Anxiety and psychosis, particularly paranoid delusions, are common in AD. Benzodiazepines can be disinhibiting in such patients and may exacerbate confusion. They should be avoided if possible. If minor tranquilizers are required, agents with a shorter duration of action (e.g., lorazepam, oxazepam) are preferred. Antipsychotic medications with high anticholinergic potential (thioridazine, chlorpromazine) may also affect memory adversely. While these agents have been favored in the past because of their tendency to produce sedation, newer agents such as olanzapine, risperidone, quetiapine and ziprasidone, have been reported to have lower incidences of neuroleptic-related side effects. Haloperidol has less anticholinergic activity but has a greater tendency toward extrapyramidal effects. These agents will be discussed in more detail in the consideration of management of delirious states. In summary, the psychopharmacological management of AD is designed to ameliorate cognitive deficits, if possible, control agitated, psychotic and dangerous behavior, and treat any underlying psychiatric disorder (e.g., major depressive disorder) that might be comorbid with dementia. The appropriate management of AD entails more than psychopharmacological intervention. Other elements of the treatment plan should be environmental manipulation and support for the family.

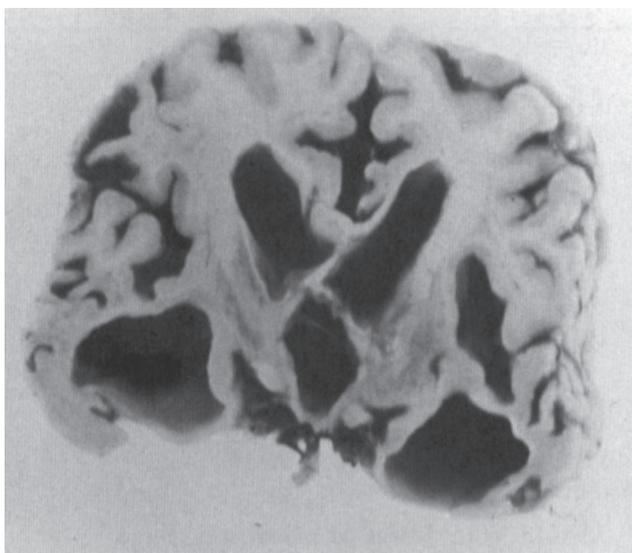

In the attempt to maintain patients with Alzheimer's disease in their homes for as long as possible, some adjustments of their environment are important. Written daily reminders can be helpful in the performance of daily activities. Prominent clocks, calendars and windows are important. An effort should be made to minimize changes in the patient's daily activities and environment. Repeated demonstrations of how to lock doors

and windows and operate appliances are helpful, and arranging for rapid dialing of essential telephone numbers can be useful. Maintaining adequate hydration, nutrition, exercise and cleanliness is essential. The family of the patient with Alzheimer's disease is also a victim of the disease. Family members must watch the gradual deterioration of the patient and accept that a significant part of their own lives must be devoted to the care of the individual. Difficult decisions about institutionalization and termination of life support are distinct possibilities, and the patients often turn their anger and paranoia toward the caregiver. Education is a valuable treatment tool for families. Information about the disease and peer support are available through Alzheimer's associations, and many such agencies provide family members with a companion for the patient to allow the family some time away. (The National Alzheimer's Education and Referral Service can be accessed by calling 1-800-621-0379.) Many studies suggest that the primary reason for institutionalization of these patients is the tremendous burden of care they pose for their families. Aimless wandering seems to be a particularly disturbing behavior. Unfortunately, the unfamiliar surroundings of a nursing home often increase the patient's level of confusion and anxiety. For these reasons, family members are at risk for depression, anxiety disorders, insomnia and a variety of other psychological manifestations. Should these occur, they should be promptly treated.

### Dementia Due to Pick's Disease

Pick's disease is a rare form of progressive dementia clinically indistinguishable from Alzheimer's disease. It is about one-fifth as common as AD. Pick's disease occurs in the sixth and seventh decades of life and has a duration that varies from 2 to 15 years. It has a strong familial tendency, but definite genetic pattern has not been established. ACh levels are reduced.

The pathology of Pick's disease involves prominent changes (e.g., sclerosis, atrophy) in the frontal and temporal lobes (Figure 32.7). The parietal and occipital lobes are spared. Alzheimer himself noted the argentophilic (staining silver) intraneuronal inclusion in Pick's bodies.

**Figure 32.7** Severe lobar sclerosis and atrophy in a patient with Pick's disease. (Courtesy of Joseph Parker, MD, Duke University Medical Center, Durham, NC.)

The clinical features of Pick's disease are quite similar to those of Alzheimer's disease, and since neither condition is curable, an elaborate differential diagnosis is unnecessary. Because of parietal sparing, such features as apraxia and agnosia are less common in Pick's disease, and visual-spatial ability, often impaired in Alzheimer's disease, is preserved (Kaufman, 1990b). Given the prominent changes in the frontal lobe, disinhibited behavior, loss of social constraints and lack of concern about appearance and matters of personal hygiene occur relatively early in Pick's disease. Such speech disorders as echolalia and logorrhea are common, and patients with Pick's disease are more likely to develop Klüver-Bucy syndrome (orality, hyperphagia, hypersexuality, placidity) indicative of damage to the temporal lobes. Significant memory impairment may occur relatively late in the course, and eventually the patient becomes listless, mute, and ultimately decerebrate and comatose. Like Alzheimer's disease, the treatment of Pick's disease is symptomatic.

### Dementia Due to Parkinson's Disease

Although dementia rarely occurs as an initial symptom of Parkinson's disease, it is found in nearly 40% of such patients older than 70 years of age. Approximately 1 million people in the USA have the disease, with 50 000 new cases being diagnosed each year. The prevalence for persons over 60 is 1%. The disease results from loss of dopamine production in the basal ganglia, and can be idiopathic or postencephalitic. Usually the patient is 50 years of age or older, and unlike Alzheimer's and Pick's dementias, this disease occurs slightly more often in men (Berg *et al.*, 1994). Dementia most commonly occurs in cases of Parkinson's disease in which the decline has been rapid and response to anticholinergics has been poor.

The pathology of Parkinson's disease involves depigmentation of the so-called pigmented nuclei of the brain (**locus coeruleus, substantia nigra**). These nuclei then contain eosinophilic Lewy bodies. As in Alzheimer's disease the cerebral cortex of many of these patients contains many senile plaques and neurofibrillary tangles, loss of neurons, and decreased concentrations of choline acetyltransferase. Patients with parkinsonian dementia also have reduced choline acetyltransferase in the cerebral cortex and substantia nigra.

The clinical features of Parkinson's disease are well described, with the cardinal triad being tremor, rigidity and bradykinesia. Associated features include postural instability, a festinating gait, micrographia, seborrhea, urinary changes, constipation, hypophonia and an expressionless facial countenance. The tremor in Parkinson's disease has a regular rate and is most prominent when the patient is sitting with arms supported; it has therefore been described as intention tremors. Paranoid delusions and visual hallucinations may occur, but auditory hallucinations are rare. Antipsychotics with low incidence of extrapyramidal symptoms such as quetiapine, olanzapine, and ziprasidone are recommended. The pharmacological treatment of Parkinson's disease involves the use of a number of types of medication and ziprasidone are recommended. These include selegiline a selective monoamine oxidase inhibitor, levodopa, other dopamine agonists (pramipexole, bromocriptine, pergolide mesylate, amantadine), and various anticholinergic agents (benztropine). Selegiline should not be given to patients on antidepressant medication as there is a risk that dopaminergic agents may activate psychosis or mania and that anticholinergic drugs may increase confusion. When discontinuing levodopa

after a long course of treatment, the drug should be tapered so as to prevent a discontinuation syndrome similar in nature to the neuroleptic malignant syndrome. Some medications (metoclopramide, droperidol, several antipsychotics) may produce parkinsonian features such as masked facies, sparsity of speech and tremor, and in those cases the appropriate course of treatment is to discontinue the offending medication. Several researchers are looking into the possibility of using embryonic stem cells implants as treatment for Parkinson's disease and several other conditions.

### Dementia Due to Huntington's Disease

Dementia is also a characteristic of Huntington's disease, an autosomal dominant inheritable condition localized to chromosome 4. Unfortunately, this condition does not become apparent until age 35 to 45 years, usually after childbearing has occurred. Fifty percent of offspring are affected. There is also a juvenile form of the disease. Huntington's disease affects about four in 100 000 people, making it a significant cause of dementia in middle-aged adults.

The pathology of Huntington's disease involves selective destruction in the caudate and putamen. In the caudate nuclei, GABA concentrations are reduced to 50% of normal. The frontal lobes of the cerebral cortex are also involved, but GABA and choline acetyltransferase concentrations in the cortex are normal.

The most noticeable clinical feature of Huntington's disease is the movement disorder, which involves both choreiform movements (frequent movements that cause a jerking motion of the body) and athetosis (slow writhing movements). In the juvenile form of Huntington's disease, which represents about 3% of all cases, the chorea is replaced by dystonia, akinesia and rigidity, and the course of the disease is more rapid than in the adult form. In the early stages of the disease, the chorea is not as noticeable and may be disguised by the patient by making the movements seem purposeful.

The dementia typically begins 1 year before or 1 year after the chorea and, unlike patients with other dementias, patients with Huntington's disease are often well aware of their deteriorating mentation. This may be a factor in the high rates of suicide and alcoholism associated with this condition. Although attempts have been made to increase ACh and GABA concentrations in these patients, such pharmacological interventions have been unsuccessful, and the dementia is untreatable. Genetic counseling is indicated.

### Vascular Dementia

Vascular dementia usually results from multiple CVAs or one significant CVA. It is generally considered the second most common cause of dementia after Alzheimer's disease, accounting for about 10% of all cases. Men are twice as likely as women to be diagnosed with this condition. Vascular dementia is characterized by a stepwise progression of cognitive deterioration with accompanying lateralizing signs. It is always associated with evidence of systemic hypertension and usually involves renal and cardiac abnormalities. Risk factors for the development of a vascular dementia include those generally associated with obstructive coronary artery disease, including obesity, hypercholesterolemia, smoking, hypertension, stress and lack of exercise. The actual incidence of vascular dementia has decreased somewhat with better standards of care, improved diagnostic techniques and lifestyle changes.

## DSM-IV-TR Criteria 290.4x

### Vascular Dementia

- A. The development of multiple cognitive deficits manifested by both
- (1) memory impairment (impaired ability to learn new information or to recall previously learned information)
  - (2) one (or more) of the following cognitive disturbances:
    - (a) aphasia (language disturbance)
    - (b) apraxia (impaired ability to carry out motor activities despite intact motor function)
    - (c) agnosia (failure to recognize or identify objects despite intact sensory function)
    - (d) disturbance in executive functioning (i.e., planning, organizing, sequencing, abstracting)
- B. The cognitive deficits in criteria A1 and A2 each cause B. significant impairment in social or occupational functioning and represent a significant decline from a previous level of functioning.
- C. Focal neurological signs and symptoms (e.g., exaggeration of deep tendon reflexes, extensorplantar response, pseudobulbar palsy, gait weakness of an extremity) or laboratory evidence abnormalities,
- D. indicative of cerebrovascular disease (e.g., multiple infarctions involving cortex and underlying white matter) that are judged to be etiologically related to the disturbance.

The deficits do not occur exclusively during the course of a delirium.

Code based on predominant features:

**290.41 With delirium:** if delirium is superimposed on the dementia

**290.42 With delusions:** if delusions are the predominant feature

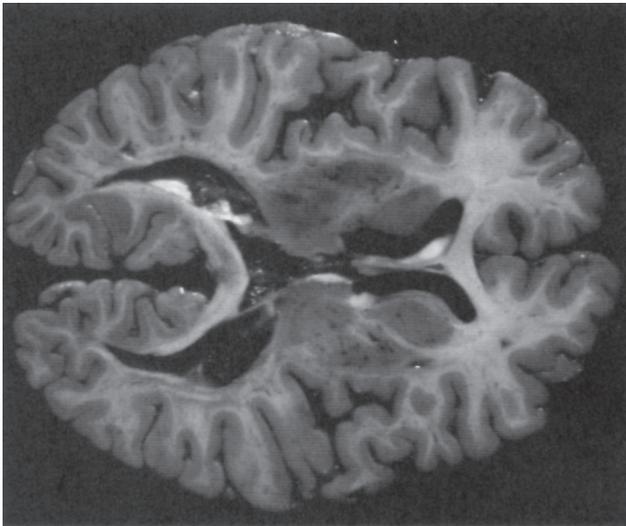

**290.43 With depressed mood:** if depressed mood (including presentations that meet full symptom criteria for a major depressive episode) is the predominant feature. A separate diagnosis of mood disorder due to a general medical condition is not given.

**209.40 Uncomplicated:** if none of the above predominates in the current clinical presentation

Specify if:

**With behavioral disturbance**

**Coding note:** Also code cerebrovascular condition on Axis III.

**Figure 32.8** Multiple lucencies in basal nuclei with reduced white matter in vascular dementia. (Courtesy of Joseph Parker, MD, Duke University Medical Center, Durham, NC.)

### Clinical Features

Vascular dementia is characterized by the early appearance of localizing neurological signs. Spasticity, hemiparesis, ataxia and pseudobulbar palsy are common. Pseudobulbar palsy is associated with injury to the frontal lobes and results in impairment of the corticobulbar tracts. It is characterized by extreme emotional lability, abnormal speech cadence, dysphagia, hyperactive jaw jerk, hyperactive deep tendon reflexes and Babinski's reflex. CT, MRI and gross specimens show cerebral atrophy and infarctions, with the radiological procedures showing multiple lucencies and the gross specimens revealing distinct white matter lesions (Figure 32.8). The EEG is abnormal but nonspecific, and positron emission tomography reveals hypometabolic areas. Vascular dementia is differentiated from AD on the basis of its mode of progression, early appearance of neurological signs, and radiographical evidence of cerebral ischemia.

### Treatment

Primary prevention and secondary prevention are important in the treatment of cerebrovascular disorders. Lifestyle changes are effective in arresting the progress of the disease; however, no known pharmacological treatment can reverse the effects of a completed stroke. Such interventions as anticoagulants for frequent transient ischemic attacks after a hemorrhagic lesion have been investigated but excluded; aspirin for decreasing platelet aggregation, and surgical removal of obstructing plaques probably do not reverse the mental state. Depression occurs in 50 to 60% of patients with CVAs and responds to traditional antidepressants. Tricyclic antidepressants, such as amitriptyline, in less than antidepressant doses, improve both CVA depression and pseudobulbar palsy. Physical rehabilitation is essential and often results in an improvement in mood and outlook.

## Infectious Causes of Dementia

### Subacute Sclerosing Panencephalitis

Subacute sclerosing panencephalitis is an infectious cause of dementia that usually appears in childhood. The average age at onset

is 10 years, and most patients are male and live in rural areas. It is diagnosed on the basis of periodic complexes on the EEG and an elevated measles titer in the cerebrospinal fluid (CSF). The CT scan shows cerebral atrophy and dilated ventricles. Myoclonus and dementia are prominent features.

It has been postulated that a mutant measles virus is the infectious agent, based on the high CSF measles antibody titer and the fact that the disease is virtually nonexistent in children who have been vaccinated for measles. Affected patients show an insidious onset of impairment of cognition usually preceded by behavioral problems.

### Creutzfeldt–Jakob Disease

This disease has received intense scientific scrutiny. The primary features of Creutzfeldt–Jakob disease are dementia, basal ganglia and cerebellar dysfunction, myoclonus, upper motor neuron lesions and rapid progression to stupor, coma, and death in a matter of months. The disease generally affects people 65 years of age or older, with a duration of 1 month to 6 years and an average life span after disease onset of 15 months (Karp, 1984). The clinical and pathological features of Creutzfeldt–Jakob have been produced experimentally by injecting animals with brain tissue from affected adults. It has unknowingly been transferred to humans by organ transplantation, cerebral electrodes and pituitary growth hormone. These incidents, although tragic, illustrated the infectious nature of this condition, and the agent of transmission is believed to be a prion-containing protein (not DNA or RNA). These prions have been detected in the cerebral cortex of autopsy specimens of both patients with Creutzfeldt–Jakob disease and victims of kuru, a fatal disease transmitted by cannibalism (Kaplan *et al.*, 1994; Prusiner, 1987). Slow viruses have also been implicated as infectious agents in kuru. Creutzfeldt–Jakob has been accidentally transferred to humans by corneal and pituitary gland transplantation, electroencephalogram electrodes, and ingesting meat infected with the disease (mad cow disease).

The memory loss in Creutzfeldt–Jakob disease involves all phases of memory, with recent (secondary) memory being the most impaired. Personality changes, immature behavior and paranoia are early signs, and virtually every aspect of brain functioning can be involved. Motor disorders including rigidity, incoordination, paresis and ataxia usually follow.

As with subacute sclerosing panencephalitis, the EEG in Creutzfeldt–Jakob disease shows periodic complexes and biopsy specimens that reveal a characteristic spongiform encephalopathy and occasional amyloid plaques.

### Acquired Immunodeficiency Syndrome

The CDC reports that as of June 1, 2001, 793 026 individuals had been diagnosed as having AIDS, with over 134 000 women included in that total. Nine thousand children under age 13 years have been diagnosed. Deaths from AIDS-related illnesses have reached 458 000. Worldwide, about 40 million people, including 3 million children, have AIDS. Forty-eight percent of the worldwide cases are women, and 95% of AIDS cases are in undeveloped countries (AIDS Surveillance Report, 2002). The number of people infected is postulated to be as much as 50 to 100 times the number of people diagnosed with AIDS, and 80 to 90% of people infected have not been tested.

