Ms E eventually agreed to continue seeing Dr A "for a few more sessions". Dr A explored the psychological meaning that Ms E had been attributing to medication interventions. She was eventually able to recognize that changes in her psychotropic regimen did not have to occur for her to feel that others understood her. Ms E was able to look at connections between her past and her current reactions within the patient–provider relationship (exploration of countertransference issues), as well as within other interpersonal relationships including her marriage. Her medication regimen was simplified, she maintained compliance with her treatment plan, and she achieved remission of her depressive symptoms.

### Clinical Vignette 2

Mr B is a 40-year-old executive for a major corporation who has been recently diagnosed with panic disorder with agoraphobia by a psychiatry resident (Dr C). Mr B reports that for the past 6 months he has experienced panic attacks three or four times each day which involve "a sudden intense wave of fear that seems to come out of nowhere", usually during the day, but sometimes waking him up from sleep. During these attacks, he reports symptoms of a racing heart rate, sweating, feelings of nausea, trembling, and a fear of losing control and doing something crazy, like running through his corporate office while yelling at people to get out of his way. Mr B's panic attacks have become so frequent and intense that he can no longer perform his job and relies on other junior executives to manage the company. In fact, he avoids business travel because he fears becoming incapacitated from panic on an airplane. Recently, he has also begun to avoid staff

**Clinical Vignette 2 Continued**

meetings out of concern that a panic attack will occur and that he would have to leave unexpectedly.

Due to the severity of Mr B's panic and avoidance symptoms, the resident suggests a trial of medication for the patient. After discussing medication options with the patient, Mr B decides he would prefer not to take medication because he fears "losing control" or "getting addicted to pills". Although the resident attempted to allay some of the patient's fears about the medication, Mr B persisted in his reluctance to the treatment and even expressed his concern that the resident "must really think I'm crazy if you think I need pills!"

In light of Mr B's resistance to medication, the resident considers the use of cognitive-behavioral therapy (CBT) in order to supply the patient with action-oriented, self-directed behavioral approaches, such as relaxation and exposure exercises. In addition, the resident addresses the patient's cognitive distortions regarding issues of control and beliefs that he is "crazy". Psychotherapy also reveals that Mr B's father was alcoholic and his mother abused benzodiazepines, which explains some of the patient's belief system regarding medications.

After five sessions of CBT, Mr B recognizes only a slight reduction in the frequency of panic attacks and agrees to an "experiment" in which he would start taking medication with a slow increase in dosage. For each subsequent session, the resident follows a structured format by asking the patient for a brief update, check on anxiety, and discussion of the medication's side effects. The resident reviews the previous session and collects Mr B's homework regarding the frequency and severity of self-monitored panic/anxiety; checking for medication treatment results and side effects. The patient practices cognitive reframing regarding any mental or physiological changes he noticed while on the medication. This reframing involves teaching the patient to use self-dialogue to view physiological changes as either expected minor medication side effects that are temporary, or as simply a nonmedication, normal physiological status change that the patient misperceives as a sign of something horribly wrong. The reframing process is accomplished by educating the patient to challenge his distorted belief systems during sessions and then the resident and patient collaboratively set homework assignments. After 15 additional sessions of integrated CT and medication, Mr B is panic-free but continues to receive treatment to address some mild avoidance features.

As demonstrated by the vignettes, the meanings that the patient attributes to medication may have to do with cognitions and feelings in a variety of spheres including the illness, the provider, and themselves (Beck, 2001).

### **Clinical Applications: Advantages and Challenges**

The vignettes also serve to highlight potential benefits and challenges surrounding integrated treatment described by Kay (2001). In Clinical Vignette 2, rapport is well established, precluding the need to reestablish rapport and for the patient to retell his "story"

to yet another provider. Integrated treatment essentially eliminates the communication difficulties encountered in split treatment settings. The practitioner of integrated treatment does face some obstacles. In both cases, the psychiatrist needs to be well trained in a variety of psychotherapy orientations, particularly in the orientation that has evidence to support its use in a particular disorder.

Clinical Vignette 1 highlights the importance of a thorough assessment of the patient using a biopsychosocial approach as described by Engel (1977). To provide a theoretical framework for formulation of the patient and treatment plan, McHugh and Slavney (1983) similarly discuss understanding the psychiatrically ill patient from four "perspectives". These multifactorial models of mental health illnesses serve as conceptual tools with which to understand the whole patient and those forces that together precipitate, perpetuate and modify illness course/progression. It stands to reason that a provider of integrated care should utilize an "integrated" model of illness description, etiology and treatment.

When a single provider directs both forms of treatment, traditional role conflicts may emerge. The role stereotype of a psychotherapist may include one who has a multidimensional understanding of the patient, is interested in intrapsychic/core conflicts and their manifestations in symptoms, behaviors, feelings and thoughts, and whose style is less authoritarian. The pharmacotherapist's traditional role stereotype is of a biological/neurochemical understanding of the patient and a prescriptive, structured, more authoritarian style in approaching diagnosis, medications and other issues. While these roles are, as described, stereotypic, they do have in common the role of the provider in establishing rapport and a therapeutic alliance with the patient. It has been suggested that the psychiatrist who uses an integrated model provides more time for development of the therapeutic alliance thus increasing the patient's comfort in disclosing embarrassing side effects of medication and, perhaps, even aiding in treatment outcome via the strength of the alliance (Gabbard and Kay, 2001). Psychotherapy studies have suggested that therapist variables accounted for 30% of the variance in outcomes, and that therapeutic alliance is perhaps the most important factor in positive treatment outcomes (Lambert, 1992; Svartberg *et al.*, 1998). The therapeutic alliance is crucial; as such, management of transitions between roles, as well as the seamless integration of roles is imperative within the practice of integrated treatment (Gabbard and Kay, 2001). These role transitions may occur rapidly and within a single session.

A familiarity with current literature and clinical practice guidelines concerning when to employ medications alone, therapy alone, or both, and when sequential treatments may lead to a greater probability of remission is a must for any clinician utilizing combined treatment.

### **Clinical Applications: Managing the Session**

This example highlights one way in which to fluidly incorporate both domains (psychotherapy and pharmacotherapy) within each patient visit. The above approach is structured in nature, following cognitive therapy's principle that sessions are structured and remain constant during therapy (Beck, 1995). Providers of psychodynamic therapy, among other types of therapy, often prefer this structured type of approach, advocating that medication use either be discussed at the beginning or at the end of the session. Proponents of the beginning method feel that discussion of medication issues ensures adequate time is spent on concerns and may provide important material for the session. Advocates

of the “set aside 5 to 10 minutes at the end of the session” approach feel that it is most important for the patients to set their own agenda, as this allows for time needed for the patient to regain composure/recompensate before the end of the session. Another approach is the nonstructured method. In this case the therapist addresses medication issues only when the need arises. As there are no evidence-based studies to guide clinical practice, it is most important to base the choice on patient and provider preference and to practice consistency with each patient (Kay, 2002).

### Clinical Applications: Individualizing Treatment

How can the psychiatrist tailor his/her treatment options to each individual patient? When would sequential approaches be indicated and in which disorders are combined treatments most likely to be helpful? During which phase of treatment (acute versus maintenance) should combined treatments be used versus solo treatments (either medications or therapy)? For what severity of illness are combined treatments preferred? Is there evidence to support sequential approaches and should they be specifically targeted to stages of the illness? How might understanding physiologic changes in the brain, which occur in the context of both medications and psychotherapy, help guide our research and clinical treatment interventions? It should be kept in mind that research regarding these issues is in its infancy, and many recommendations may require further studies definitively to aid with the establishment of critical pathways for each of the disorders. In spite of the need for further research, combined treatment appears useful for all major categories of psychotic illness, including

anxiety and mood disorders, psychotic disorders, eating disorders and substance abuse.