In the developed countries, the death rate from AIDS has been on the decline since the advent of new medication regimens utilizing traditional antiretrovirals and the newer protease

inhibitors. These medication cocktails have also decreased the incidence of AIDS dementia complex, so that physicians are now more likely to see AIDS-related delirium secondary to infection, metabolic disarray and medication rather than traditional AIDS dementia.

In the truest sense, AIDS is not a disease but an increased susceptibility to a variety of diseases caused by loss of immunocompetence. It results from infection with HIV, a retrovirus that attaches to the CD4 molecule on the surface of the T4 (thymus-derived) lymphocyte. Then, using reverse transcriptase, the virus reverses the usual sequence of genetic information and becomes integrated into the host cell's DNA. The ultimate result is destruction of the T4 cell, replication of the virus, a defect in cell-mediated immunity and the development of various opportunistic infections and neoplasms.

The epidemiology of HIV spectrum diseases has changed significantly in the 16 years since its identification. Initially, homosexual and bisexual men with multiple partners were the highest-risk group. Intravenous drug abusers and recipients of tainted blood products were soon added to high-risk groups. In the 1990s, the number of new infections among homosexual men decreased significantly and rates for women, intravenous drug abusers who shared contaminated needles, and infants born to infected mothers increased significantly. Intravenous drug abusers, regardless of sexual orientation, represent the fastest growing population of the newly infected people. Conversely, instances of transmission by blood products have decreased since the development of laboratory testing for HIV antibodies. The CDC has now established a reactive HIV antibody screen, presence of an opportunistic condition, and a CD4<sup>+</sup> cell count of 200 or less (normal being 1000–1500) as criteria for the diagnosis of AIDS.

AIDS is now best considered as part of the spectrum of HIV infection. There are four stages of infection.

**Stage 1: Acute Infection:** Most infected persons remember no signs or symptoms at the time of the initial infection. The acute syndrome follows infection by 4 to 6 weeks and is characterized by fevers, rigors, muscle aches, maculopapular rash, diarrhea and abdominal cramps. These symptoms, often mistaken for those of influenza, resolve spontaneously after 2 to 3 weeks.

**Stage 2: Asymptomatic carrier:** This stage follows the acute infection. The patient is without symptoms for a variable amount of time. The mean symptom-free period has increased significantly since the disease was first identified and is now about 10 years. Most of the estimated 2 million infected Americans are at this stage. Even though these individuals are asymptomatic, they are carriers of the disease and can infect others.

**Stage 3: Generalized adenopathy:** In older terminology, this stage was referred to as the AIDS-related complex. It is characterized by palpable lymph nodes that persist for longer than 3 months. These nodes must be outside the inguinal area and due to no other condition except HIV.

**Stage 4: Other diseases:**

1. Constitutional symptoms such as lingering fever, wasting syndromes and intractable diarrhea.
2. Secondary infections including *P. carinii* pneumonia, cytomegalovirus retinitis, parasitic colitis, and oral esophageal thrush.

3. Secondary neoplasms such as Kaposi's sarcoma and B-cell lymphomas.
4. Neurological diseases (AIDS dementia complex).

Thus, the diagnosis of AIDS is made when an infected individual develops either a CD4<sup>+</sup> cell count of less than 200 or a certain condition listed in the stages.

## Dementia Due to HIV Diseases

Initially, the behavioral abnormalities observed in HIV-positive patients were attributed to the emotional reaction to the disease. Subsequent investigations demonstrated that neurological complications occur in 40 to 45% of patients with AIDS, and in about 10% of cases neurological signs are the first feature of the disease (Berg *et al.*, 1994). The neurological signs present in AIDS are believed to be related to both the direct effects of the virus on cells (such as macrophages) that enter the central nervous system and the neurological conditions that opportunistically affect these patients. Ho and colleagues (1987) reported that 90% of the brains of AIDS patients examined showed neuropathological abnormalities. AIDS dementia must be considered in the differential diagnosis of dementia in older patients, because about 10% of AIDS patients are older than 50 years of age.

Patients with AIDS dementia present with impairments of cognitive, behavioral and motor systems. The cognitive disorders include memory impairment, confusion and poor concentration. Behavioral features include apathy, reclusivity, anhedonia, depression, delusions, and hallucinations. Motor symptoms include incoordination, lower extremity paresis, unsteadiness, and difficulty with fine motor movements like handwriting and buttoning clothes. As the disease progresses, parkinsonism and myoclonus develop.

Localizing signs such as tremors, focal seizures, abnormal reflexes and hemiparesis can result. The protozoan *Toxoplasma gondii* commonly infects the central nervous system and can be diagnosed by CT or by increased toxoplasmosis antibody titers. Discrete cerebral lesions are also produced by fungi such as *Candida* and *Aspergillus*, *Mycobacterium tuberculosis*, and viruses such as cytomegalovirus and papovavirus. Papovavirus causes progressive multifocal leukoencephalopathy. Tertiary syphilis has increased significantly since the advent of AIDS, and neoplasms such as lymphomas, metastatic Kaposi's sarcoma and gliomas are also causes of AIDS dementia.

Many confounding factors can increase cognitive dysfunction in AIDS, including a high incidence of drug and alcohol abuse; medications such as histamine H<sub>2</sub> receptor antagonists (cimetidine), corticosteroids, narcotics and antiviral drugs (e.g., zidovudine [formerly azidothymidine, AZT]) that increase confusion; and coexistent depression (Table 32.5).

The CT scan shows cerebral atrophy and MRI reveals nonspecific white matter abnormalities (Kaufman, 1990b). Neoplasms and lesions such as toxoplasmosis are also visible. Lumbar puncture reveals a pleocytosis and elevated protein levels, and autopsy demonstrates an atrophic brain with demyelination, multinuclear giant cells and gliosis of the cerebral cortex (Kaufman, 1990b).

## Treatment

The increase in life span of patients affected by HIV is directly related to improvements in treating the opportunistic conditions that occur. Aerosol pentamidine as prophylaxis for *P. carinii*

**Table 32.5** Neuropsychiatric Effects of AIDS-related Drugs

Drug	Use	Effect
Ketoconazole	Antifungal	Severe depression Suicidality (rare)
Foscarnet	Cytomegalovirus retinitis Herpes	Depression Confusion
Ganciclovir	Cytomegalovirus retinitis	Anxiety Psychosis
Bactrim	<i>Pneumocystis pneumonia</i>	Hallucinations Depression Apathy
Pentamidine	<i>Pneumocystis pneumonia</i>	Delirium Hallucinations
Interferon alpha	Cancer	Depression
Rifampin	Tuberculosis	Delirium Behavioral changes
Isoniazid	Tuberculosis	Memory disturbance Psychosis
Dronabinol (Marinol)	Appetite stimulant Wasting syndrome Nausea	Depression Anxiety Psychosis Euphoria
Zalcitabine (DDC)	Antiviral	Psychosis Amnesia Confusion Depersonalization Depression Mania Suicidality Mood swings
Didanosine	Antiviral	Anxiety
Zidovudine (AZT)	Antiviral	Confusion, mania Depression, anxiety

pneumonia and ganciclovir for cytomegalovirus retinitis are examples of effective intervention. The use of antiviral agents has generated some controversy. Zidovudine, the first antiviral treatment for AIDS approved by the USFDA, increased or stabilized CD4<sup>+</sup> cell concentrations in early studies. Later investigations revealed that zidovudine has a narrow window of effectiveness and may not be appropriate immediately after such exposure as a needle stick. Side effects of zidovudine include blood dyscrasias, peripheral neuropathy, seizures, lymphomas, confusion, anxiety, mania and a Wernicke–Korsakoff type of picture (Kaufman, 1990b).

Studies suggest that administration of zidovudine to HIV-positive patients during pregnancy, intravenously during delivery, and to the neonate for 6 weeks after birth can decrease the percentage of infants who seroconvert from 30% to as low as 10%. However, results of studies of the effectiveness of zidovudine in children already HIV-positive have been disappointing. Subsequent antiviral agents such as dideoxyinosine and dideoxycytidine (DDC) have been associated with painful neuropathy

and pancreatic disorders. DDC in particular can produce serious neuropsychiatric complications. Combined therapy with two antiviral agents may be more effective than single-drug therapy. Many pharmaceutical companies are combining two antivirals into a single pill, and the development of protease inhibitor agents such as indinavir and nelfinavir have been especially effective in retarding the progression of the disease. The treatment of neuropsychiatric disorders in AIDS involves utilizing agents that are least likely to interfere with other medications prescribed, or to exacerbate the symptoms of the disease. AIDS-related depression has responded well to the selective serotonin reuptake inhibitors (SSRIs) and to psychostimulants. Some HIV drugs can have interactions with SSRIs, particularly ritonavir and the SSRIs themselves, especially paroxetine and fluoxetine can interact with other agents the HIV patient may have been prescribed, such as antiarrhythmics, benzodiazepines and anti-convulsants by inhibiting the cytochrome P-450 enzyme system. Some individuals have suggested that citalopram is less likely to inhibit this enzyme system. Careful attention to drug–drug

interactions, using lower starting doses of certain psychiatric drugs, and monitoring of blood levels of affected medications are recommended. Among the psychostimulants, methylphenidate is preferred to dextroamphetamine because of the latter's tendency to produce dyskinesias. Use of stimulants for treating patients with a history of substance abuse is not recommended. Anticholinergic agents have a number of side effects such as mydriasis, decreased gastrointestinal motility and postural hypotension. However, low dose tricyclic antidepressants are often used for their sedative, analgesic and appetite stimulant properties. Most antidepressants and some mood stabilizers and antipsychotics can cause bone marrow suppression so they should be used with care, and hematologic parameters routinely monitored. Lithium carbonate, which produces a leukocytosis, may be of benefit in recurrent unipolar and treatment resistant depression, but may potentiate AIDS-related diarrhea. Many of the drugs used to treat AIDS-related conditions may produce untoward psychiatric effects. Depression has been well documented as a side effect of indinavir and nelfinavir has been associated with anxiety, depression, mood lability and even suicidality. St John's Wort may decrease the concentration of many of the protease inhibitors and is therefore contraindicated in patients taking these agents. In summary, AIDS dementia is best treated by identifying the associated medical condition, instituting appropriate therapy and managing behavior in the interim.

### Neurosyphilis

The rise of AIDS in the 1980s and 1990s has led to an increase in the number of diagnosed cases of neurosyphilis.

Late syphilis consists of ongoing inflammatory disease most likely in the aorta or nervous system (neurosyphilis), the latter occurring in about 10% of patients. The neurosyphilis of the late stage can consist of 1) asymptomatic neurosyphilis, 2) meningovascular syphilis, and 3) parenchymal neurosyphilis which has two forms. One form of parenchymal neurosyphilis consists of general paresis, which occurs about 20 years after infection and includes cognitive impairment, myoclonus, dysarthria, personality changes, irritability, psychosis, grandiosity and mania. Untreated general paresis leaves the patient a helpless invalid. The second form of parenchymal neurosyphilis is **tabes dorsalis** with onset 25 to 30 years after initial infection. Tabes features loss of position and vibratory sense, areflexia in lower extremities, chronic pain, ataxia and incontinence.

The original screening test for syphilis is the venereal disease research laboratory (VDRL) test. This test has a significant false-positive rate, especially in the elderly and in patients with addictions and autoimmune disorders (Kaufman, 1990b). The VDRL test may revert to negative after a number of years, and 20 to 30% of patients in the stage of late syphilis have a negative (nonreactive) VDRL result. A more specific test is the fluorescent treponemal antibody screen, which is positive 95% of the time in neurosyphilis. The false-positive rate for the fluorescent treponemal antibody screen is extremely low, and reversion to a nonreactive state is unlikely. In addition to a positive VDRL result, the CSF in patients with neurosyphilis generally shows pleocytosis.

Dementia secondary to neurosyphilis produces various physical findings in advanced cases. These may include dysarthria, Babinski's reflex, tremor, Argyll Robertson pupils, myelitis and optic atrophy. Although notorious, delusions of grandeur in neurosyphilis are rare. A reactive CSF VDRL result or a positive serum fluorescent treponemal antibody result in a patient with

neurological symptoms who cannot document treatment should be treated with appropriate therapy. Penicillin often improves cognitive deficits and corrects CSF abnormalities, but complete recovery is rare.

### Dementia Due to Head Trauma

Head trauma is the leading cause of brain injury for children and young adults. It is estimated that more than 7 million head injuries and 500 000 hospital admissions related to the same cause occur in the USA annually. Traumatic head injuries result in concussions, contusions, or open head injuries, and the physical examination often reveals such features as blood behind the tympanic membranes (Battle's sign), infraorbital ecchymosis and pupillary abnormalities. The psychiatric manifestations of an acute brain injury are generally classified as a delirium or amnesic disorder; however, head trauma-induced delirious states often merge into a chronic dementia.

A single head injury may result in a postconcussional syndrome with resultant memory impairment, alterations in mood and personality, hyperacusis, headaches, easy fatigability, anxiety, belligerent behavior and dizziness. Alcohol abuse, postural hypotension and gait disturbances are often associated with head injuries that result in dementia.

### Substance-induced Persisting Dementia

In instances in which the features of dementia result from central nervous system effects of a medication, toxin, or drug of abuse (including alcohol), the diagnosis of dementia due to the persisting effects of a substance should be made (American Psychiatric Association, 1994). The most common dementias in this category are those associated with alcohol abuse, accounting for about 10% of all dementias. The diagnosis of alcohol abuse dementia requires that the cognitive changes persist after the cessation of alcohol use and are not the result of changes in mentation associated with early abstinence, amnesic episodes (blackouts), or Wernicke-Korsakoff syndrome. In addition to various nutritional deficiencies and the toxic effects of alcohol itself, alcohol abusers are more prone to develop dementia as a result of head trauma and chronic hepatic encephalopathy.

### Alcohol-induced Dementia

#### Epidemiology

Severe alcohol dependence is the third leading cause of dementia. Alcohol-induced dementia is a relatively late occurrence, generally following 15 to 20 years of heavy drinking. Dementia is more common in individuals with alcoholism who are malnourished. The CT scan shows cortical atrophy and ventricular dilatation after about 10 years with neuronal loss, pigmentary degeneration and glial proliferation. The frontal lobes are the most affected, followed by parietal and temporal areas. The amount of deterioration is related to age, number of episodes of heavy drinking and total amount of alcohol consumed over time.

#### Clinical Features

Alcohol-induced dementia, secondary to the toxic effects of alcohol, develops insidiously and often presents initially with changes in personality. Increasing memory loss, worsening cognitive processing and concrete thinking follow. The dementia may be affected by periodic superimposed delirious states including those caused by recurrent use of alcohol and cross-sensitive drugs, respiratory disease related to smoking, central nervous system

## DSM-IV-TR Criteria

### Substance-induced Persisting Dementia

- A. The development of multiple cognitive deficits manifested by both
- (1) memory impairment (impaired ability to learn new information or to recall previously learned information)
  - (2) one (or more) of the following cognitive disturbances:
    - (a) aphasia (language disturbance)
    - (b) apraxia (impaired ability to carry out motor activities despite intact motor function)
    - (c) agnosia (failure to recognize or identify objects despite intact sensory function)
    - (d) disturbance in executive functioning (i.e., planning, organizing, sequencing, abstracting)
- B. The cognitive deficits in criteria A1 and A2 each cause significant impairment in social or occupational functioning and represent a significant decline from a previous level of functioning.
- C. The deficits do not occur exclusively during the course of a delirium and persist beyond the usual duration of substance intoxication or withdrawal.
- D. There is evidence from the history, physical examination, or laboratory findings that the deficits are etiologically related to the persisting effects of substance use (e.g., a drug of abuse, a medication).

**Code:** [specific substance]–induced persisting dementia:

(291.2 alcohol; 292.82 inhalant; 292.82 sedative, hypnotic, or anxiolytic; 292.82 other [or unknown] substance)

hemorrhage secondary to trauma, chronic hypoxia related to recurrent seizure activity, folic acid deficiency and higher rates of some neoplasms among those with alcoholism (Table 32.6).

**Table 32.6** Central Nervous System Sequelae of Alcohol Abuse

Blackouts  
 Dementia  
 Marchiafava–Bignami disease  
 Wernicke–Korsakoff syndrome  
 Hepatic encephalopathy  
 Delirium tremens  
 Withdrawal seizures  
 Episodic dyscontrol (pathological intoxication)  
 Alcoholic hallucinosis  
 Head injury

## Treatment

The presence of dementia makes the treatment of alcoholism more difficult. Most treatment programs depend on education about substance abuse, working the 12 steps, some degree of sociability, and such relatively abstract concepts as secondary gratification and a higher power. Such treatment programs are often reluctant to engage in the painstaking repetition that patients with alcohol-induced dementia often require. These patients may become frustrated in peer support groups such as Alcoholics Anonymous. Despite these obstacles, patients with alcoholism who complete a treatment program and remain sober do have some improvement in their mental state. There is an initial improvement that peaks at 3 to 4 weeks, followed by a slow but steady improvement detected at 6 to 8 months. In general, the presence of a cognitive deficit (dementia) dictates an alcohol treatment program that is behavior based, concrete, structured, supportive and repetitive.

## Other Substances

Many other agents can produce dementia as a result of their persisting effects. Exposure to such heavy metals as mercury and bromide, chronic contact with various insecticides, and use of various classes of drugs of abuse may produce dementia. In particular, the abuse of organic solvents (inhalants) has been associated with neurological changes. The inhalants are generally classified as anesthetics (halothane, chloroform, ether, nitrous oxide), solvents (gasoline, paint thinner, antifreeze, kerosene, carbon tetrachloride), aerosols (insecticides, deodorants, hair sprays) and nitrites (amyl nitrite). The solvent category is particularly toxic to the brain. In addition, acute anoxia may result from the common practice of inhaling a substance with a plastic bag around the head. Such neurological findings as peripheral neuropathy, paresis, paresthesias, areflexia, seizures, signs of cerebellar damage and Babinski's sign are common. Although the cerebellum is often involved, any area of the cerebral cortex may be affected (Table 32.7).