### Split Treatment

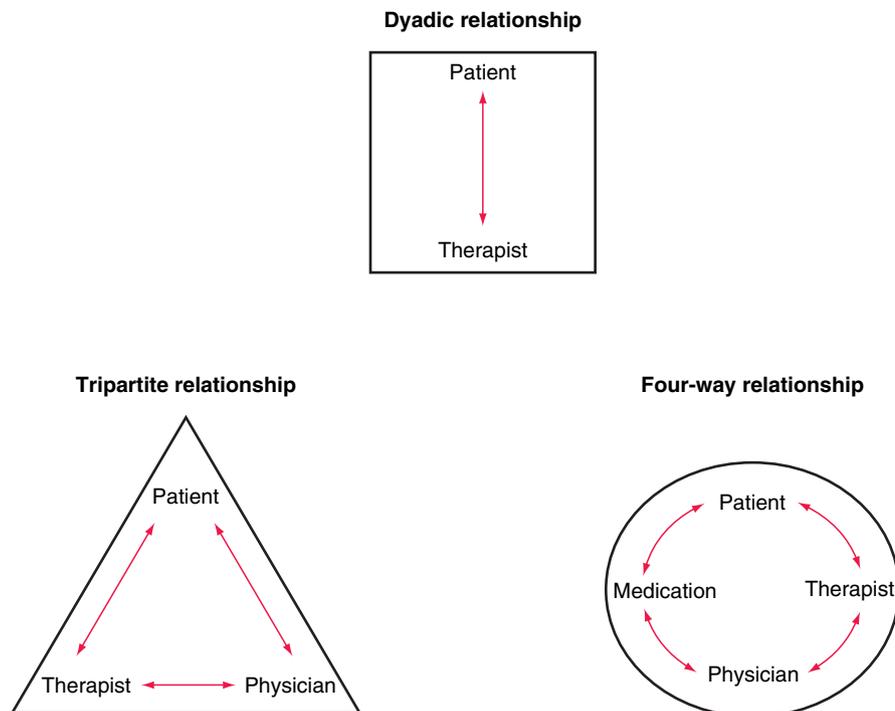

The last few decades have seen an increasing shift from a single relationship between patient and psychiatrist towards a tripartite relationship with the inclusion of medication, or to a four-way or systemic relationship with the addition or deletion of medications (Figure 87.1). Thus, combined treatments are commonly provided by two or more clinicians, hence the term “split”.

### Positive Aspects

There are several positive aspects of split treatment, including the increased time that patients have with more than one clinician; better utilization of resources; enhanced opportunity for alignment of gender, ethnicity between patient and clinician; more professional support for each clinician; and, perhaps, better adherence of the overall treatment plan by the patient and family.

### Increased Time with Clinicians

Within the structure of split treatment, patients actually meet with at least two different clinicians: one for psychotropic medication or other somatic treatment and the other clinician for psychotherapy. Under ideal circumstances, the patient is seen by the nonmedical therapist at appointed intervals between the physician appointments. This could then allow for the patient to get longitudinal care by two clinicians and to therefore be seen on a continuum by both. Under this type of arrangement, there would not be too long an interval in which the patient is not seen by a mental health professional. With good communication, the therapist relays all important information to the physician in a

**Figure 87.1** Changes in relationships as therapy and medications are added or deleted. Copyright, American Psychiatric Press, Washington DC, pp. 1–29.

timely manner. If there are planned vacations by either clinician, the other clinician is aware and can make different plans accordingly to see the patient. The patient may be able to provide more useful information in this treatment approach, given that she has more time to spend in overall treatment.

### Better Utilization of Resources

With the growing realization of the importance of evaluating for emotional problems in the primary care setting, there is better recognition of psychiatric symptoms and disorders. In rural areas where there may not be enough mental health clinicians to serve the needed population, splitting the duties of the various clinicians might be a cost-effective way to ensure allocation of care. Similarly, there are certain types of psychotherapeutic treatments with documented efficacy, such as cognitive-behavioral treatment of depression and behavioral treatment of obsessive-compulsive disorder, panic disorder and phobias, which must be delivered by knowledgeable clinicians (Fawcett, 2001).

### Greater Choice of Clinicians

Split treatment allows for more choices in the selection of clinicians based on gender, race or ethnicity, and religion or cultural values. Such matching may help the patient and clinician avoid certain difficulties that arise in psychotherapy when there is not a full appreciation of cultural issues (Foulks and Pena, 1995).

### Improved Adherence to the Treatment Plan

Patients attribute certain meanings to the prescription and taking of medication, depending on their illness-belief system (Rolland, 1994; Winer and Andriukatis, 1989). Some patients hear an explanation of the need to take medications as having a “chemical imbalance” and embrace the idea that there is a biochemical reason for the problem. Other patients feel ashamed or guilty over having a defect and develop a strong resistance to taking their medication as prescribed (Paykel, 1995).

It is important for the clinicians involved in split treatment to appreciate how the patient understands the need for medication. Similarly, it is valuable for the physician to be aware of how the nonphysician therapist understands the role of medication in the overall treatment. The physician and therapist must help support medication and psychotherapy so as to help the patient succeed in having a good outcome. In this way, the patient will receive support from both treaters with neither the medication nor the therapy undermined.

### Enhanced Support for Clinicians

There are several levels of support that accrue to clinicians involved in split treatment. With particularly difficult patients, such as those with severe personality disorders or hard-to-treat depressions or psychoses, it is very valuable for clinicians to be able to feel a mutual caring for one another and an empathy for the difficult clinical situations that can arise. Split treatment allows for a sharing of information that can help clinicians help patients through crises. As Silk points out, patients with borderline personality disorder, for example, are noted for fueling strong countertransference feelings of anger, fear, and worry in clinicians (Silk *et al.*, 1995). It is very helpful when clinicians in split treatment can present a unified front to the patient, acknowledging that they are capable of handling the patient’s affective storms but also provide support to one another to diminish feelings of burn-out. Balon (1999) has noted

that psychiatry residents, in particular, value the teaching and support they receive from seasoned, mature social workers and psychologists while providing split treatment.