## Dementia Due to Other General Medical Conditions

### Normal-pressure Hydrocephalus

Normal-pressure hydrocephalus is generally considered the fifth leading cause of dementia after Alzheimer's, vascular, alcohol-related, and AIDS dementias. Long considered reversible but often merely arrestable, normal-pressure hydrocephalus is a syndrome consisting of dementia, urinary incontinence and gait apraxia. It results from subarachnoid hemorrhage, meningitis, or trauma that impedes CSF absorption. Unlike other dementias, the dementia caused by normal-pressure hydrocephalus has physical effects that often overshadow the mental effects. Psychomotor retardation, marked gait disturbances and, in severe cases, complete incontinence of urine occur. A cisternogram is often helpful in the diagnosis, and CT and MRI show ventricular dilatation without cerebral atrophy. CSF analysis reveals a normal opening pressure, and glucose and protein determinations are within the normal range.

The hydrocephalus can be relieved by insertion of a shunt into the lateral ventricle to drain CSF into the chest or abdominal cavity, where it is absorbed. Clinical improvement with shunting approaches 50% with a neurosurgical complication rate of 13 to 25%. Infection remains the most common complication.

**Table 32.7 Neurological Effects of Selected Inhalants**

Agent	Use	Effect
<i>n</i> -Hexane	Organic solvent	Peripheral neuropathy
Methyl butyl ketone	Paint thinner	Polyneuropathy
Toluene	Paint thinner	Cognitive dysfunction Cerebellar ataxia Optic neuropathy loss Sensorineural hearing Dementia
Trichloroethylene	Metal degreasing Extracting oils	Trigeminal neuropathy
Methylene chloride	Paint stripping, propellant Aerosol	Carbon monoxide poisoning Hypoxic encephalopathy
1,1,1-trichloroethane	Solvent Industrial degreasing	Cerebral hypoxia

### Wilson's Disease

Hepatolenticular degeneration (Wilson's disease) is an inherited autosomal recessive condition associated with dementia, hepatic dysfunction and a movement disorder. Localized to chromosome 13, this disorder features copper deposits in the liver, brain and cornea. Symptoms begin in adolescence to the early twenties and cases are often seen in younger children. Wilson's disease should be considered along with Huntington's disease, AIDS dementia, substance abuse dementia, head trauma and subacute sclerosing panencephalitis in the differential diagnosis of dementia that presents in adolescence and early adulthood. Personality, mood and thought disorders are common, and physical findings include a wing-beating tremor, rigidity, akinesia, dystonia and the pathognomonic Kayser–Fleischer ring around the cornea. Wilson's disease can mimic other conditions including Huntington's disease, Parkinson's disease, atypical psychosis and neuroleptic-induced dystonia. Slit-lamp ocular examination, abnormal liver function tests and markedly decreased serum ceruloplasmin levels are diagnostic. Chelating agents such as penicillamine, if administered early, can reverse central nervous system and nonneurological findings in about 50% of cases.

### Other Medical Conditions

In addition to the conditions mentioned previously, other medical illnesses can be associated with dementia. These include endocrine disorders (hypothyroidism, hypoparathyroidism), chronic metabolic conditions (hypocalcemia, hypoglycemia), nutritional deficiencies (thiamine, niacin, vitamin B<sub>12</sub>), structural lesions (brain tumors, subdural hematomas) and multiple sclerosis.

### Treatment of Dementia

Most of the treatment strategies for dementia have been discussed previously (see treatment of dementia of the Alzheimer type). In summary, the management of dementia involves 1) identification and, if possible, correction of the underlying cause; 2) environmental manipulation to reorient the patient; 3) intervention with the family by means of education, peer support, providing access to community organizations, discussing powers of attorney, living wills, and institutionalization if appropriate, and arranging therapy if indicated; and 4) pharmacological management of psychiatric symptoms and behavior. Low dose antipsychotics with minimal anticholinergic potential and occasionally short-acting benzodiazepines (e.g., lorazepam) are the drugs of choice. Because depression occasionally accompanies dementia, pharmacotherapy with antidepressants of low anticholinergic and hypotensive potential is often indicated. For patients with dementia, secondary to drug or alcohol abuse, appropriate referral for rehabilitation is essential.

### Delirium

Delirium (also known as acute confusional state, toxic metabolic encephalopathy) is the behavioral response to widespread disturbances in cerebral metabolism. Like dementia, delirium is not a disease but a syndrome with many possible causes that result in a similar constellation of symptoms. DSM-IV-TR describes five categories of delirium based on etiology. These include delirium due to a general medical condition, substance intoxication, withdrawal delirium, delirium due to multiple etiologies and delirium not otherwise specified.

### Epidemiology

The overall prevalence of delirium in the community is low, but delirium is common in hospitalized patients. Lipowski (Saito, 1987) reported studies of elderly patients and suggested that about 40% of them admitted to general medical wards showed signs of delirium at some point during the hospitalization. Because of the increasing numbers of elderly in this country and the influence of life-extending technology, the population of hospitalized elderly is rising; and so is the prevalence of delirium. The intensive care unit, geriatric psychiatry ward, emergency department, alcohol treatment units and oncology wards have particularly high rates of delirium. Massie and colleagues (Lipowski, 1987) reported that 85% of terminally ill patients studied had symptoms that met criteria for delirium, as did 100% of postcardiotomy patients in a study by Theobald (Lipowski, 1989). Overall, it is estimated that 10% of hospitalized patients are delirious at any particular point in time.

Predisposing factors in the development of delirium include old age, young age (children), previous brain damage, prior episodes of delirium, malnutrition, sensory impairment (especially vision) and alcohol dependence. In general, the mortality and morbidity of any serious disease are doubled if delirium ensues. The risk of dying after a delirious episode is greatest in the first two years after the illness, with a higher risk of death from heart disease and cancer in women and from pneumonia in men. Overall, the 3-month mortality rate for persons who have an episode of delirium is about 28%, and the 1-year mortality rate for such patients may be as high as 50%.

**DSM-IV-TR Criteria 294.1****Dementia due to Other General Medical Conditions**

- A. The development of multiple cognitive deficits manifested by both
- (1) memory impairment (impaired ability to learn new information or to recall previously learned information)
  - (2) one (or more) of the following cognitive disturbances:
    - (a) aphasia (language disturbance)
    - (b) apraxia (impaired ability to carry out motor activities despite intact motor function)
    - (c) agnosia (failure to recognize or identify objects despite intact sensory function)
    - (d) disturbance in executive functioning (i.e., planning, organizing, sequencing, abstracting)
- B. The cognitive deficits in criteria A1 and A2 each cause significant impairment in social or occupational functioning and represent a significant decline from a previous level of functioning.
- C. There is evidence from the history, physical examination, or laboratory findings that the disturbance is the direct physiological consequence of one of the general medical conditions listed below.
- D. The deficits do not occur exclusively during the course of a delirium.

**Coding note:** Also code the general medical condition on Axis III.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association. Table 32.8 summarizes the causes of dementia.

**Pathophysiology**

ACh is the primary neurotransmitter believed to be involved in delirium, and the primary neuroanatomical site involved is the reticular formation. Thus, one of the frequent causes of delirium is the use of drugs with high anticholinergic potential. As the principal site of regulation of arousal and attention, the reticular formation and its neuroanatomical connections play a major role in the symptoms of delirium. The major pathway involved in delirium is the dorsal tegmental pathway projecting from the mesencephalic reticular formation to the tectum and the thalamus.

**Clinical Features**

According to DSM-IV-TR, the primary feature of delirium is a diminished clarity of awareness of the environment (American Psychiatric Association, 1994). Symptoms of delirium are characteristically global, of acute onset, fluctuating and of relatively brief duration. In most cases of delirium, an often overlooked prodrome of altered sleep patterns, unexplained fatigue, fluctuating mood, sleep phobia, restlessness, anxiety and nightmares occurs. A review of nursing notes for the days before the recognized onset of delirium often illustrates early warning signs of the condition.

Several investigators have divided the clinical features of delirium into abnormalities of 1) arousal, 2) language and cognition, 3) perception, 4) orientation, 5) mood, 6) sleep and wakefulness, and 7) neurological functioning (Kaplan *et al.*, 1994).

The state of arousal in delirious patients may be increased or decreased. Some patients exhibit marked restlessness, heightened startle, hypervigilance and increased alertness. This pattern is often seen in states of withdrawal from depressive substances (e.g., alcohol) or intoxication by stimulants (phencyclidine, amphetamine, lysergic acid diethylamide). Patients with increased arousal often have such concomitant autonomic signs as pallor, sweating, tachycardia, mydriasis, hyperthermia, piloerection and gastrointestinal distress. These patients often require sedation with neuroleptics or benzodiazepines. Hypoactive arousal states such as those occasionally seen in hepatic encephalopathy and hypercapnia are often initially perceived as depressed or demented states. The clinical course of delirium in any particular patient may include both increased and decreased arousal states. Many such individuals display daytime sedation with nocturnal agitation and behavioral problems (sundowning).

Perceptual abnormalities in delirium represent an inability to discriminate sensory stimuli and to integrate current perceptions with past experiences. Consequently, patients tend to personalize events, conversations and so forth that do not directly pertain to them, become obsessed with irrelevant stimuli and misinterpret objects in their environment. The misinterpretations generally take the form of auditory and visual illusions. Patients with auditory illusions, for example, might hear the sound of leaves rustling and perceive it as someone whispering

about them. Paranoia and sleep phobia may result. Typical visual illusions are that intravenous tubing is a snake or worm crawling into the skin, or that a respirator is a truck or farm vehicle about to collide with the patient. The former auditory illusion may lead to tactile hallucinations, but the most common hallucinations in delirium are visual and auditory.

Orientation is often abnormal in delirium. Disorientation in particular seems to follow a fluctuating course, with patients unable to answer questions about orientation in the morning, yet fully oriented by the afternoon. Orientation to time, place, person and situation should be evaluated in the delirious patient. Generally, orientation to time is the sphere most likely impaired, with orientation to person usually preserved. Orientation to significant people (parents, children) should also be tested. Disorientation to self is rare and indicates significant impairment. The examiner should always reorient patients who do not perform well on any portion of the orientation testing of the mental status examination, and serial testing of orientation on subsequent days is important.

### Language and Cognition

Patients with delirium frequently have abnormal production and comprehension of speech. Nonsensical rambling and incoherent

### DSM-IV-TR Criteria 290.0

#### Delirium due to... [Indicate the General Medical Condition]

- A. Disturbance of consciousness (i.e., reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention.
- B. A change in cognition (such as memory deficit, disorientation, language disturbance) or the development of a perceptual disturbance that is not better accounted for by a preexisting, established, or evolving dementia.
- C. The disturbance develops over a short period of time (usually hours to days) and tends to fluctuate during the course of the day.
- D. There is evidence from the history, physical examination, or laboratory findings that the disturbance is caused by the direct physiological consequences of a general medical condition.

**Coding note:** If delirium is superimposed on a preexisting dementia of the Alzheimer's type or vascular dementia, indicate the delirium by coding the appropriate subtype of the dementia, e.g., 290.3 dementia of the Alzheimer's type, with late onset, with delirium.

**Coding note:** Include the name of the general medical condition on Axis I, e.g., 293.0 delirium due to hepatic encephalopathy; also code the general medical condition on Axis III.

speech may occur. Other patients may be completely mute. Memory may be impaired, especially primary and secondary memory. Remote memory may be preserved, although the patient may have difficulty distinguishing the present from the distant past.

### Mood

Patients with delirium are susceptible to rapid fluctuations in mood. Unprovoked anger and rage reactions occasionally occur and may lead to attacks on hospital staff. Fear is a common emotion and may lead to increased vigilance and an unwillingness to sleep because of increased vulnerability during somnolence. Apathy, such as that seen in hepatic encephalopathy, depression, use of certain medications (e.g., sulfamethoxazole [Bactrim]) and frontal lobe syndromes, is common as is euphoria secondary to medications (e.g., corticosteroids, DDC, zidovudine) and drugs of abuse (phencyclidine, inhalants).

### Neurological Symptoms

Neurological symptoms often occur in delirium. These include dysphagia as seen after a CVA, tremor, asterixis (hepatic encephalopathy, hypoxia, uremia), poor coordination, gait apraxia, frontal release signs (grasp, suck), choreiform movements,

seizures, Babinski's sign and dysarthria. Focal neurological signs occur less frequently.

### Sleep–Wakefulness Disturbances

Sleeping patterns of delirious patients are usually abnormal. During the day they can be hypersomnolent, often falling asleep in midsentence, whereas at night they are combative and restless. Sleep is generally fragmented, and vivid nightmares are common. Some patients may become hypervigilant and develop a sleep phobia because of concern that something untoward may occur while they sleep.

### Causes of Delirium

The cause of delirium may lie in intracranial processes, extracranial ones, or a combination of the two. The most common etiological factors are as follows (Francis *et al.*, 1990).

#### Infection Induced

Infection is a common cause of delirium in hospitalized patients and typically, infected patients will display abnormalities in hematology and serology. Vital signs are noted except in persons (elderly, chronic alcohol abusers, chemotherapy patients, those with HIV spectrum disease) who may not be able to mount the typical response. Bacteremic septicemia (especially that caused by gram-negative bacteria), pneumonia, encephalitis and meningitis are common offenders. The elderly are particularly susceptible to delirium secondary to urinary tract infections.

#### Metabolic and Endocrine Disturbances

Metabolic causes of delirium include hypoglycemia, electrolyte disturbances and vitamin deficiency states. The most common endocrine causes are hyperfunction and hypofunction of the thyroid, adrenal, pancreas, pituitary and parathyroid. Metabolic causes may involve consequences of diseases of particular organs, such as hepatic encephalopathy resulting from liver disease, uremic encephalopathy and postdialysis delirium resulting from kidney dysfunction, and carbon dioxide macrosis and hypoxia resulting from lung disease. The metabolic disturbance or endocrinopathy must be known to induce changes in mental status and must be confirmed by laboratory determinations or physical examination, and the temporal course of the confusion should coincide with the disturbance (Francis *et al.*, 1990). In some individuals, particularly the elderly, brain injured and demented, there may be a significant lag time between correction of metabolic parameters and improvement in mental state.

#### Low-perfusion States

Any condition that decreases effective cerebral perfusion can cause delirium. Common offenders are hypovolemia, congestive heart failure and other causes of decreased stroke volume such as arrhythmias and anemia, which decreases oxygen binding. Maintenance of fluid balance and strict measuring of intake and output are essential in delirious states.

#### Intracranial Causes

Intracranial causes of delirium include head trauma, especially involving loss of consciousness, postconcussive states and hemorrhage; brain infections; neoplasms; and such vascular abnormalities as CVAs, subarachnoid hemorrhage, transient ischemic attacks and hypertensive encephalopathy.

### Postoperative States

Postoperative causes of delirium may include infection, atelectasis, postpump confusion from maintenance on a heart–lung machine, lingering effects of anesthesia, thrombotic and embolic phenomena, and adverse reactions to postoperative analgesia. General surgery in an elderly patient has been reported to be followed by delirium in 10 to 14% of cases and may reach 50% after surgery for hip fracture (Lipowski, 1989).

### Sensory and Environmental Changes

Many clinicians underestimate the disorienting potential of an unfamiliar environment. The elderly are especially prone to develop environment-related confusion in the hospital. Individuals with preexisting dementia, who may have learned to compensate for cognitive deficits at home, often become delirious once hospitalized. In addition, the nature of the intensive care unit often lends itself to periods of high sensory stimulation (as during a “code”) or low sensory input, as occurs at night. Often, patients use such external events as dispensing medication, mealtimes, presence of housekeeping staff, and physicians' rounds to mark the passage of time. These parameters are often absent at night, leading to increased rates of confusion during night-time hours. Often, manipulating the patient's environment (see section on treatment) or removing the patient from the intensive care unit can be therapeutic.

### Substance Intoxication Delirium

The list of medications that can produce the delirious state is extensive (Table 32.9). The more common ones include such antihypertensives as methyldopa and reserpine, histamine (H<sub>2</sub>) receptor antagonists (cimetidine), corticosteroids, antidepressants, narcotics (especially opioid) and nonsteroidal analgesics, lithium carbonate, digitalis, baclofen, anticonvulsants, antiarrhythmics, colchicine, bronchodilators, benzodiazepines, sedative-hypnotics and anticholinergics. Of the narcotic analgesics, meperidine can produce an agitated delirium with tremors, seizures and myoclonus. These features are attributed to its active metabolite normeperidine, which has potent stimulant and anticholinergic properties and accumulates with repeated intravenous dosing. In general, adverse effects of narcotics are more common in those who have never received such agents before (the narcotically naive) or who have a history of a similar response to narcotics.

**Table 32.9 Selected Drugs Associated with Delirium**

Antihypertensives	Indomethacin
Amphotericin B	Ketamine
Antispasmodics	Levodopa
Antituberculous agents	Lidocaine
Baclofen	Lithium
Barbiturates	Meperidine
Cimetidine	Morphine
Corticosteroids	Procainamide
Colchicine	Pentamidine
Contrast media	Tricyclic antidepressants
Digitalis	Zalcitabine (DDC)
Ephedrine	Zidovudine (AZT)

## DSM-IV-TR Criteria

### Substance Intoxication Delirium

- A. Disturbance of consciousness (i.e., reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention.
- B. A change in cognition (such as memory deficit, disorientation, language disturbance) or the development of a perceptual disturbance that is not better accounted for by a preexisting, established, or evolving dementia.
- C. The disturbance develops over a short period of time (usually hours to days) and tends to fluctuate during the course of the day.
- D. There is evidence from the history, physical examination, or laboratory findings of either (1) or (2):
  - (1) the symptoms in criteria A and B developed during substance intoxication
  - (2) medication use is etiologically related to the disturbance

**Note:** This diagnosis should be made instead of a diagnosis of substance intoxication only when the cognitive symptoms are in excess of those usually associated with the intoxication syndrome and when the symptoms are sufficiently severe to warrant independent clinical attention.