## Negative Aspects

### Communication

While communication is probably the most important factor in successful split treatment, it is rarely done well (Hansen-Grant and Riba, 1995). Without a systematic way for clinicians and the patient to have regular, documented communication, there often arise misunderstandings and misconceptions. Further, patients are sometimes put in the middle of having to be the messenger between the clinicians. Needing to communicate puts additional burdens and stress on busy clinicians with the telephone or in-person time not usually reimbursable. Poor communication leads to misinterpretation of what should be attributable to psychodynamic issues or medication side effects, or both – a poorly constructed treatment plan, ill-defined plans for discharge from treatment, lack of coordination with family members, neither the clinician nor patient fully understanding vacation or coverage issues, and so on.

### Interdisciplinary Issues

The literature demonstrates that when clinicians know one another, they are more comfortable with split treatment (Goldberg *et al.*, 1991; Weiner and Riba, 1997). Unfortunately, often the clinicians do not know one another, which leads to basic mistrust, competition, or inequality in the relationship (Baggs and Schmitt, 1988). Further, this devaluation can be displaced onto the patient during critical treatment decisions, with certain patients exploiting this competition even further (Kelly, 1991). The psychotherapy skills of psychiatrists and nonmedical therapists and the psychopharmacologic education of social workers and psychologists are all highly variable, contributing to mistrust (Neal and Calarco, 1999). In such circumstances, the patient may actually be seen more often by both clinicians and have ill-defined treatment goals.

### Transference and Countertransference

When patients are referred by their therapists for medication evaluations, the reactions are variable, but often negative. Such reactions include feeling abandoned or rejected, as if the therapist has lost interest or given up, like a failure because therapy did not work, devaluation of the psychotherapy and the therapist, idealization of the physician, shame, resistance to further psychodynamic exploration of issues and a narcissistic injury (Busch and Gould, 1993). Busch and Gould note the difficulties for the therapist who needs to make the referral: shame that help is needed and anger towards the patient for needing additional help. The psychiatrist could then collude with the patient’s negative transference towards the therapist and the psychodynamic process.

Results of such negative transference could lead to premature closure within the therapeutic process (Bradley, 1990). There may be a flight into health by the patient when the medication is first prescribed. The patient and physician may then realize too late that there was an overreliance on biologic interventions. The dyadic relationship between the therapist and patient is changed with the addition of a physician and medication (see Figure 87.1) leading to distortions and transference changes in all the relationships.

## Legal Issues

Split treatment means a sharing of authority and control over patient care, meaning a loss of autonomy for each clinician. There is a widespread perception therefore that split treatment is associated with significantly greater risks (Macbeth, 2001).

What are the sources of legal exposure? There is potential liability for all psychiatrists who prescribe psychotropic medications, see patients with depression and anxiety, especially those patients with severe disorders, and treat patients with significant suicide potential. Further, informed consent is an important area of concern.

Since patients are shared in split treatment and it is difficult for clinicians to communicate with one another, there is ample opportunity for there to be a rise in missing information, miscommunication and a decrease in quality of the doctor–patient relationship. Patients are usually seen less frequently by the physician in a split-treatment relationship and the patient is often not clear whom to call in certain emergency situations. Families are usually seen by one of the clinicians, not both. Sometimes there is a supposition that the therapist is being supervised by the physician when the physician believes the relationship to be collaborative rather than supervisory. Macbeth offers the following risk-management strategies:

1. Psychiatrists should familiarize themselves with the operations and routines of all practice settings. The psychiatrist must be knowledgeable about the expertise and authority of those involved in care management.
2. The most problematic practice sites should be weeded out. Issues include looking at staff turnover, peer review procedures and credentials of key staff members. The psychiatrist should find out about opportunities for consultation and staff interaction, system immunities and insurance of nonphysician clinicians.
3. There must be careful coordination with therapists who have greater access to patients. The psychiatrist must inform the therapists what information the psychiatrist needs; when she/he needs to be told about changes in the patient's symptoms and condition, and the strengths and weaknesses of the therapists. The psychiatrist must inform the therapist about the medication regimens (potential side effects). This information must be updated regularly.
4. Psychiatrists must understand the system review and appeals procedures to be able to act quickly when there are problems.
5. Either consultation or supervision schedules should be set up and documented regularly to review specific patients.
6. Personal assessment of individual patients must be set up with reference to her/his condition, status and treatment.
7. Psychiatrists should be extremely careful not to issue an insurance policy to a managed care organization or other system. All proposed contracts must be carefully reviewed and not used to indemnify by accident.

## Ethical Issues in Split Treatment

There are many areas of potential ethical conflict when mental health professionals get into split-treatment relationships. These include state licensing laws, competency issues, psychiatrists being used as figureheads, delegation of medical judgment and financial arrangements (Lazarus, 2001).

The potential ethical pitfalls in split treatment arise from economic, manpower and clinical pressures. There is very little research, for example, into whether patients with severe borderline personality disorder should be in split treatment. These patients often do not tell the same story to each clinician (Main, 1957); they externalize their problems (Silk *et al.*, 1995); threaten self-harm (Leibenluft *et al.*, 1987); have emotional lability and substance abuse problems (Springer *et al.*, 1995). If there is no close communication between the clinicians regarding goals, treatment planning, and role of medication and psychotherapy, the clinical and ethical problems in treating such patients are great.

It is important to recognize how complex and difficult split treatment can be for patients and clinicians. Key to this is recognizing the extra time and effort it will take to make obligations and responsibilities of all parties overt rather than covert. Implied duties must be minimized. Some clinicians advocate the use of treatment contracts to cover the various issues and responsibilities that accrue in split-treatment arrangements (Appelbaum, 1991).

## Toward Successful Split Treatment

The following suggestions are offered as organizing principles for these three stages (with permission from American Psychiatric Press, Riba and Balon, 2001):

A key aspect of split treatment is how complex and difficult such treatment is for the clinicians, the patient and the patient's family. Unless one works in a clinic or organized setting where relationships between clinicians are well-delineated (e.g., one psychiatrist works with a specific group of nonmedical therapists), much thought must go into managing safe and effective split treatment.

It may be helpful to think of split therapy having a beginning, middle course, and end (Table 87.1). In order to avoid or minimize the pitfalls associated with split treatment, the following clinical suggestions are provided as organizing principles for its three stages (Rand, 1999; Tasman and Riba, 2000):

## Beginning of Treatment

- Communication is key to providing excellent care in split treatment. At the beginning, both clinicians should obtain a signed release-of-information form from the patient. Communication must be regular and frequent between the clinicians and the patient should be made aware of these discussions. The forms of regular communication should be decided at the onset – routine telephone calls, faxes, emails, follow-up letters and the like. The patient should not be a messenger between the clinicians.
- Issues of confidentiality should be discussed and reviewed at the beginning of treatment. Confidentiality should not be used as a cover to hide from taking the time to make telephone calls, to send copies of evaluations and follow-up notes, to send emails or faxes, or to have joint sessions with both clinicians and the patient.
- Diagnostic impressions should be independently arrived at, then discussed and agreed upon. If there is a difference of opinion, an understanding must be reached before treatment proceeds.

- The clinicians must work with each other and with the patient to determine the treatment plan. The treatment plan should specify how often each of the clinicians expects to see the patient and what process to pursue if the patient does not follow-up or if there is a missed appointment. If the patient wishes to end either the therapy, the medications, or both, it has to be understood that all parties will discuss this important decision. It is desirable for a written contract to be drawn up between the clinicians and the patient so that all parties understand what the agreement for services will entail. Included in the contract should be a delineation of the clinicians' roles and responsibilities, as well as those of the patient.
- Clinicians vacation schedules and other on-call and coverage issues must be discussed regularly and documented. The patient needs to know whom to call in an emergency. At the beginning of split treatment, both clinicians and the patient should be aware of their respective beliefs regarding medication and psychotherapy.
- There must be a discussion about what type of care would be optimal for the patient and if there are barriers to such care. The patient should be informed of this review; if possible, he or she should participate in it.
- The clinicians should discuss their professional backgrounds and training with each other at the beginning of the patient's treatment. Issues such as licensure, ethics, violations, malpractice claims, hospital privileges, coverage of professional liability insurance, participation on managed care panels and commitment to split treatment should all be made clear.
- The clinicians need to agree who will communicate with third parties regarding the patient's care. Further, each clinician should know the patient's mental health benefits and means of payment. There needs to be an agreement by all parties as to the use of such benefits.
- The clinicians need to understand how best to interface with the patient's family or significant others.
- If the patient has health providers other than the psychiatrist and therapist (e.g., primary care physician, cardiologist or physical therapist), it should be decided which clinician will be the designated communicator or coordinator with those other providers.
- At the beginning of treatment there should be a review of how each clinician will assess and manage the patient's thoughts regarding or attempts at suicide, homicide, violence and domestic abuse.
- It should be made clear to the patient what symptoms or types of issues should be brought to the attention of which clinician.
- It is helpful for the clinicians to decide how problems will be handled as the need arises.
- The clinicians should discuss differences in fee schedules, cancellation policies, length of visits and frequency of visits.