**Note:** The diagnosis should be recorded as substance-induced delirium if related to medication use.

**Code:** [specific substance] intoxication delirium:

(291.0 alcohol; 292.81 amphetamine [or amphetamine-like substance]; 292.81 cannabis; 292.81 cocaine; 292.81 hallucinogen; 292.81 inhalant; 292.81 opioid; 292.81 phencyclidine [or phencyclidine-like substance]; 292.81 sedative, hypnotic, or anxiolytic; 292.81 other [or unknown] substance [e.g., cimetidine, digitalis, benztrapine])

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

Lithium-induced delirium occurs at blood levels greater than 1.5 mEq/L and is associated with early features of lethargy, stuttering and muscle fasciculations. The delirium may take as long as 2 weeks to resolve even after lithium has been discontinued, and other neurological signs such as stupor and seizures commonly occur. Maintenance of fluid and electrolyte balance is essential in lithium-induced delirium. Facilitation of excretion with such agents as aminophylline and acetazolamide helps, but hemodialysis is often required.

Principles to remember in cases of drug-induced delirium include the facts that 1) blood levels of possibly offending agents are helpful and should be obtained, but many persons can become delirious at therapeutic levels of the drug, 2) drug-induced delirium may be the result of drug interactions and polypharmacy and not the result of a single agent, 3) over-the-counter medications and preparations (e.g., agents containing caffeine or phenylpropanolamine) should also be considered, and 4) delirium can

be caused by the combination of drugs of abuse and prescribed medications (e.g., cocaine and dopaminergic antidepressants).

The list of drugs of abuse that can produce delirium is extensive. Some such agents have enjoyed a resurgence after years of declining usage. These include lysergic acid diethylamide, psilocybin (hallucinogenic mushrooms), heroin and amphetamines. Other agents include barbiturates, cannabis (especially dependent on setting, experience of the user and whether it is laced with phencyclidine [“superweed”] or heroin), jimsonweed (highly anticholinergic) and mescaline. In cases in which intravenous use of drugs is suspected, HIV spectrum illness must be ruled out as an etiological agent for delirium.

The physical examination of a patient with suspected illicit drug-induced delirium may reveal sclerosed veins, “pop” scars caused by subcutaneous injection of agents, pale and atrophic nasal mucosa resulting from intranasal use of cocaine, injected conjunctiva and pupillary changes. Toxicological screens are helpful but may not be available on an emergency basis.

### Substance Withdrawal Delirium

Alcohol and certain sedating drugs can produce a withdrawal delirium when their use is abruptly discontinued or significantly reduced. Withdrawal delirium requires a history of use of a potentially addicting agent for a sufficient amount of time to produce dependence. It is associated with such typical physical findings as abnormal vital signs, pupillary changes, tremor, diaphoresis, nausea and vomiting, and diarrhea. Patients generally

## DSM-IV-TR Criteria

### Substance Withdrawal Delirium

- A. Disturbance of consciousness (i.e., reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention.
- B. A change in cognition (such as memory deficit, disorientation, language disturbance) or the development of a perceptual disturbance that is not better accounted for by a preexisting, established, or evolving dementia.
- C. The disturbance develops over a short period of time (usually hours to days) and tends to fluctuate during the course of the day.
- D. There is evidence from the history, physical examination, or laboratory findings that the symptoms in criteria A and B developed during, or shortly after, a withdrawal syndrome.

**Note:** This diagnosis should be made instead of a diagnosis of substance withdrawal only when the cognitive symptoms are in excess of those usually associated with the withdrawal syndrome and when the symptoms are sufficiently severe to warrant independent clinical attention.

**Code:** [specific substance] withdrawal delirium:

(291.0 alcohol; 292.81 sedative, hypnotic, or anxiolytic; 292.81 other [or unknown] substance)

complain of abdominal and leg cramps, insomnia, nightmares, chills, hallucinations (especially visual) and a general feeling of “wanting to jump out of my skin”. Some varieties of drug withdrawal, although uncomfortable, are not life threatening (e.g., opioid withdrawal). Others such as alcohol withdrawal delirium are potentially fatal. Withdrawal delirium is much more common in hospitalized patients than in patients living in the community. The incidence of delirium tremens, for example, is found in 1% of all alcoholics, but in 5% of hospitalized alcohol abusers. Improvement of the delirium occurs when the offending agent is reintroduced or a cross-sensitive drug (e.g., a benzodiazepine for alcohol withdrawal) is employed. The causes of delirium are summarized in Table 32.10).

## Diagnosis

Appropriate workup of delirious patients includes a complete physical status, mental status and neurological examination.

History taking from the patient, any available family, previous physicians, the old chart and the patient’s current nurse is essential. Previous delirious states, etiologies identified in the past and interventions that proved effective should be elucidated. The appropriate evaluation of the delirious patient is reviewed in Figure 32.9

## Differential Diagnosis

Delirium must be differentiated from dementia because the two conditions may have different prognoses. In contrast to the changes in dementia, those in delirium have an acute onset. The symptoms in dementia tend to be relatively stable over time, whereas clinical features of delirium display wide fluctuation with periods of relative lucidity. Clouding of consciousness is

an essential feature of delirium, but demented patients are usually alert. Attention and orientation are more commonly disturbed in delirium, although the latter can become impaired in advanced dementia. Perception abnormalities, alterations in the sleep–wakefulness cycle, and abnormalities of speech are more common in delirium. Most important, a delirium is more likely to be reversible than is a dementia.

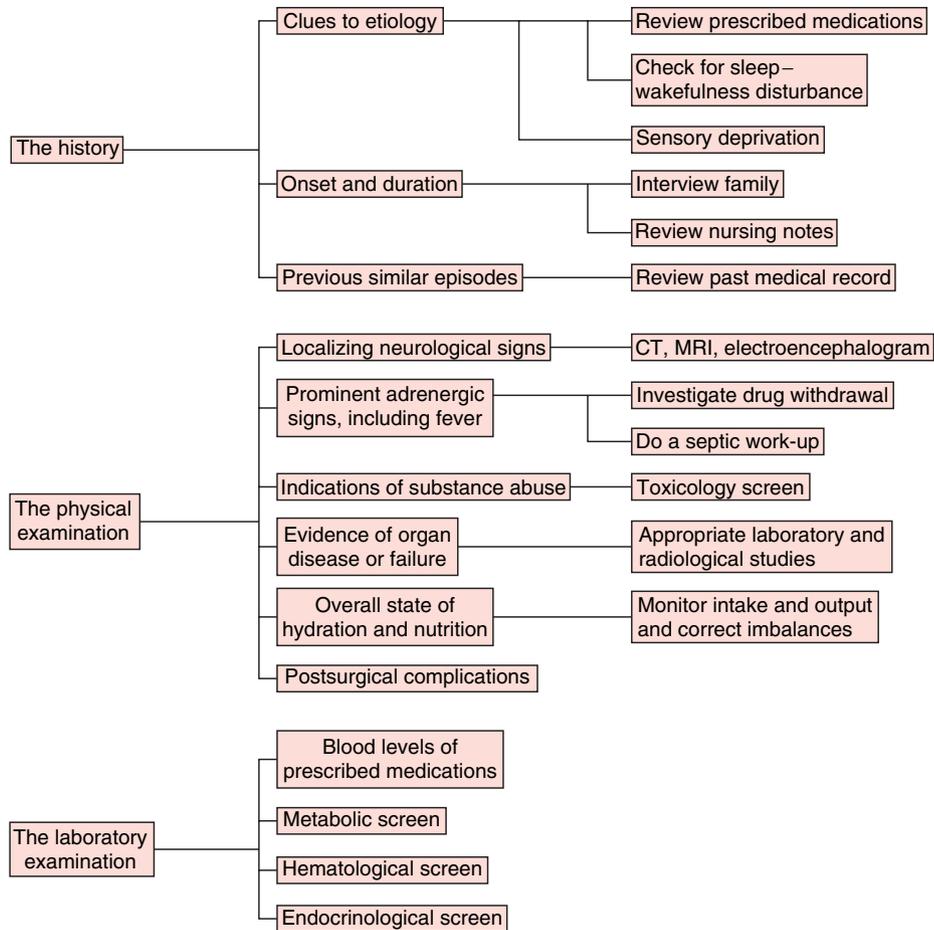

Delirium and dementia can occur simultaneously; in fact, the presence of dementia is a risk factor for delirium. Some studies suggest that about 30% of hospitalized patients with dementia have a superimposed delirium.

Delirium must often be differentiated from psychotic states related to such conditions as schizophrenia or mania and factitious disorders with psychological symptoms or malingering. Generally, the psychotic features of schizophrenia are more constant and better organized than are those in delirium, and patients with schizophrenia seldom have the clouding of consciousness seen in delirium. The “psychosis” of patients with factitious disorder or malingering is inconsistent, and these persons do not exhibit many of the associated features of delirium. Apathetic and lethargic patients with delirium may occasionally resemble depressed individuals, but tests such as EEG distinguish between the two. The EEG demonstrates diffuse slowing in most delirious states, except for the low-amplitude, fast activity EEG pattern seen in alcohol withdrawal. The EEG in a functional depression or psychosis is normal.

## Management

Once delirium has been diagnosed, the etiological agent must be identified and treated. For the elderly, the first step generally involves discontinuing or reducing the dosage of potentially offending medications. Some delirious states can be reversed with medication, as in the case of physostigmine administration for anticholinergic delirium. However, most responses are not as immediate, and attention must be directed toward protecting the patient from unintentional self-harm, managing agitated and psychotic behavior, and manipulating the environment to minimize additional impairment. Supportive therapy should include fluid and electrolyte maintenance and provision of adequate nutrition. Reorienting the patient is essential and is best accomplished in a well-lit room with a window, clock and visible wall calendar. Familiar objects from home such as a stuffed animal, favorite blanket, or photographs are helpful. Patients who respond incorrectly to questions of orientation should be provided with the correct answers. Because these individuals often see many consultants, physicians should introduce themselves and state their purpose for coming at every visit. Physicians must take into account that impairments of vision and hearing can produce confusional states, and the provision of appropriate prosthetic devices may be beneficial. Around-the-clock accompaniment by hospital-provided “sitters” or family members may be required (see Table 32.11).

Despite these conservative interventions, the delirious patient often requires pharmacological intervention. The liaison psychiatrist is the most appropriate person to recommend such treatment. The drug of choice for the agitated delirious patients has traditionally been haloperidol. It is particularly beneficial when given by the intravenous route and some authors have reported using dosages as high as 260 mg/day without adverse effect. Extrapyramidal symptoms may be less common with haloperidol administered intravenously as opposed to orally and intramuscularly. In general, doses in the range of 0.5 to 5 mg intravenously

**Figure 32.9** Evaluation of delirium.

are used, with the frequency of administration depending on a variety of factors including the patient's age. An electrocardiogram should be obtained before administering haloperidol. If the QT interval is greater than 450, use of intravenous haloperidol can precipitate an abnormal cardiac rhythm known as **Torsades de pointes**. Lorazepam has also been proven effective in doses of 0.5 to 2 mg intravenously. Some authors have suggested that haloperidol and lorazepam act synergistically when given to the agitated delirious patient. If the delirium is secondary to drug or alcohol abuse, benzodiazepines or clonidine should be used.

**Table 32.11** Managing the Delirious Patient

Identify and correct the underlying cause.  
 Protect the patient from unintentional self-harm.  
 Stabilize the level of sensory input.  
 Reorient patient as often as possible.  
 Employ objects from the patient's home environment.  
 Provide supportive therapy (fever control, hydration).  
 Streamline medications.  
 Correct sleep deprivation.  
 Manage behavior with appropriate pharmacotherapy.  
 Address postdelirium guilt and shame for behavior that occurred during confusion.

For patients who are mildly agitated or amenable to taking medications by mouth, oral haloperidol or lorazepam is appropriate. Recent studies have advocated the use of newer atypical antipsychotics for management of behavior and psychotic features in delirium. Such agents as quetiapine, olanzapine, and risperdal and ziprasidone have been used successfully to treat delirium. Newer agents may have lower incidences of dystonias and dyskinesias, but still carry the risk of QT interval prolongation, particularly in patients with electrolyte abnormalities. Quetiapine and olanzapine are quite sedating, and occasionally a combination of bedtime olanzapine and "as needed" haloperidol is utilized. Olanzapine may raise blood glucose levels and precipitate weight gain, but is available as a Zydys preparation, which is absorbed through the oral mucosa and can therefore be given to patients who are unable to take medications by mouth. A parenteral form of ziprasidone is also available. Whatever antipsychotic is chosen, the patient should be carefully monitored for muscle rigidity, unexplained fever, tremor and other warning signs of neuroleptic side effects.

### Outcome of Delirium

After elimination of the cause of the delirium, the symptoms gradually recede within 3 to 7 days. Some symptoms in certain populations may take weeks to resolve. The age of the patient and the period of time during which the patient was delirious affect the symptom resolution time. In general, the patient has a spotty memory for events that occurred during delirium. These remem-

branches are reinforced by comments from the staff (“You’re not as confused today”), or the presence of a sitter, or use of wrist restraints. Patient should be reassured that they were not responsible for their behavior while delirious, and that no one hates or resents them for the behavior they may have exhibited. As mentioned earlier, delirious patients have an increased risk of mortality in the year following their first episode. Patients with underlying dementia show residual cognitive impairment after resolution of delirium, and it has been suggested that a delirium may merge into a dementia (Kaplan *et al.*, 1994).

## Amnestic Disorders

The amnestic disorders are characterized by a disturbance in memory related to the direct effects of a general medical condition or the persisting effects of a substance (American Psychiatric Association, 1994). The impairment should interfere with social and occupational functioning and represent a significant decline from the previous level of functioning. The amnestic disorders are differentiated on the basis of the etiology of the memory loss. These disorders should not be diagnosed if the memory deficit is a feature of a dissociative disorder, is associated with dementia, or occurs in the presence of clouded sensorium, as in delirium. Amnestic disorders are predominately comprised of those caused by a general medical condition or those whose etiology is substance-induced.

## Epidemiology

The exact prevalence and incidence of the amnestic disorders are unknown (Kaplan *et al.*, 1994). Memory disturbances related to specific conditions such as alcohol dependence and head trauma have been studied and these appear to be the two most common causes of amnestic disorders. Kaplan and coworkers (Torres *et al.*, 2001) reported that in the hospital setting the incidence of alcohol-induced amnestic disorders is decreasing while that of amnestic disorders, secondary to head trauma, is on the rise. This may be related to rigorous efforts by hospital personnel to decrease the incidence of iatrogenic amnestic disorder by giving thiamine before glucose is administered to a patient with chronic alcohol dependence and nutritional deficiencies.

## Etiology

Amnesia results from generally bilateral damage to the areas of the brain involved in memory. The areas and structures so involved include the dorsomedial and midline thalamic nuclei, such temporal lobe-associated structures as the hippocampus, amygdala and mamillary bodies. The left hemisphere may be more important than the right in the occurrence of memory disorders. Frontal lobe involvement may be responsible for such commonly seen symptoms as apathy and confabulation.

The specific causes of amnestic disorders include 1) systemic medical conditions such as thiamine deficiency; 2) brain conditions, including seizures, cerebral neoplasms, head injury, hypoxia, carbon monoxide poisoning, surgical ablation of temporal lobes, electroconvulsive therapy and multiple sclerosis; 3) altered blood flow in the vertebral vascular system, as in transient global amnesia; and 4) effects of a substance (drug or alcohol use and exposure to toxins).

Conditions that affect the temporal lobes such as herpes infection and Kluver–Bucy syndrome can produce amnesia. Among drugs that can cause amnestic disorders, triazolam has received the most attention, but all benzodiazepines can produce

## DSM-IV-TR Criteria 294.0

### Amnestic Disorder

- A. The development of memory impairment as manifested by impairment in the ability to learn new information or the inability to recall previously learned information.
- B. The memory disturbance causes significant impairment in social or occupational functioning and represents a significant decline from a previous level of functioning.
- C. The memory disturbance does not occur exclusively during the course of a delirium or a dementia.
- D. There is evidence from the history, physical examination, or laboratory findings that the disturbance is the direct physiological consequence of a **general medical condition** (including physical trauma).

Or

- D. D. There is evidence from the history, physical examination, or laboratory findings that the memory disturbance is etiologically related to the **persisting effects of substance use** (e.g., a drug of abuse, a medication).

*Specify if:*

**Transient:** if memory impairment lasts for 1 month or less

**Chronic:** if memory impairment lasts for more than 1 month

**Coding note:** Include the name of the general medical condition on Axis I, e.g., 294.0 amnestic disorder due to head trauma; also code the general medical condition on Axis III.

Or

Coding note:[specific substance]-induced persisting amnestic disorder:

(291.1 alcohol;292.83 sedative, hypnotic, or anxiolytic;292.83 [or unknown substance])

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

memory impairment, with the dose utilized being the determining factor (Kirk *et al.*, 1990) (Table 32.12).

## Clinical Features

Patients with amnestic disorder have impaired ability to learn new information (anterograde amnesia) or cannot remember material previously learned (retrograde amnesia). Memory for the event that produced the deficit (e.g., a head injury in a motor vehicle accident) may also be impaired.

Remote recall (tertiary memory) is generally good, so patients may be able to relate accurately incidents that occurred during childhood but not remember what they had for breakfast. As illustrated by such conditions as thiamine amnestic syndrome, immediate memory is often preserved. In some instances, disorientation to time and place may occur, but disorientation to person is unusual.