### Middle Course

- Special attention must be paid to transference and countertransference in this type of system of care. Disparaging and negative remarks made by the patient concerning either clinician, therapy, or medication must be understood and managed in the context of this complex type of treatment.
- Clinicians should review how many cases of split treatment they have in their practices and whether or not this is a safe

mix. Factors to consider include the clinical complexity of the cases, how busy the practice is, the influence of third-party payers and the hassle factor, the number of different clinicians one is working with, the psychiatric disorders of one's patients, and so on. It may be prudent to determine the risks involved in having a large patient population in split treatment and to weed the number of such patients down to an acceptable level. Further, clinicians should minimize the number of collaborators, since it is virtually impossible to keep track of a large number of clinicians' credentials, vacation schedules, communication patterns, and so on.

- Adherence to medications and to psychotherapy should be addressed equally.
- Treatment plans should be regularly reviewed and updated between the clinicians and the patient.
- Use of the patient's mental health benefits should be regularly reviewed and discussed between the clinicians and the patient when appropriate.
- There must be an agreement that either clinician can terminate the split therapy but that the patient must be provided adequate and appropriate warning and referrals to other clinicians. In other words, the patient cannot be abandoned.

### Ending Split Treatment

- After reviewing the treatment plan, both clinicians and the patient will decide together on the goals that have been met or have not been realized and the best time for termination. They should decide how to stagger the discontinuation of therapy and of medication.
- It is important to consider how to manage follow-up and recurrence of symptoms.

The clinicians must have a system for giving each other feedback on the care each is providing to the patient. Ideally, after the treatment is complete, the clinicians should review any aspects of the case that could have been managed or handled differently. Ideally, the patient should be part of this evaluation process as a way of assuring continuous quality improvement. Most importantly, throughout all stages of the split treatment process, clinicians need to respect both the patient and each other's professional understanding.

Although the challenges of split treatment are great, there are many reasons for clinicians and patients to try to surmount the obstacles. Good communication patterns between clinicians and many of the suggestions noted here may be guideposts on the path toward successful split treatment.

## Introduction

Compliance, or the degree to which patients' behaviors coincide with the recommendations of health care providers, is an important component in the understanding of patient outcomes, particularly in light of a growing regimen of efficacious and expensive medical treatments. There is an evident gap between the efficacy of regimens tested in tightly controlled clinical trials and their effectiveness when applied to "real world" patient experiences. One explanation for this "efficacy-effectiveness gap", when treatment regimens move from efficacy trials into everyday practice, is the apparent decline in patient compliance. Other terms closely related to compliance include "adherence", "fidelity", and "maintenance".

Compliance is difficult to quantify for several reasons. Completely attributing the difference between an expected and observed treatment effect to problems with medication compliance may be overly simplistic. Several other factors such as differences in population, degree of comorbidity with other psychiatric or medical diagnoses, and severity of illness may all adversely affect the potential benefit to the patient. Poor or partial compliance with treatment may have a variable effect on treatment outcomes depending on the pharmacokinetic profile of the medication in question. For example, occasional missed doses of very long half-life medications will alter serum drug levels to a lesser extent than in short half-life compounds. Therefore, the issue of partial compliance with treatment regimens may become more critical depending on the specific regimen.

## A Theoretical Construct for Compliance: The Health Beliefs Model

The health beliefs of individuals play a major role in their decision-making processes regarding participation in recommended treatment. A framework that may be useful in understanding the complex nature of compliance with medical regimens is the health beliefs model (HBM). Derived from social psychological theories of Kurt Lewin, the HBM is grounded in the phenomenological orientation of perception driving action (Rosenstock, 1974). While this model was originally designed to study the utilization of screening tests for detection of asymptomatic diseases, it has been adapted to the areas of medication compliance among psychiatric patients (Kelly *et al.* 1987).

Five components of the HBM apply directly to issues of patient compliance. Figure 88.1 depicts the relationship between these components and ultimate compliance with treatment.

1. Susceptibility: patients must see themselves as vulnerable to a serious illness.

2. Severity: patients must realize that he/she has an illness with health consequences that will continue without medical attention.
3. Perceived benefits: patients must recognize that an effective treatment exists for their condition. Benefits from psychotropic medication treatment may include the understanding that treatment ameliorates mental problems or helps avoid rehospitalization.
4. Barriers: common barriers to pharmacologic interventions involve access to medication, adequate psychiatric follow-up, and adverse effects from the medication.
5. Cues to action: lastly, patients must experience an internal or external motivation or "cue" to engage in the specified action that may benefit them.

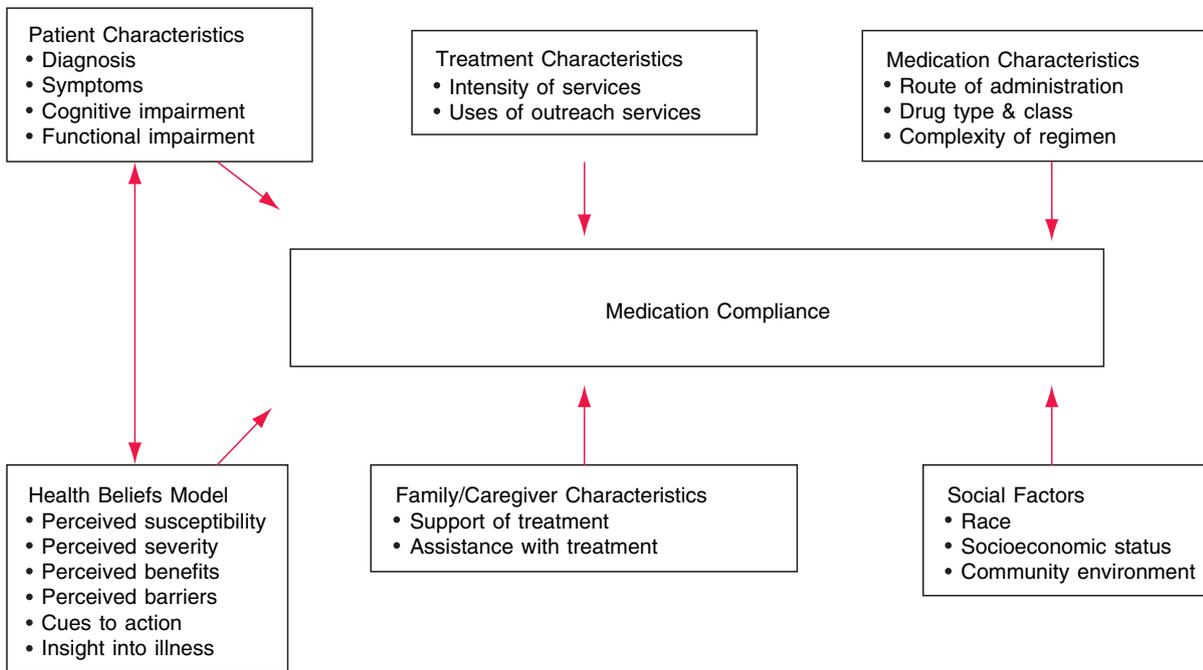

Cues that may trigger a patient to participate in their medication regimen typically relate to a return of symptoms attributed to their mental illness such as anxious, depressive, or psychotic states.

## Another Conceptual Model of Compliance

Another approach to understanding compliance behavior involves the categorization of problems with compliance along the three domains of psychological problems, planning problems, and medical problems. These three domains have been used to develop a compliance checklist as seen in Table 88.1 (Corrigan *et al.*, 1990, Cramer 1991). **Psychological problems** include issues such as nonacceptance of diagnosis or treatment, negative emotional reactions or negative thoughts, and social criticism from family or friends. **Problems with planning** consist of forgetting to take medications, disruption of usual schedules, and issues with availability of medication. **Medical problems that affect compliance** include adverse reactions, exacerbation of illness that leads to incapacity to administer or tolerate medications, or perceptions that medications may lack efficacy in a given individual. Both HBM and the compliance checklist provide useful starting points to begin the analysis of problems with compliance in specific patients or patient populations.

## Interventions to Enhance Compliance

General strategies to enhance compliance take many forms and can be tailored to the specific needs identified in individual patients. Most approaches to enhance compliance involve the introduction of techniques to improve outpatients' self-administration of oral medication therapies. Cramer (1991) identifies several strategies to approach problems with compliance (Table 88.2).

**Figure 88.1** Understanding medication compliance in mental illness.

**Table 88.1** Compliance Checklist

Psychological Problems
<ul style="list-style-type: none"> <li>• Nonacceptance: Patient does not accept the diagnosis or recommendations for treatment.</li> <li>• Emotions: Strong emotional reactions (anger, anxiety) prevent the patient from following the treatment plan.</li> <li>• Other priorities: Patient has placed a higher value on priorities (job, family) other than medication treatment.</li> <li>• Social criticism: Patient does not take medication due to criticism from others (family, friends, coworkers).</li> </ul>
Planning Problems
<ul style="list-style-type: none"> <li>• Routine forgetfulness: Patient does not follow a standard schedule and often misses doses.</li> <li>• Disruption of schedule: Extraordinary events prevent patient from following medication regimen.</li> <li>• No medication: Patient ran out of medication before it could be refilled or medication was no longer available for other reasons, including economic factors.</li> <li>• Lack of information: Patient received inadequate or incorrect information about medication regimen.</li> </ul>
Medical Problems
<ul style="list-style-type: none"> <li>• Adverse reaction: Patient stopped taking medication due to an adverse reaction.</li> <li>• Illness: Medical or psychiatric illness interrupted patient's medication regimen.</li> <li>• Testing efficacy: Patient decided to omit doses in order to determine need for medication.</li> </ul>