**Table 32.12 Causes of Amnesic Disorders**

Types simplex encephalopathy
Substance-induced (alcohol) blackouts
Wernicke–Korsakoff syndrome
Multiple sclerosis
Klüver–Bucy syndrome
Electroconvulsive therapy
Seizures
Head trauma
Carbon monoxide poisoning
Metabolic
Hypoxia
Hypoglycemia
Medications
Triazolam
Barbiturates (thiopental sodium)
Diltiazem (Cardizem)
Zalcitabine (DDC)
Cerebrovascular disorders

The onset of the amnesia is determined by the precipitant and may be acute as in head injury or insidious as in poor nutritional states. DSM-IV characterizes short-duration amnesic disorder as lasting less than 1 month and long-duration disorder lasting 1 month or longer. Often individuals lack insight into the memory deficit and vehemently insist that their inaccurate responses on a Mental Status Examination are correct.

## Selected Amnesic Disorders

### Blackouts

Blackouts are periods of amnesia for events that occur during heavy drinking (Tarter and Schneider, 1976). Typically, a person awakens the morning after consumption and does not remember what happened the night before. Unlike delirium tremens, which is related to chronicity of alcohol abuse, blackouts are more a measure of the amount of alcohol consumed at any one time. Thus, blackouts are common in binge pattern drinkers and may occur the first time a person ingests a large amount of alcohol. Blackouts are generally transient phenomena, but some patients may continue to have blackouts for weeks even after they have stopped using alcohol. These memory lapses are similar to blackouts experienced while using alcohol. With continued sobriety, the blackouts should end, but information forgotten during past blackouts is never remembered. Blackouts may also be produced by agents with cross-sensitivity to alcohol, such as benzodiazepines. Blackouts should not be confused with alcohol-induced dementia, which presents with cortical atrophy on CT scans, associated features of dementia and a usually irreversible course.

### Korsakoff's Syndrome

Korsakoff's syndrome is an amnesic disorder caused by thiamine deficiency. Although generally associated with alcohol abuse, it can occur in other malnourished states such as marasmus, gastric carcinoma and HIV spectrum disease (Reulen *et al.*, 1985; Victor, 1987). This syndrome is usually associated with Wernicke's encephalopathy, which involves ophthalmoplegia,

ataxia and confusion. Korsakoff's syndrome is often associated with a neuropathy and occurs in about 85% of untreated patients with Wernicke's disease (Kaplan *et al.*, 1994). Complete recovery from Korsakoff's syndrome is rare.

### Head Injury

Head injuries can produce a wide variety of neurological and psychiatric disorders, even in the absence of radiological evidence of structural damage. Delirium, dementia, mood disturbances, behavioral disinhibition, alterations of personality and amnesic disorders may result (Torres *et al.*, 2001). Amnesia in head injury is for events preceding the incident and the incident itself, leading some physicians to consider these patients as having factitious disorders or being malingerers. The eventual duration of the amnesia is related to the degree of memory recovery that occurs in the first few days after the injury. Amnesia after head injury has become a popular plot device in novels and motion pictures, many of which are depictions that erroneously suggest that a second blow to the head is curative.

### Differential Diagnosis

Amnesic disorders must be differentiated from the less disruptive changes in memory that occur in normal aging, the memory impairment that is accompanied by other cognitive deficits in dementia, the amnesia that might occur with clouded consciousness in delirium, the stress-induced impairment in recall seen in dissociative disorders, and the inconsistent amnesic deficits seen in factitious disorder and malingering.

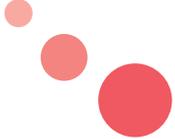

### Treatment

As in delirium and dementia, the primary goal in the amnesic disorders is to discover and treat the underlying cause. Because some of these causes of amnesic disorder are associated with dangerous self-damaging behavior (e.g., suicide attempts by hanging, carbon monoxide poisoning, deliberate motor vehicle accidents, self-inflicted gunshot wounds to the head and chronic alcohol abuse), some form of psychiatric involvement is often necessary. In the hospital, continuous reorientation by means of verbal redirection, clocks and calendars can allay the patient's fears. Supportive individual psychotherapy and family counseling are beneficial.

# Mental Disorders Due to a General Medical Condition

---

## Introduction

This chapter deals with disorders characterized by mental symptoms which occur due to the direct physiological effect of a general medical condition. In evaluating patients with mental symptoms of any sort, one of the first questions to ask is whether those symptoms are occurring as part of a primary psychiatric disorder or are caused by a general medical condition, and Figure 33.1 presents a decision tree designed to help in making this decision. The first step is to review the history, physical examination and laboratory tests to see if there is evidence for the presence of a general medical disorder that could plausibly cause the mental symptoms in question. In making this determination, one looks not only for a temporal correlation (e.g., the onset of a psychosis shortly after starting or increasing the dose of a medication), but also keeps in mind well-documented associations between certain mental symptoms (e.g., depression) and certain general medical conditions (e.g., Cushing's syndrome). If it appears, at this point, that the mental symptoms could indeed be occurring secondary to a general medical condition, the next step involves determining whether or not these symptoms could be better accounted for by a primary psychiatric disorder. For example, consider the case of a 45-year-old man with a history of recurrent major depression, currently euthymic, who begins a course of steroids for asthma and then, within a week, becomes depressed. The steroids are stopped but the depression continues. In this case, if the depression had cleared shortly after stopping the steroids, one might make the case that the depression occurred secondary to the steroid treatment; the persistence of the symptoms, however, argues strongly that this depression represents rather a recurrence of the major depression.

Once it appears that the mental symptoms in question could well directly result from a general medical condition and could not be better accounted for by a primary psychiatric disorder, then it remains to classify these symptoms into one of the specific types noted in Figure 33.1, and to proceed to the appropriate section below. There is also, at the end of the decision tree, a residual category for "unspecified" mental symptoms, and in this chapter two such syndromes, not uncommonly found in consult-liaison work, are included, namely pseudobulbar palsy and the Klüver–Bucy syndrome.

In caring for patients with mental disorders due to a general medical condition, the question arises as to whether or not symptomatic treatment for these mental symptoms should be offered. First, one must determine whether the mental symptoms demand emergent treatment. Consider, for example, a postictal psychosis characterized by delusions of persecution which prompt the patient

to become assaultive: here, even though the condition itself will eventually resolve spontaneously, symptomatic treatment of the psychosis is required to protect the patient or others. In cases where the mental symptoms do not present an emergency, one looks to whether the underlying general medical condition is treatable or not. For example, in the case of psychosis due to Huntington's disease, as the underlying condition is not treatable, one generally proceeds directly to symptomatic treatment. In cases where the underlying condition is treatable, then one must make a judgment as to whether, with treatment of the underlying general medical condition, the mental symptoms will resolve at a clinically acceptable rate. Consider, for example, a patient with anxiety due to hyperthyroidism who has just begun treatment with an antithyroid drug. In such a case, the decision as to whether to offer a benzodiazepine as symptomatic treatment for the anxiety depends not only on the severity and tolerability of the anxiety, but also on the expected time required for the antithyroid drug to resolve the hyperthyroidism: here, clearly, considerable clinical judgment is required.

## Psychotic Disorder Due to a General Medical Condition

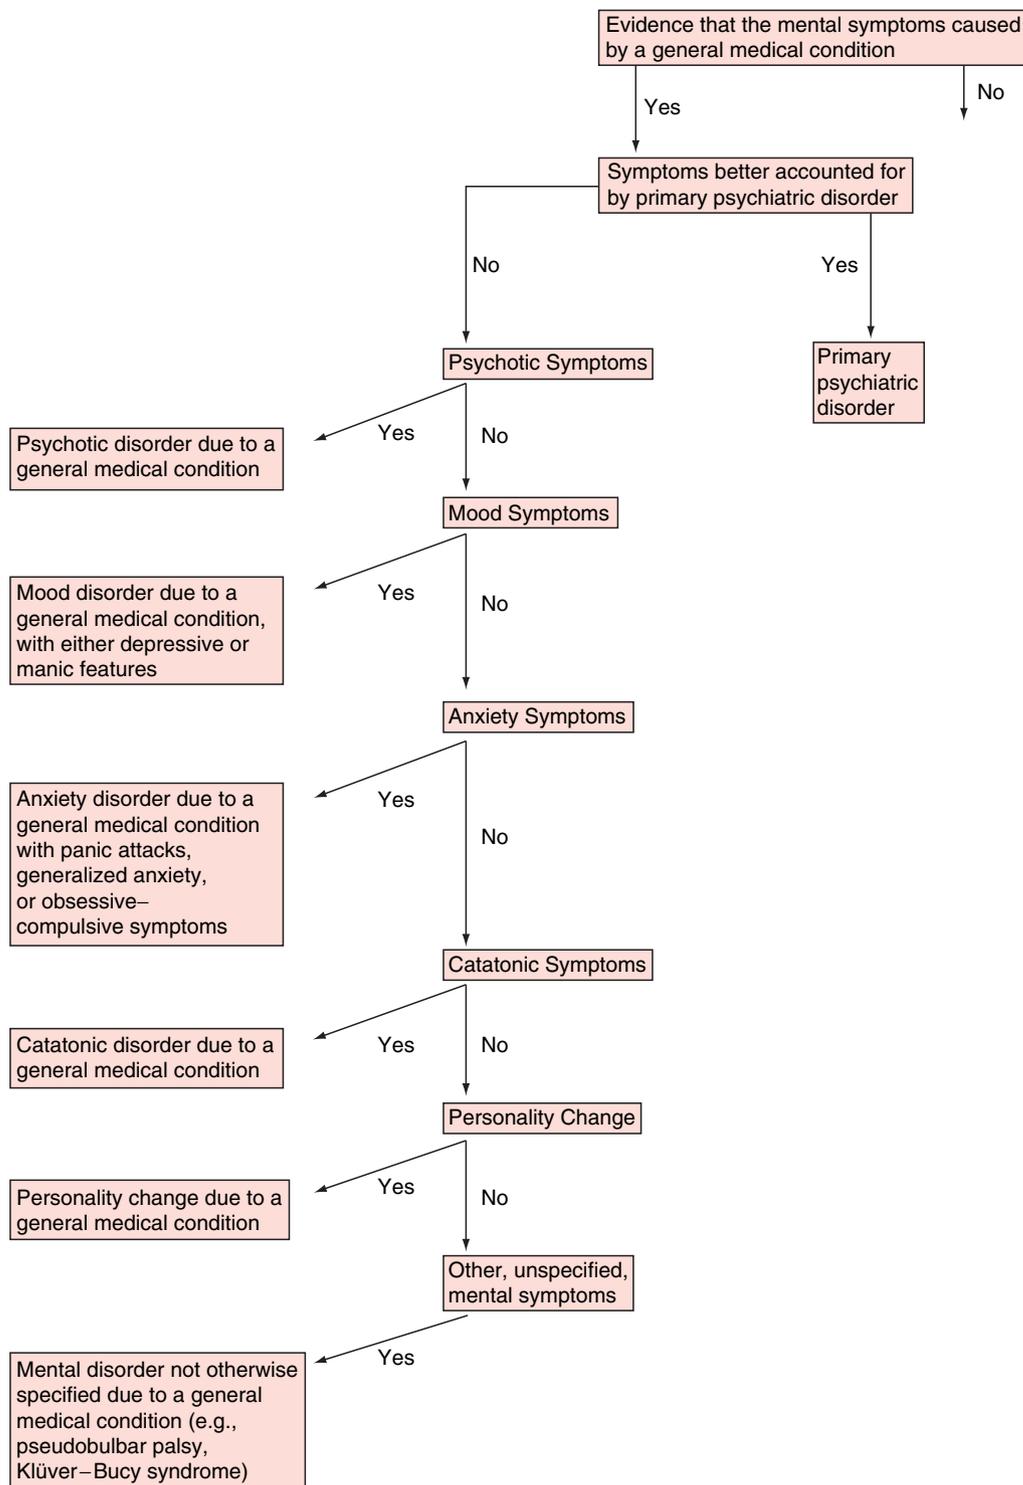

### Definition

A psychotic disorder due to a general medical condition is characterized clinically by hallucinations or delusions occurring in a clear sensorium, without any associated decrement in intellectual abilities. Furthermore, one must be able to demonstrate, by history, physical examination or laboratory findings, that the psychosis is occurring on the basis of a general medical disorder.

### Etiology and Pathophysiology

Of all the causes of psychosis, the most commonly encountered are three primary psychiatric disorders, namely, schizophrenia, schizoaffective disorder and delusional disorder, each of these being covered elsewhere in this text. Table 33.1 lists the various secondary causes of psychosis dividing them into those occurring **secondary to precipitants** (e.g., medications), those occurring **secondary to diseases with distinctive features** (e.g., the chorea of Huntington's disease) and finally a group occurring **secondary to miscellaneous causes** (e.g., cerebral tumors).

Psychosis occurring **secondary to precipitants** is perhaps the most common form of secondary psychosis. Among the various possible precipitants, substances, that is to say, drugs of abuse, are perhaps the most common, but these are treated in the

**Figure 33.1** *Diagnostic decision tree.*

chapters on stimulants, hallucinogens, phencyclidine, cannabis and alcohol. After drugs of abuse, various medications are the next most common precipitants, and of the medications listed in Table 33.1, the most problematic are the neuroleptics themselves. It appears that in a very small minority of patients treated chronically with neuroleptics, a “supersensitivity psychosis” (or, as it has also been called, on analogy with tardive dyskinesia, “tardive psychosis”) may occur. Making such a diagnosis in the case of

patients with schizophrenia may be difficult, as one may well say that any increase in psychotic symptoms, rather than evidence for a supersensitivity psychosis, may merely represent an exacerbation of the schizophrenia; in the case of patients treated with antipsychotics for other conditions (e.g. Tourette’s syndrome), however, the appearance of a psychosis is far more suggestive, as it could not be accounted for on the basis of the disease for which the neuroleptic was prescribed. Dopaminergic drugs capable

**Table 33.1 Causes of Psychosis Due to a General Medical Condition**

Secondary to Precipitants	
Medications	Creutzfeldt–Jakob disease (myoclonus)
Neuroleptics (supersensitivity psychosis)	Hashimoto's encephalopathy (myoclonus)
Dopaminergic drugs	Wilson's disease (various abnormal involuntary movements)
Disulfiram	AIDS (thrush, <i>Pneumocystis</i> pneumonia)
Sympathomimetics	Systemic lupus erythematosus (arthralgia, rash, pericarditis, pleurisy)
Bupropion	Hyperthyroidism (tremor, tachycardia)
Fluoxetine	Hypothyroidism (cold intolerance, voice change, constipation, hair loss, myxedema)
Baclofen (upon discontinuation)	Cushing's syndrome ("Cushingoid" habitus, e.g., "moon" facies)
Other precipitants	Adrenocortical insufficiency (abdominal complaints and dizziness)
Postencephalitic psychosis	Hepatic porphyria (abdominal pain)
Posthead trauma	Autosomal dominant cerebellar ataxia
	Dentatorubropallidolusian atrophy (ataxia)
	Prader–Willi syndrome (massive obesity)
Secondary to Diseases with Distinctive Features	
Associated with epilepsy	
Ictal psychosis	
Postictal psychosis	
Psychosis of forced normalization	
Chronic interictal psychosis	
Encephalitic onset	
Herpes simplex encephalitis	
Encephalitis lethargica	
Infectious mononucleosis	With other specific features:
With other specific features:	
Huntington's disease (chorea)	
Sydenham's chorea	
Chorea gravidarum	
Manganism (parkinsonism)	
	Secondary to Miscellaneous Causes
	Cerebral tumors
	Cerebral infarction
	Multiple sclerosis
	Neurosyphilis
	Vitamin B <sub>12</sub> deficiency
	Metachromatic leukodystrophy
	Subacute sclerosing panencephalitis
	Fahr's syndrome
	Thalamic degeneration
	Velo–cardio–facial syndrome

of causing a psychosis include levodopa itself, and such direct-acting dopamine agonists as bromocriptine and lergotriole. The other medications noted in Table 33.1 only very rarely cause a psychosis.

Of the various encephalitides which may have a psychosis as a sequela, the most classic is encephalitis lethargica (von Economo's disease), a disease which, though no longer occurring in epidemic form, may still be seen sporadically.

Of the psychoses **secondary to diseases with distinctive features**, the psychoses of epilepsy are by far the most important, and these may be ictal, postictal, or interictal. Ictal psychoses represent complex partial seizures and are immediately suggested by their exquisitely paroxysmal onset. Postictal psychoses are typically preceded by a "flurry" of grand mal or complex partial seizures and, importantly, are separated from the last of this "flurry" of seizures by a "lucid" interval lasting from hours to days. Interictal psychoses appear in one of two forms, namely, the psychosis of forced normalization and the chronic interictal psychosis. The psychosis of forced normalization appears when anticonvulsants have not only stopped seizures but have essentially "normalized" the EEG: a disappearance of the psychosis with the resumption of seizure activity secures the diagnosis. The chronic interictal psychosis, often characterized by delusions of persecution and reference and auditory hallucinations, appears subacutely, over weeks or months, in patients with longstanding, uncontrolled grand mal or complex partial seizures.

Encephalitic psychoses are suggested by such typical "encephalitic" features such as headache, lethargy and fever. Prompt

diagnosis is critical, especially in the case of herpes simplex encephalitis, given its treatability.

The other specific features listed in Table 33.1 are fairly straightforward. In the past, the differential between Huntington's disease and schizophrenia complicated by tardive dyskinesia was difficult; today, the availability of genetic testing has greatly simplified this diagnostic task.