**Table 88.2** Strategies for Improving Compliance

Collect Information
<ul style="list-style-type: none"> <li>• Understand patient's particular problem with compliance</li> <li>• Address issues related to compliance in every clinical encounter with the patient</li> </ul>
Provide Information
<ul style="list-style-type: none"> <li>• Education about the illness</li> <li>• Education about the treatment</li> <li>• Understanding about problems with compliance</li> </ul>
Increase Motivation
<ul style="list-style-type: none"> <li>• Use motivational interviewing techniques to overcome resistance</li> <li>• Help the patient overcome psychosocial problems that interfere with compliance</li> </ul>
Modify Medication Regimen
<ul style="list-style-type: none"> <li>• Schedule doses around standard cues (brushing teeth, meals)</li> <li>• Discuss coping skills regarding potential situations that may interfere with compliance</li> <li>• Change the dosage schedule or route of administration</li> </ul>
Change Contingencies
<ul style="list-style-type: none"> <li>• Discuss negative consequences of medication compliance (shame, criticism)</li> <li>• Address adverse reactions</li> <li>• Specify a formal medication compliance contract</li> <li>• Associate medication compliance with specific positive reinforcement</li> </ul>

The action of monitoring compliance itself may improve adherence to proposed medical regimens, just as frequent weight monitoring may promote weight loss even without a specific diet regimen. Some data indicate that compliance rates improve significantly when outpatients with psychiatric disorders are given continuous feedback on their medication dosing (Cramer and Rosenheck, 1999).

Compliance-enhancement interventions that have been studied include individual, group and family formats and involve diverse theoretical orientations. Unfortunately, many of the studies that investigate compliance therapies do not also assess the distal impact on treatment outcomes leaving the clinician unable to evaluate whether marginal improvements in compliance would in fact lead to cost-effective improvement in treatment outcomes.

One intervention referred to as **compliance therapy** utilizes a specific approach to individual or group psychotherapy with cognitive therapy and motivational interviewing techniques (Goldstein, 1992; Hayward *et al*, 1995). Therapists attempt to help the patients form a cognitive link between discontinuation of medication treatment and relapse of symptoms. Using the patient's frame of reference, therapists seek to instill a sense of cognitive dissonance between discontinuation of medication and achievement of the patient's own goals. Problem-solving techniques are also employed to identify internal and external cues that may compromise future medication compliance.

Other psychosocial interventions to increase compliance in patients with schizophrenia have also been demonstrated to be effective. Kelly and Scott (1990) found that strategies aimed at education of patients' families about compliance and those directed at patients themselves both improved compliance. No significant difference between the two interventions could be demonstrated. It is important to note that, given the multiple factors associated with clinical course, not all improvement in treatment outcomes in schizophrenia is directly attributable to improved medication compliance. Psychosocial interventions that lack a specific focus on treatment compliance may nonetheless have salutatory effects on patient outcomes, regardless of changes in compliance behavior. Zhang and colleagues (1994) found that family therapy without a specific focus on compliance produced improvement in relapse rates in schizophrenic patients independent of changes in medication compliance.

Another approach to increasing compliance involves the change in route of administration of medication from oral preparations that must be taken at least once daily to depot injections, such as haloperidol decanoate and fluphenazine decanoate, that are typically administered every 2 to 4 weeks. The advantages to depot preparations include supervised administration of the medication by health care providers, decreased variability in serum concentrations of the active medication, and no significant difference in adverse effects as compared with similar oral agents. Disadvantages include the limited number of medications available in depot form, the difficulty of scheduling potentially more frequent clinic visits for injections, and the increased cost

in clinic staffs' time with administration of the treatments. At the time of this publication, no atypical antipsychotic agents were available in depot form. Therefore, a comparison of compliance with conventional depot agents and atypical oral agents may be limited in utility. Few studies of depot antipsychotic preparations address the issues of long-term compliance and differences in health outcomes when compared with oral agents (Adams and Eisenbruch, 2002; Quraishi and David, 2002). However, some evidence suggests that depot antipsychotic agents do confer a marginal improvement in reducing relapse rates (Glazer and Kane, 1992).

## Conclusion

Understanding patient compliance with prescribed medications involves an appreciation of multiple factors pertaining to the specific patient and his/her environment. Likewise, designing interventions to enhance compliance with medications requires an individualized approach in the context of proven therapeutic modalities. In the end, improving patient compliance improves patient outcomes without major modification of existing treatment strategies.