Of the **miscellaneous causes** capable of causing psychosis, cerebral tumors are perhaps the most important, with psychosis being noted with tumors of the frontal lobe, corpus callosum and temporal lobe. Suggestive clinical evidence for such a cause includes prominent headache, seizures, or certain focal signs, such as aphasia. Cerebral infarction is likewise an important cause, and is suggested not only by accompanying focal signs, but also by its acute onset: infarction of the frontal lobe, temporo-parietal and thalamus have all been implicated. Neurosyphilis should never be forgotten as a differential possibility in cases of psychosis of obscure origin, and an FTA (Fluorescent Treponemal Antibody) is appropriate in such cases. Vitamin B<sub>12</sub> deficiency, likewise, should be borne in mind, especially as this may present with psychosis without any evidence of spinal cord or hematologic involvement. The remaining disorders listed in Table 33.1 are extremely rare causes of psychosis, and represent the "zebras" of this differential listing. Among these "zebras", however, one is of particular interest, namely velo–cardio–facial syndrome. This genetic disorder, characterized by cleft palate, cardiovascular malformations and dysmorphic facies (micrognathia and prominent nose), and, often, mental retardation, also appears, in

**DSM-IV-TR Criteria** 293.xx**Psychotic Disorder Due to... [Indicate the General Medical Condition]**

- A. Prominent hallucinations or delusions.
- B. There is evidence from the history, physical examination, or laboratory findings that the disturbance is the direct physiological consequence of a general medical condition.
- C. The disturbance is not better accounted for by another mental disorder.
- D. The disturbance does not occur exclusively during the course of a delirium.

Code based on predominant symptom:

**.81 With Delusions:** if delusions are the predominant symptom

**.82 With Hallucinations:** if hallucinations are the predominant symptom

**Coding note:** Include the name of the general medical condition on Axis I. e.g., 293.81 Psychotic Disorder Due to Malignant Lung Neoplasm. With Delusions: also code the general medical condition on Axis III (see Appendix G for codes).

**Coding note:** If delusions are part of a preexisting dementia, indicate the delusions by coding the appropriate subtype of the dementia if one is available e.g., 290.20 Dementia of the Alzheimer's Type. With Late Onset. With Delusions.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

a substantial minority of cases, to cause a psychosis phenotypically very similar to that caused by schizophrenia.

### Assessment and Differential Diagnosis

As noted earlier, psychotic disorder due to a general medical condition is a disorder which by definition occurs in a clear sensorium, without any associated decrement in intellectual abilities: both delirium and dementia are commonly accompanied by hallucinations and delusions, but these conditions are clearly distinguished from psychotic disorder due to a general medical condition by the presence of confusion or significant intellectual deficits. When these features are present, one should proceed to the differential for delirium and dementia described in Chapter 32 of this book (see DSM-IV criteria).

In most cases, a thorough history and physical examination will disclose evidence of the underlying cause of the psychosis in question. In those cases, however, where the patient's symptomatology is atypical for one of the primary causes of psychosis (e.g., schizophrenia), yet the history and physical examination fail to disclose clear evidence for another cause, a "laboratory screen," as listed in Table 33.2, may be appropriate. Clearly, one does not order all these tests at once, but begins with

**Table 33.2** A "Laboratory Screen" for Secondary Psychosis

Serum or urine drug screen
Testosterone level (reduced in anabolic steroid abusers)
Red blood cell mean corpuscular volume (elevated in alcoholism and many cases of B <sub>12</sub> deficiency)
Liver transaminases (elevated in alcoholism)
HIV testing
FTA
B <sub>12</sub> levels (or, for increased sensitivity, plasma methylmalonic acid and homocysteine levels)
ANA
Antithyroid antibodies (present in Hashimoto's encephalopathy)
Thyroid profile with TSH
Cortisol and ACTH levels and 24-hour urine for free cortisol
Copper and ceruloplasmin levels
MRI
EEG
Lumbar puncture

those most likely, given the overall clinical picture, to be most informative.

### Epidemiology and Comorbidity

The overwhelming majority of patients with a chronic psychosis have one of the primary disorders, that is, schizophrenia, schizoaffective disorder or delusional disorder: secondary causes of psychosis are relatively uncommon.

### Course

This is determined by the underlying cause. For example, whereas a psychosis occurring secondary to a medication, such as a dopaminergic drug, generally clears within days of discontinuation of the drug, the psychosis due to a chronic condition, such as Huntington's disease, is likewise chronic.

### Treatment

Treatment, if possible, is directed at the underlying cause. In those cases where such treatment is unavailable or ineffective, or where control of the psychosis is emergently required, neuroleptics are indicated. Although conventional neuroleptics, such as haloperidol, have long been used successfully, newer atypical agents, such as olanzapine or risperidone, may be better tolerated. In general, it is best to start with a low dose (e.g., 2.5 mg of haloperidol, 5 mg olanzapine or 1 mg of risperidone) with incremental increases, if necessary, performed slowly.

### Mood Disorder Due to a General Medical Condition

Mood disorders due to general medical conditions may occur either with depressive features or manic features, and each is covered in turn.

**Table 33.3** Causes of Depression Due to a General Medical Condition

Secondary to Precipitants	
Medications	Multiple sclerosis (various focal findings)
Propranolol	Down syndrome
Interferon	Epilepsy
ACTH	Ictal depression
Prednisone	Chronic interictal depression
Reserpine	Occurring as Part of Certain Neurodegenerative or Dementing Disorders
Alpha-methyl dopa	
Nifedipine	Alzheimer's disease
Ranitidine	Multi-infarct dementia
Bismuth subsalicylate	Diffuse Lewy body disease
Pimozide	Parkinson's disease
Subdermal estrogen/progestin	Fahr's syndrome
Anticholinergic withdrawal ("cholinergic rebound")	Tertiary neurosyphilis
Poststroke depression	Limbic encephalitis
Head trauma	
Whiplash	Miscellaneous or Rare Causes
Secondary to Diseases with Distinctive Features	Cerebral tumors
Hypothyroidism (hair loss, dry skin, voice change)	Hydrocephalus
Hyperthyroidism (weight loss with <b>increased</b> appetite, tachycardia, and, in the elderly, atrial fibrillation or congestive heart failure)	Pancreatic cancer
Cushing's syndrome (moon facies, hirsutism, acne, "buffalo hump", abdominal striae)	New-variant Creutzfeldt–Jakob disease
Chronic adrenocortical insufficiency (nausea, vomiting, abdominal pain, postural dizziness)	Hyperparathyroidism
Obstructive sleep apnea (severe snoring)	Systemic lupus erythematosus
	Pernicious anemia
	Pellagra
	Lead encephalopathy
	Hyperaldosteronism

## Mood disorder with Depressive Features

### Definition

A mood disorder secondary to a general medical condition with depressive features is characterized by a prominent and persistent depressed mood or loss of interest, and by the presence of evidence, from the history, physical examination or laboratory tests, of a general medical condition capable of causing such a disturbance. Although other depressive symptoms (e.g., lack of energy, sleep disturbance, appetite change or psychomotor change) may be present, they are not necessary for the diagnosis.

### Etiology and Pathophysiology

The overwhelming majority of cases of depression occur as part of one of the primary mood disorders, including major depressive disorder, dysthymic disorder, bipolar disorder, cyclothymic disorder, or premenstrual dysphoric disorder, all of which are covered elsewhere in this text. The various secondary causes of depression are listed in Table 33.3.

In utilizing Table 33.3, the first question to ask is whether the depression could be **secondary to precipitants**. Of the various possible precipitants, substances of abuse (e.g., as seen in alcoholism or during stimulant withdrawal) are very common causes, and these are treated in their respective chapters. Medications are particularly important, however it must be borne in mind that most patients are able to take the medications listed in Table 33.3 without untoward effect: consequently, before ascribing a depression to any medication it is critical to demonstrate

that the depression did not begin before the medication was begun and, ideally, to demonstrate that the depression resolved after the medication was discontinued. Anticholinergic withdrawal may occur within days after abrupt discontinuation of highly anticholinergic medications, such as benzotropine or certain tricyclic antidepressants, and is characterized by depressed mood, malaise, insomnia and gastrointestinal symptoms such as nausea, vomiting, abdominal cramping and diarrhea. Poststroke depression is not uncommon, and may be more likely when the anterior portion of the left frontal lobe is involved; although spontaneous remission within a year is the rule, depressive symptoms, in the meantime, may be quite severe. Both head trauma and whiplash injuries may be followed by depressive symptoms in close to half of all cases.

Depression may occur **secondary to diseases with distinctive features**, and keeping such features in mind whenever evaluating depressed patients will lead to a gratifying number of diagnostic "pick-ups". These features are noted in Table 33.3, and are for the most part self-explanatory; depression associated with epilepsy, however, may merit some further discussion. Ictal depressions are, in fact, simple partial seizures whose symptomatology is for the most part restricted to affective changes. The diagnosis of ictal depression is suggested by the paroxysmal onset of depression (literally over seconds): although such simple partial seizures may last only minutes, longer durations, up to months, have also been reported. Interictal depressions, rather than occurring secondary to paroxysmal electrical activity within the brain, occur as a result of long-lasting changes in neuronal

**DSM-IV-TR Criteria 293.83****Mood Disorder Due to ... [Indicate the General Medical Condition]**

- A. A prominent and persistent disturbance in mood predominates in the clinical picture, and is characterized by either (or both) of the following:
- (1) depressed mood or markedly diminished interest or pleasure in all, or almost all, activities.
  - (2) elevated, expansive, or irritable mood.
- B. There is evidence from the history, physical examination, or laboratory findings that the disturbance is the direct physiological consequence of a general medical condition.
- C. The disturbance is not better accounted for by another mental disorder (e.g., Adjustment Disorder With Depressed Mood in response to the stress of having a general medical condition).
- D. The disturbance does not occur exclusively during the course of a delirium.
- E. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Specify type:

**With Depressive Features:** if the predominant mood is depressed but the full criteria are not met for a Major Depressive Episode

**With Major Depressive-Like Episode:** if the full criteria are met (except Criterion D) for a Major Depressive Episode (see p. 327)

**With Manic Features:** if the predominant mood is elevated, euphoric, or irritable

**With Mixed Features:** if the symptoms of both mania and depression are present but neither predominates

**Coding note:** Include the name of the general medical condition on Axis I. e.g., 293.83 Mood Disorder Due to Hypothyroidism. With Depressive Features: also code the general medical condition on Axis III (see Appendix G for codes).

**Coding note:** If depressive symptoms occur as part of a preexisting dementia, indicate the depressive symptoms by coding the appropriate subtype of the dementia if one is available, e.g., 290.21 Dementia of the Alzheimer's Type. With Late Onset. With Depressed Mood.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

activity, perhaps related to “kindling” within the limbic system, in patients with chronically recurrent seizures, either grand mal or, more especially, complex partial (Indaco *et al.*, 1992; Perini *et al.*, 1996). Such interictal depressions are of gradual onset and are chronic.

Depression occurring as part of certain neurodegenerative or dementing disorders is immediately suggested by the presence of other symptoms of these disorders, such as dementia or distinctive physical findings, for example, parkinsonism.

The **miscellaneous or rare causes** represent, for the most part, the “zebras” in the differential for depression, and should be considered when, despite a thorough investigation, the diagnosis of a particular case of depression remains unclear.

### Assessment and Differential Diagnosis

Although the foregoing list of possible causes of depression due to a general medical condition is long, utilizing it in the clinical evaluation of depressed patients need not be burdensome. Evidence for most of the **precipitants, diseases with distinctive features and neurodegenerative or dementing disorders** will be uncovered in the course of a standard interview and examination and, after using the list a few times, the physician will immediately recognize their diagnostic relevance. The **miscellaneous or rare** “zebras,” as with zebras in any other branch of medicine, are only considered when one is at the end of one's diagnostic rope, a situation often reached when patients fail to respond to treatment which, if the diagnosis were correct, should have led to relief, but did not.

### Epidemiology and Comorbidity

Depression is the most common of psychiatric symptoms and although, as noted earlier, the vast majority of cases of depression occur as part of one of the primary depressive disorders (most commonly major depressive disorder), depressions due to a general medical condition, in certain settings, should nevertheless, by virtue of their frequency, receive prime diagnostic consideration. Examples include treatment with ACTH or prednisone as in multiple sclerosis or collagen-vascular diseases and cases of cerebral infarction involving the left frontal area.

### Course

Most medication-induced depressions begin to clear within days of discontinuation of the offending medication; depression as part of withdrawal from stimulants or anabolic steroids clears within days or weeks, and from anticholinergics, within days. Post-stroke depression, as noted above, typically remits within a year. The course of depression secondary to head trauma or whiplash is generally prolonged, though quite variable. Most of the other conditions or disorders in the list are chronic, and depression occurring secondary to them likewise tends to be chronic: exceptions include depression in multiple sclerosis, which may have a relapsing and remitting course, corresponding to the appearance and disappearance of appropriately situated plaques.

### Treatment

Treatment efforts should be directed at relieving, if possible, the underlying cause. When this is not possible, antidepressants should be considered. Controlled studies have demonstrated the effectiveness of both nortriptyline (Robinson *et al.*, 2000) and citalopram (Anderson *et al.*, 1994) for poststroke depression, and nortriptyline for depression seen in Parkinson's disease (Anderson *et al.*, 1980). For other secondary depressions, citalopram is probably a good choice, given its benign side-effect profile and notable lack of drug-drug interactions; nortriptyline should be used with caution in patients with cardiac conduction defects (as it may prolong conduction time) and in those at risk for seizures as in head trauma as this agent may also lower the seizure threshold.

**Table 33.4** Causes of Mania Due to a General Medical Condition

Secondary to Precipitants	
Medications	Multiple sclerosis (various focal findings)
Corticosteroids or adrenocorticotrophic hormone	Cerebral infarction (sudden onset with associated localizing signs)
Levodopa	Sydenham's chorea
Zidovudine	Chorea gravidarum
Oral contraceptives	Hepatic encephalopathy (asterixis, delirium)
Isoniazid	Uremia (asterixis, delirium)
Buspirone	Epilepsy
Procyclidine	Ictal mania
Procarbazine	Postictal mania
Propofeone	
Baclofen, upon discontinuation after long-term use	Occurring as Part of Certain Neurodegenerative or Dementing Diseases
Reserpine upon discontinuation after long-term use	Alzheimer's disease
Methylodopa upon discontinuation after long-term use	Neurosyphilis
Closed head injury	Huntington's disease
Hemodialysis	Creutzfeldt–Jakob disease
Encephalitis	
Aspartame	Miscellaneous or Rare Causes
Metrizamide	Cerebral tumors
	Systemic lupus erythematosus
Secondary to Diseases with Distinctive Features	Vitamin B <sub>12</sub> deficiency
Hyperthyroidism (proptosis, tremor, tachycardia)	Metachromatic leukodystrophy
Cushing's syndrome (moon facies, hirsutism, acne, "buffalo hump", abdominal striae)	Adrenoleukodystrophy
	Tuberous sclerosis

## Mood Disorder with Manic Features

### Definition

Mood disorder due to a general medical condition with manic features is characterized by a prominent and persistently elevated, expansive or irritable mood which, on the basis of the history, physical or laboratory examinations can be attributed to an underlying general medical condition. Other manic symptoms, such as increased energy, decreased need for sleep, hyperactivity, distractibility, pressured speech and flight of ideas, may or may not be present.

### Etiology and Pathophysiology

The vast majority of cases of sustained, elevated or irritable mood occur as part of four primary disorders, namely bipolar I disorder, bipolar II disorder, cyclothymic disorder and schizoaffective disorder (bipolar type). Cases of elevated or irritable mood secondary to other causes (e.g., secondary to treatment with corticosteroids) are much less common. Table 33.4 lists secondary causes of elevated or irritable mood, with these causes divided into categories designed to facilitate the task of differential diagnosis.

In utilizing Table 33.4, the first step is to determine whether the mania could be **secondary to precipitants**. Substance-induced mood disorder related to drugs of abuse is covered in the relevant substance-related disorders chapters in this textbook. Of the precipitating factors listed in Table 33.4, medications are the most common offenders. Before, however, attributing the mania to one of these medications, it is critical to demonstrate that the mania occurred only after initiation of that medication; ideally, one would also want to show that the

mania spontaneously resolved subsequent to the medication's discontinuation. Of the medications listed, corticosteroids, such as prednisone, are likely to cause mania, with the likelihood increasing in direct proportion to dose: in one study (Wolkowitz *et al.*, 1990), 80 mg of prednisone produced mania within five days in 75% of subjects. Levodopa is the next most likely cause, and in the case of levodopa the induced mania may be so pleasurable that some patients have ended up abusing the drug (Giovannoni *et al.*, 2000). Anabolic steroid abuse may cause an irritable mania, and such a syndrome occurring in a "bulked up" patients should prompt a search for other clinical evidence of abuse, such as gynecomastia and testicular atrophy. Closed head injury may be followed by mania either directly upon emergence from postcoma delirium, or after an interval of months. Hemodialysis may cause mania, and in one case (Jack *et al.*, 1983) mania occurred as the presenting sign of an eventual dialysis dementia. Encephalitis may cause mania, as, for example, in postinfectious encephalomyelitis, with the correct diagnosis eventually being suggested by more typical signs such as delirium or seizures. Encephalitis lethargica (Von Economo's disease; European Sleeping Sickness) may also be at fault, with the diagnosis suggested by classic signs such as sleep reversal or oculomotor paralyses.

Mania occurring **secondary to disease with distinctive features** is immediately suggested by these features, as listed in Table 33.4. Some elaboration may be in order regarding mania secondary to cerebral infarction. This cause, of course, is suggested by the sudden onset of the clinical disturbance, with the mania being accompanied by various other more or less localizing signs: what is most remarkable here is the variety of structures which, if infarcted, may be followed by mania.

Thus, mania has been noted with infarction of the midbrain, thalamus (either on the right side or bilaterally, anterior limb of the internal capsule and adjacent caudate on the right, and subcortical white matter or cortical infarction on the right in the frontoparietal or temporal areas. Mania associated with epilepsy may also deserve additional comment. Ictal mania is characterized by its paroxysmal onset, over seconds and the diagnosis of postictal mania is suggested when mania occurs shortly after a “flurry” of grand mal or complex partial seizures.

Mania occurring as part of certain neurodegenerative or dementing diseases is suggested, in general, by a concurrent dementia, and in most cases the mania plays only a minor role in the overall clinical pictures. Neurosyphilis, however, is an exception to this rule, for in patients with general paresis of the insane (dementia paralytica) mania may dominate the picture.

Of the miscellaneous or rare causes of mania, cerebral tumors are the most important to keep in mind, with mania being noted with tumors of the midbrain, tumors compressing the hypothalamus, e.g., a craniopharyngioma or a pituitary adenoma, and tumors of the right thalamus, right cingulate gyrus or one or both frontal lobes.

### Assessment and Differential Diagnosis

In most cases of mania secondary to precipitants, the cause (e.g., treatment with high dose prednisone) is fairly straightforward; in cases secondary to diseases with distinctive features or occurring as part of certain neurodegenerative or dementing diseases, the cause is generally readily discernible if the clinician is alert to the telltale distinctive features (e.g., a Cushingoid habitus) and to the presence of dementia indicating one of the dementing disorders listed in Table 33.4. The miscellaneous or rare causes represent the “zebras” in the differential of secondary mania, and are generally only resorted to when other investigations prove unrewarding.

As a rule, it is very rare for mania to constitute the initial presentation of any of the disease or disorders listed in Table 33.4; thus, other evidence of their presence will become evident during the routine history and physical examination. Exceptions to the rule include neurosyphilis, vitamin B<sub>12</sub> deficiency and Creutzfeldt–Jakob disease, however in all these cases continued observation will eventually disclose the appearance of other evidence suggestive of the correct diagnosis.

It must always be kept in mind that certain medications (e.g., antidepressants) may precipitate mania in patients with bipolar disorder: in such cases, history will reveal earlier episodes of either depression, or mania, or both and such cases of mania should not be considered secondary.

### Epidemiology and comorbidity

Relative to cases of primary mania (e.g., bipolar disorder), secondary mania is relatively rare. In certain settings, however, secondary mania may be so common as to merit a “top” position on the differential diagnosis; a prime example would be when prednisone is used in high doses, as in the treatment of multiple sclerosis or rheumatoid arthritis.

### Course

Most cases of medication-induced mania begin to clear in a matter of days; for other causes, the course of the mania generally reflects the course of the underlying disease.

### Treatment

Treatment, if possible, is directed at the underlying cause. In cases where such etiologic treatment is not possible, or not rapidly effective enough, pharmacologic measures are in order. Mood stabilizers, such as lithium or divalproex used in a fashion similar to that for the treatment of mania occurring in bipolar disorder, are commonly used: both lithium and divalproex are effective in the prophylaxis of mania occurring secondary to prednisone; case reports also support the use of lithium for mania secondary to zidovudine and divalproex for mania secondary to closed head injury. As between lithium and divalproex, in cases where there is a risk for seizures (e.g., head injury, encephalitis, stroke or tumors), divalproex clearly is preferable.

### Clinical Vignette 1

Liebson (2000) reported the case of a 53-year-old man with a right thalamic hemorrhage, who presented with headache and left-sided hemiparesis and hemianesthesia. Four days later he displayed significant anosognosia for his hemiparesis; more remarkable, however, was the change in his mood. One week after the stroke his “mood was remarkably cheerful and optimistic... he was noted to praise extravagantly the hospital food, and the nurses found him ‘talkative’. When he arrived on our ward 11 days after the stroke he was flirtatious with female staff and boasted of having fathered 64 children. His girlfriend was surprised when he kissed her in front of the staff because he had never publicly displayed affection before. He reported excellent energy and expansively invited all the staff to his home for Thanksgiving... The mania resolved gradually over a 10-week period after (the) stroke”.

In cases where emergent treatment is required, before lithium or divalproex could have a chance to become effective, oral or intramuscular lorazepam or haloperidol (in doses of 2 mg and 5 mg, respectively) may be utilized, again much as in the treatment of mania in bipolar disorder.

### Anxiety Disorder Due to a General Medical Condition with Panic Attacks or with Generalized Anxiety

#### Definition

Pathologic anxiety secondary to a general medical condition may occur in the form of well-circumscribed and transient panic attacks or in a generalized, more chronic form. As the differential diagnoses for these two forms of anxiety are quite different, it is critical clearly to distinguish between them.

Panic attacks have an acute or paroxysmal onset, and are characterized by typically intense anxiety or fear which is accompanied by various “autonomic” signs and symptoms, such as tremor, diaphoresis and palpitations. Symptoms rapidly crescendo over seconds or minutes and in most cases the attack will clear within anywhere from minutes up to a half-hour. Although attacks tend to be similar one to another in the same patient, there is substantial interpatient variability in the symptoms seen.

Generalized anxiety tends to be of subacute or gradual onset, and may last for long periods of time, anywhere from days to

**Table 33.5** Causes of Panic Attacks Due to a General Medical Condition

Partial seizures  
 Paroxysmal atrial tachycardia  
 Hypoglycemia  
 Angina or acute myocardial infarction  
 Pulmonary embolus  
 Acute asthmatic attack  
 Pheochromocytoma  
 Parkinson's disease

months, depending on the underlying cause. Here, some patients, rather than complaining of feeling anxious *per se*, may complain of being worried, tense or ill at ease. Autonomic symptoms tend not to be as severe or prominent as those seen in panic attacks: shakiness, palpitations (or tachycardia) and diaphoresis are perhaps most common.

### Etiology and Pathophysiology

Panic attacks are most commonly seen in one of the primary anxiety disorders, namely, panic disorder, agoraphobia, specific phobia, social phobia, obsessive–compulsive disorder or post traumatic stress disorder, all of which are covered elsewhere in this book. The causes of secondary panic attacks are listed in Table 33.5. Substance-induced anxiety disorder related to drugs of abuse (e.g., cannabis, LSD) is covered in the relevant substance-related disorders chapters in this textbook. Partial seizures and paroxysmal atrial tachycardia are both characterized by their exquisitely paroxysmal onset, over a second or two; in addition, paroxysmal atrial tachycardia is distinguished by the prominence of the tachycardia and by an ability, in many cases, to terminate the attack with a Valsalva maneuver. Hypoglycemia is often suspected as a cause of anxiety, but before the diagnosis is accepted, one must demonstrate the presence of “Whipple’s triad”: hypoglycemia (blood glucose  $\leq 45$  mg/dL), typical symptoms, and the relief of those symptoms with glucose. Angina or acute myocardial infarction can present with a panic attack, with the diagnosis being suggested by the clinical setting, for example, multiple cardiac risk factors. A pulmonary embolus, at the moment of its lodgment in a pulmonary artery, may also present with a panic attack, and again here the correct diagnosis is suggested by the clinical setting, for example, situations, such as prolonged immobilization, which favor deep venous thrombosis. Acute asthmatic attacks are suggested by wheezing, and pheochromocytoma by associated hypertension. Parkinson’s disease patients treated with levodopa may experience panic attacks during “off” periods.

Generalized anxiety is most commonly seen in the primary psychiatric disorder, generalized anxiety disorder, and is discussed elsewhere in this book. The secondary causes of generalized anxiety are listed in Table 33.6. Sympathomimetics and theophylline, as used in asthma and COPD, are frequent causes, as are many of the antidepressants. Hyperthyroidism is suggested by heat intolerance and proptosis, and Cushing’s syndrome by the typical Cushingoid habitus (i.e., moon facies, hirsutism, acne, “buffalo hump” and abdominal striae). Hypocalcemia may be suggested by a history of seizures or tetany. Both chronic obstructive pulmonary disease and congestive heart failure are suggested by marked dyspnea. Stroke and severe head trauma may be followed by chronic anxiety, but this is seen in only a minority of these patients.

### DSM-IV-TR Criteria 293.89

#### Anxiety Disorder Due to ... [Indicate the General Medical Condition]

- A. Prominent anxiety, Panic Attacks, or obsessions or compulsions predominate in the clinical picture.
- B. There is evidence from the history, physical examination, or laboratory findings that the disturbance is the direct physiological consequence of a general medical condition.
- C. The disturbance is not better accounted for by another mental disorder (e.g., Adjustment Disorder With Anxiety in which the stressor is a serious general medical condition).
- D. The disturbance does not occur exclusively during the course of a delirium.
- E. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

*Specify if:*

**With Generalized Anxiety:** if excessive anxiety or worry about a number of events or activities predominates in the clinical presentation

**With Panic Attacks:** if Panic Attacks (see p. 395) predominate in the clinical presentation

**With Obsessive–Compulsive Symptoms:** if obsessions or compulsions predominate in the clinical presentation

**Coding note:** Include the name of the general medical condition on Axis I, e.g., 293.89 Anxiety Disorder Due to Pheochromocytoma. With Generalized Anxiety; also code the general medical condition on Axis III (see Appendix G for codes).

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

### Assessment and Differential Diagnosis

Should one be fortunate enough to observe a patient during the panic attack, it is critical, in addition to carefully noting the specific symptoms of the attack, to obtain vital signs, auscultate the

**Table 33.6** Causes of Generalized Anxiety Due to a General Medical Condition

Sympathomimetics  
 Theophylline  
 Various antidepressants (tricyclics, SSRIs, etc.)  
 Hyperthyroidism  
 Cushing’s syndrome  
 Hypocalcemia  
 Chronic obstructive pulmonary disease  
 Congestive heart failure  
 Poststroke  
 Posthead trauma

heart and lungs, perform an EKG, and obtain blood for glucose and toxicology.

In evaluating a patient who complains of chronic anxiety, it is important, before deciding that this is, indeed, a case of pathologic generalized anxiety, first to determine whether or not the patient has a depression, whether it be primary or secondary: depression is often accompanied by anxiety, and such anxiety clears upon adequate treatment of the depression. Assuming that the patient, however, is not depressed, a work-up should include the following: auscultation of the heart and lungs; CBC and liver enzymes (looking for the telltale “alcoholic” combination of an elevated mean corpuscular volume and elevated transaminases); thyroid profile; cortisol level and calcium level.

### Epidemiology and Comorbidity

Although epidemiologic studies are lacking, the clinical impression is that anxiety secondary to a general medical condition is common.

### Course

This is determined by the underlying cause.

### Treatment

Treatment is directed at the underlying cause, and this is sufficient for all cases of secondary panic attacks and most cases of secondary generalized anxiety: exceptions include poststroke and posthead trauma anxiety, and in these cases benzodiazepines have been used with success.

## Mood Disorder with Obsessive–Compulsive Symptoms

### Definition

Obsessions consist of unwanted, and generally anxiety-provoking, thoughts, images or ideas which repeatedly come to mind despite patients’ attempts to stop them. Allied to this are compulsions, which consist of anxious urges to do or undo things, urges which, if resisted, are followed by rapidly increasing anxiety which can often only be relieved by giving into the compulsion to act. The acts themselves which the patients feel compelled to perform are often linked to an apprehension on the patients’ part that they have done something that they ought not to have done or have left undone something which they ought to have done. Thus, one may feel compelled repeatedly to subject the hands to washing to be sure that all germs have been removed, or repeatedly to go back and check on the gas to be sure that it had been turned off.

### Etiology and Pathophysiology

In the vast majority of cases, obsessions and compulsions occur as part of certain primary psychiatric disorders, including obsessive–compulsive disorder, depression, schizophrenia and Tourette’s syndrome. Those rare instances where obsessions and compulsions are secondary to a general medical condition or medication are listed in Table 33.7.

In most cases, these causes of secondary obsessions or compulsions are readily discerned, as for example, a history of encephalitis, anoxia, closed head injury or treatment with clozapine. Sydenham’s chorea is immediately suggested by the appearance of chorea, however, it must be borne in mind that obsessions and compulsions may constitute the presentation of Sydenham’s chorea, with the appearance of chorea being delayed for days

**Table 33.7 Causes of Obsessions and Compulsions Due to a General Medical Condition**

Postencephalitic
Postanoxic
Postclosed head injury
Clozapine
Sydenham’s chorea
Huntington’s disease
Simple partial seizures
Infarction of the basal ganglia or right parietal lobe
Fahr’s syndrome

(Swedo *et al.*, 1989). Ictal obsessions or compulsions, constituting the sole clinical manifestation of a simple partial seizure, may, in themselves, be indistinguishable from the obsessions and compulsions seen in obsessive–compulsive disorder, but are suggested by a history of other seizure types, for example, complex partial or grand mal seizures. Infarction of the basal ganglia or parietal lobe is suggested by the subacute onset of obsessions or compulsions accompanied by “neighborhood” symptoms such as abnormal movements or unilateral sensory changes. Fahr’s syndrome, unlike the foregoing, may be an elusive diagnosis, only suggested perhaps when CT imaging incidentally reveals calcification of the basal ganglia.

### Assessment and Differential Diagnosis

Most causes of secondary obsessions and compulsions are picked up on the routine history and physical examination, with the possible exception of ictal cases, and here it is critical to make a close inquiry as to a history of other seizure types: ictal EEGs are not reliable here, as they are often normal in the case of simple partial seizures. In doubtful cases a “diagnosis by treatment response” to a trial of an anticonvulsant may be appropriate.

### Epidemiology and Comorbidity

As noted earlier, secondary obsessions and compulsions are relatively rare.

### Course

Although the course of obsessions and compulsions due to fixed lesions, such as those seen with head trauma or cerebral infarction tends to be chronic, some spontaneous recovery may be anticipated over the following months to a year.

### Treatment

When treatment of the underlying cause is not possible, a trial of an SSRI, as used for obsessive–compulsive disorder, might be appropriate.

## Mental Conditions Due to a General Medical Disorder not Elsewhere Classified

### Catatonic Disorder Due to a General Medical Condition

#### Definition

Catatonias exist in two subtypes, namely, stuporous catatonia (also known as the akinetic or “retarded” subtype) and excited catatonia, and each will be described in turn.

Stuporous catatonia is characterized by varying combinations of mutism, immobility and waxy flexibility; associated features include posturing, negativism, automatic obedience and “echo” phenomena. Mutism ranges from complete to partial: some patients may mumble or perhaps utter brief, often incomprehensible, phrases. Immobility, likewise, ranges in severity: some patients may lie in bed for long periods, neither moving, blinking or even swallowing; others may make brief movements, perhaps to pull at a piece of clothing or to assume a different posture. Waxy flexibility, also known by its Latin name, *cerea flexibilitas*, is characterized by a more or less severe “lead pipe” rigidity combined with a remarkable tendency for the limbs to stay in whatever position they are placed, regardless of whether the patient is asked to maintain that position or not. Posturing is said to occur when patients spontaneously assume more or less bizarre postures, which are then maintained: one patient crouched low with his arm wrapped over his head, another stood with one arm raised high and the other stuffed inside his belt. Negativism entails a mulish, intractable and automatic resistance to whatever is expected, and may be either “passive” or “active”. Passively negativistic patients simply fail to do what is asked or expected: if clothes are laid out they will not dress; if asked to eat or take pills, their lips remain frozen shut. Active negativism manifests in doing the opposite of what is expected: if asked to come into the office, the patient may back into the hallway or if asked to open the eyes wide to allow for easier examination, they may cramp the eyes closed. Automatic obedience, as may be suspected, represents the opposite of negativism, with affected patients doing exactly what they are told, even should it place them in danger. Echo phenomena represent a kind of automatic obedience: in echolalia patients simply repeat what they hear and in echopraxia they mimic the gestures and activity of the examiner.

### DSM-IV-TR Criteria 293.89

#### Catatonic Disorder Due to... [Indicate the General Medical Condition]

- A. The presence of catatonia as manifested by motoric immobility, excessive motor activity (that is apparently purposeless and not influenced by external stimuli), extreme negativism or mutism, peculiarities of voluntary movement, or echolalia or echopraxia.
- B. There is evidence from the history, physical examination, or laboratory findings that the disturbance is the direct physiological consequence of a general medical condition.
- C. The disturbance is not better accounted for by another mental disorder (e.g., a Manic Episode).
- D. The disturbance does not occur exclusively during the course of a delirium.

**Coding note:** Include the name of the general medical condition on Axis I. e.g., 293.89 Catatonic Disorder Due to Hepatic Encephalopathy; also code the general medical condition on Axis III (see Appendix G for codes).

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

It should be noted that in negativism, automatic obedience and echo phenomena there is nothing natural or fluid about the patient’s behavior. To the contrary, movements are often awkward, wooden and tinged with the bizarre.

Excited catatonia manifests with varying degrees of bizarre, frenzied and purposeless behavior. Such patients typically keep to themselves: one marched in place, all the while chanting and gesticulating; another tore at his hair and clothing, broke plates in a corner then crawled under the bed where he muttered and thrashed his arms.

### Etiology and Pathophysiology

Stuporous catatonia, in the majority of cases, occurs as part of such primary psychiatric disorders as schizophrenia or a depressive episode of either major depression or bipolar disorder, and these are discussed elsewhere in this text. The causes of catatonia due to a general medical condition or medications are listed in Table 33.8.

Stuporous catatonia occurring in association with epilepsy is often suggested by a history of grand mal or complex partial seizures. Ictal catatonia is further suggested by its exquisitely paroxysmal onset, and postictal catatonia by an immediately preceding “flurry” of grand mal or complex partial seizures. Psychosis of forced normalization is an interictal condition distinguished by the appearance of symptoms subsequent to effective control of seizures. The chronic interictal psychosis is also, as suggested by the name, an interictal condition which, however, appears not after seizures are controlled but rather in the setting of ongoing, chronic uncontrolled epilepsy. Of medications capable of causing catatonia, neuroleptics are by far the most common. Viral

**Table 33.8** Causes of Catatonia Due to a General Medical Condition

Stuporous Catatonia
Associated with epilepsy
Ictal catatonia
Postictal catatonia
Psychosis of forced normalization
Chronic interictal psychosis
Medication
Neuroleptics
Disulfiram
Benzodiazepine withdrawal
Viral encephalitis
Herpes simplex encephalitis
Encephalitis lethargica
Focal lesions, especially of the frontal lobes
Focal lesions, especially of the frontal lobes
Miscellaneous conditions
Hepatic encephalopathy
Limbic encephalitis
Systemic lupus erythematosus
Lyme disease, in stage III
Subacute sclerosing panencephalitis, in stage I
Tay–Sachs disease
Thrombotic thrombocytopenic purpura
Excited Catatonia
Viral encephalitis

encephalitis is suggested by concurrent fever and headache: herpes simplex encephalitis should always be considered in such cases, given its treatability; further it must be kept in mind that although encephalitis lethargica no longer occurs in epidemics, sporadic cases do still occur. Focal lesions capable of causing catatonia are typically found in the medial or inferior portions of the frontal lobes. The miscellaneous conditions listed are all quite rare causes of catatonia.

Excited catatonia, in the vast majority of cases, is caused by either schizophrenia or bipolar disorder (during a manic episode): only rarely is it seen due to a general medical condition, as for example, a viral encephalitis.

### Assessment and Differential Diagnosis

Stuporous catatonia must be distinguished from akinetic mutism and from stupor of other causes. Akinetic mutes appear quite similar to immobile and mute catatonics: akinetic mutes, however, lack such signs as waxy flexibility, posturing and negativism, all of which are typically seen in catatonia. Stupor of other causes is readily distinguished from catatonic stupor by the salient fact that catatonics remain alert, in stark contrast with the somnolence or decreased level of consciousness seen in all other forms of stupor.

Excited catatonia must be distinguished from mania. Mania is typified by hyperactivity, which at times may be quite frenzied: the difference with catatonia is that patients with mania want to be involved, whereas those with catatonia keep to themselves; as Kraepelin (Bear *et al.*, 1982) noted, in catatonia “the excitement, even when extremely violent, frequently takes place within the *smallest space*.... The patients have not as a rule any tendency to influence their surroundings, but their restlessness exhausts itself in wholly aimless activity...”.

### Epidemiology and Comorbidity

Stuporous catatonia due to a general medical condition overall is, in general, a rare condition.

### Course

This is determined by the course of the underlying cause.

### Treatment

In addition to treating, if possible, the underlying cause, catatonia may be symptomatically relieved by lorazepam given parenterally in a dose of 2 mg; in severe cases wherein lorazepam is not sufficiently effective and the patient is at immediate risk, consideration should be given to emergency ECT, which is typically dramatically effective, generally bringing relief after but a few treatments.

## Personality Change Due to a General Medical Condition

### Definition

The personality of an adult represents a coalescence of various personality traits present in childhood and adolescence, and is generally quite enduring and resistant to change. Thus, the appearance of a significant change in an adult's personality is an ominous clinical sign and indicates the presence of intracranial pathology. Patients themselves may not be aware of the change, however to others, who have known the patient over time, the change is often quite obvious: such observers often note that the patient is “not himself” anymore.

## DSM-IV-TR Criteria 310.1

### Personality Change Due to... [Indicate the General Medical Condition]

- A. A persistent personality disturbance that represents a change from the individual's previous characteristic personality pattern. (In children, the disturbance involves a marked deviation from normal development or a significant change in the child's usual behavior patterns lasting at least 1 year).
- B. There is evidence from the history, physical examination, or laboratory findings that the disturbance is the direct physiological consequence of a general medical condition.
- C. The disturbance is not better accounted for by another mental disorder (including other Mental Disorders Due to a General Medical Condition).
- D. The disturbance does not occur exclusively during the course of a delirium and does not meet criteria for a dementia.
- E. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

*Specify type:*

**Labile Type:** if the predominant feature is affective lability

**Disinhibited Type:** if the predominant feature is poor impulse control as evidenced by sexual indiscretions, etc.

**Aggressive Type:** if the predominant feature is aggressive behavior

**Apathetic Type:** if the predominant feature is marked apathy and indifference

**Paranoid Type:** if the predominant feature is suspiciousness or paranoid ideation

**Other Type:** if the predominant feature is not one of the above, e.g., personality change associated with a seizure disorder

**Combined Type:** if more than one feature predominates in the clinical picture

**Unspecified Type**

**Coding note:** Include the name of the general medical condition on Axis I, e.g., 310.1 Personality Change Due to Temporal Lobe Epilepsy; also code the general medical condition on Axis III (see Appendix G for codes).

In most cases, the change is nonspecific in nature: there may be either a gross exaggeration of hitherto minor aspects of the patient's personality or the appearance of a personality trait quite uncharacteristic for the patient. Traits commonly seen in a personality change, as noted in DSM-IV-TR, include lability, disinhibition, aggressiveness, apathy, or suspiciousness.

In addition to these nonspecific changes, there are two specific syndromes which, though not listed in DSM-IV-TR, are well-described in the literature, namely, the **frontal lobe syndrome** and the **interictal personality syndrome** (also known as the “Geschwind syndrome”).

The **frontal lobe syndrome** is characterized by a variable mixture of disinhibition, affective changes, perseveration and abulia. Disinhibition manifests with an overall coarsening of behavior. Attention to manners and social nuances is lost: patients may eat with gluttony, make coarse and crude jokes, and may engage in unwelcome and inappropriate sexual behavior, perhaps by propositioning much younger individuals or masturbating in public. Affective changes tend toward a silly, noninfectious euphoria; depression, however, may also be seen. Perseveration presents with a tendency to persist in whatever task is currently at hand, and patients may repeatedly button and unbutton clothing, open and close a drawer or ask the same question again and again. Abulia is characterized by an absence of desires, urges or interests, and such patients, being undisturbed by such phenomena, may be content to sit placidly for indefinite periods of time. Importantly, such abulic patients are not depressed, nor are they incapable of activity: indeed, with active supervision they may be able to complete tasks; however, once supervision stops, so too do the patients, as they lapse back into quietude.

The **interictal personality syndrome**, a controversial entity (Bear *et al.*, 1982; Rodin and Schmaltz, 1984) is said to occur as a complication of longstanding uncontrolled epilepsy, with repeated grand mal or complex partial seizures. The cardinal characteristic of this syndrome is what is known as “viscosity”, or, somewhat more colloquially, “stickiness”. Here, patients seem unable to let go or diverge from the current emotion or train of thought: existing affects persist long after the situation which occasioned them, and a given train of thought tends to extend itself indefinitely into a long-winded and verbose circumstantiality or tangentiality. This viscosity of thought may also appear in written expression as patients display “hypergraphia”, producing long and rambling letters or diaries. The inability to “let go” may even extend to such simple acts as shaking hands, such that others may literally have to extract their hand to end the handshake. The content of the patient’s viscous speech and writing generally also changes, and tends toward mystical or abstruse philosophical speculations. Finally, there is also a tendency to hyposexuality, with an overall decrease in libido (Blumer, 1970).

## Etiology and Pathophysiology

A personality change is not uncommonly seen as the prodrome to schizophrenia, however in such cases the eventual appearance of the typical psychosis will indicate the correct diagnosis.

Personality change of the nonspecific or of the frontal lobe type, as noted in Table 33.9, may occur **secondary to precipitants** (e.g., closed head injury), **secondary to cerebral tumors** (especially those of the frontal or temporal lobes) or **as part of certain neurodegenerative or dementing disorders**. Finally, there is a group of **miscellaneous causes**. In Table 33.9, those disorders or diseases which are particularly prone to cause a personality change of the frontal lobe type are indicated by an asterisk. The interictal personality syndrome occurs only in the setting of chronic repeated grand mal or complex partial seizures, and may represent microanatomic changes in the limbic system which have been “kindled” by the repeated seizures (Adamec and Stark-Adamec, 1983; Bear, 1979).

**Table 33.9** Causes of Personality Change of the Nonspecific or Frontal Lobe Type

Metachromatic leukodystrophy
Adrenoleukodystrophy
Mercury intoxication
Manganism

\*Particularly likely to cause a frontal lobe syndrome.

In the case of personality change occurring **secondary to precipitants**, the etiology is fairly obvious; an exception might be cerebral infarction, but here the acute onset and the presence of “neighborhood” symptoms are suggestive. In addition to infarction of the frontal lobe, personality change has also been noted with infarction of the caudate nucleus and of the thalamus.

Personality change occurring **secondary to cerebral tumors** may not be accompanied by any distinctive features, and indeed a personality change may be the only clinical evidence of a tumor for a prolonged period of time.

Personality change **occurring as part of certain neurodegenerative or dementing disorders** deserves special mention, for in many instances the underlying disorder may present with a personality change; this is particularly the case with Pick’s disease, fronto-temporal dementia and Alzheimer’s disease. The inclusion of amyotrophic lateral sclerosis here may be surprising to some, but it is very clear that, albeit in a small minority,

cerebral symptoms may not only dominate the early course of ALS, but may even constitute the presentation of the disease. In the case of the other neurodegenerative disorders (i.e., progressive supranuclear palsy, cortico–basal ganglionic degeneration, multiple system atrophy, Huntington’s disease and Wilson’s disease) a personality change, if present, is typically accompanied by abnormal involuntary movements of one sort or other, such as parkinsonism, ataxia or chorea. The lacunar syndrome, occurring secondary to multiple lacunar infarctions affecting the thalamus, internal capsule or basal ganglia, deserves special mention as it very commonly causes a personality change of the frontal lobe type by interrupting the connections between the thalamus or basal ganglia and the frontal lobe. Normal pressure hydrocephalus is an important diagnosis to keep in mind, as the condition is treatable: other suggestive symptoms include a broad-based shuffling gait and urinary urgency or incontinence. AIDS should be suspected whenever a personality change is accompanied by clinical phenomena suggestive of immunodeficiency, such as thrush. Neurosyphilis may present with a personality change characterized by slovenliness and disinhibition. Creutzfeldt–Jakob disease may also present with a personality change, and this appears particularly likely with the “new variant” type: the eventual appearance of myoclonus suggests the correct diagnosis.

The **miscellaneous causes** represent the diagnostic “zebras” in the differential for personality change. Of them two deserve comment, given their treatability: granulomatous angiitis is suggested by prominent headache, and vitamin B<sub>12</sub> deficiency by the presence of macrocytosis or a sensory polyneuropathy.

### Assessment and Differential Diagnosis

Personality change must be clearly distinguished from a personality disorder. The personality disorders (e.g., antisocial personality disorder, borderline personality disorder), all discussed elsewhere in this book, do not represent a change in the patient’s personality but rather have been present in a lifelong fashion. In gathering a history on a patient with a personality change, one finds a more or less distinct time when the “change” occurred; by contrast, in evaluating a patient with a personality disorder, one can trace the personality traits in question in a more or less seamless fashion back into adolescence, or earlier.

The frontal lobe syndrome, at times, may present further diagnostic questions, raising the possibility of either mania, when euphoria is prominent, or depression, when abulia is at the forefront. Mania is distinguished by the quality of the euphoria, which tends to be full and infectious in contrast with the silly, shallow and noninfectious euphoria of the frontal lobe syndrome. Depression may be distinguished by the quality of the patients’ experience: depressed patients definitely feel something, whether it be a depressed mood or simply a weighty sense of oppression. By contrast, the patient with abulia generally feels nothing: the “mental horizon” is clear and undisturbed by any dysphoria or unpleasantness.

MRI scanning is diagnostic in most cases: where this is uninformative, further testing is dictated by one’s clinical suspicions (e.g., HIV testing).

The interictal personality syndrome must be distinguished from a personality change occurring secondary to a slowly growing tumor of the temporal lobe. In some cases, very small tumors, which may escape detection by routine MRI scanning, may cause epilepsy, and then, with continued

growth, also cause a personality change. Thus, in the case of a patient with epilepsy who develops a personality change, the diagnosis of the interictal personality syndrome should not be made until a tumor has been ruled out by repeat MRI scanning.

### Epidemiology and Comorbidity

Personality change is common, and is seen with especial frequency after closed head injury and as a prodrome to the dementia occurring with such neurodegenerative disorders as Pick’s disease, fronto-temporal dementia and Alzheimer’s disease.

### Course

This is determined by the underlying cause; in the case of the interictal personality syndrome it appears that symptoms persist even if seizure control is obtained.

### Treatment

Treatment, if possible, is directed at the underlying cause. Mood stabilizers (i.e., lithium, carbamazepine or divalproex) may be helpful for lability, impulsivity and irritability; propranolol, in high dose, may also have some effect on irritability. Neuroleptics (e.g., olanzapine, risperidone, haloperidol) may be helpful when suspiciousness or disinhibition are prominent. Antidepressants (e.g., an SSRI) may relieve depressive symptoms. Regardless of which agent is chosen, it is prudent, given the general medical condition of many of these patients, to “start low and go slow”. In many cases, some degree of supervision will be required.

### Mental Disorder not Otherwise Specified Due to a General Medical Condition

This is a residual category in DSM-IV for those clinical situations in which the mental disorder occurring secondary to a general medical condition does not fall into one of the specific categories described earlier. Of these various disorders, two are worthy of detailed description, namely, pseudobulbar palsy and the Klüver–Bucy syndrome. Both disorders are commonly seen in dementia clinics, and their occurrence often prompts a request for psychiatric consultation.

### Pseudobulbar Palsy

#### Definition

When fully developed, this syndrome is characterized by emotional incontinence (also known as “pathological laughing and crying”), dysarthria, dysphagia, a brisk jaw-jerk and gag reflex, and difficulty in protruding the tongue.

The most remarkable aspect of the syndrome is the emotional incontinence. Here, patients experience uncontrollable paroxysms of laughter or crying, often in response to minor stimuli, such as the approach of the physician to the bedside (Lieberman and Benson, 1977). Importantly, despite the strength of these outbursts, patients do not experience any corresponding sense of mirth or sadness; some may attempt to stop the emotional display, only to become acutely distressed at their inability to do so: one patient, who experienced “gales

**Table 33.10** Causes of Pseudobulbar Palsy

Closed head injury
Multiple sclerosis
Behçet's syndrome

of laughter” whenever he attempted to speak, “felt foolish and ashamed, and had tears in his eyes because he could not ‘control the laughter’ ” (Davison and Kelman, 1939). Some may go out of their way to avoid having these paroxysms. In one case, described by Wilson (1924), the patient “used to walk about the hospital with his eyes glued to the ground (because) if he so much as raised them to meet anyone else’s gaze he was immediately overcome by compulsory laughter, which sometimes lasted for 4 or 5 minutes”.

### Etiology and Pathophysiology

Pseudobulbar palsy results from bilateral interruption of corticobulbar fibers, with this interruption occurring anywhere from the cortex through the centrum semiovale to the internal capsule and down to the midbrain and pons. Thus “released” from upper motor neuron control, the bulbar nuclei act reflexively, creating, in a sense, a kind of “spasticity” of emotional display. The various disorders capable of causing such a bilateral interruption are listed in Table 33.10.

**Vascular disorders** are by far the most common cause of bilateral interruption of the corticobulbar tracts, as may be seen with infarctions of the cortex or with lacunar infarctions in the corona radiata or internal capsule. Although in some cases it appears that the syndrome occurs after only one stroke, further investigation typically reveals evidence of a preexisting lesion on the contralateral side, a lesion which had been clinically “silent” (Besson *et al.*, 1991). Other vascular causes include Binswanger’s disease, characterized by diffuse white matter damage in the centrum semiovale, and CADASIL (Cerebral Autosomal Dominant Arteriopathy with Subcortical Infarcts and Leukoencephalopathy), characterized by both subcortical infarctions and a widespread leukoencephalopathy.

Of the **neurodegenerative disorders** associated with pseudobulbar palsy, the most prominent is amyotrophic lateral sclerosis, wherein approximately one-half of patients are eventually so affected (Gallagher, 1989).

Of the **miscellaneous causes**, cerebral tumors which bilaterally compress or invade the brainstem are particularly important.

### Assessment and Differential Diagnosis

The diagnosis should be suspected whenever patients present with exaggerated and uncontrollable emotional displays. Lability of affect, as may be seen in mania, is ruled out by the fact that the labile patient, while displaying the affect, also experiences a congruent emotional feeling: by contrast, in emotional incontinence the patient often feels nothing, except perhaps consternation at the unmotivated and uncontrollable emotional display. Inappropriate affect, as may be seen in schizophrenia, is similar to emotional incontinence in that patients with schizophrenia may not experience any corresponding feeling: in schizophrenia, however, one sees other accompanying symptoms, such as mannerisms, hallucinations and delusions, symptoms which are absent in pseudobulbar palsy. “Emotionalism”, as may be seen after strokes, may suggest the diagnosis, especially given the clinical setting, however here, as with lability, patients also experience a concurrent feeling that is congruent with the emotional display.

Findings on the neurologic examination are also helpful. Bilateral interruption of corticobulbar tracts, as noted above, typically leads to cranial nerve dysfunction with dysarthria, dysphagia and brisk jaw-jerk and gag reflexes. Given the proximity of the corticospinal tracts, one often also finds evidence of long-tract damage, such as hemiplegia or Babinski signs.

MRI scanning is generally diagnostic in cases secondary to vascular lesions, tumors and multiple sclerosis. Amyotrophic lateral sclerosis is suggested by the gradual progression of upper and lower motor neuron signs and symptoms; progressive supranuclear palsy by the presence of parkinsonism and supranuclear gaze palsy, and Alzheimer’s disease by the long history of a gradually progressive dementia.

### Epidemiology and Comorbidity

Pseudobulbar palsy is not uncommon: as noted above, it is found in almost half of patients with amyotrophic lateral sclerosis. It may also be seen in a much smaller, but still clinically significant, proportion of patients with vascular lesions, Alzheimer’s disease and multiple sclerosis.

### Course

The overall course of the syndrome reflects the course of the etiologic disorder. The appearance of dysphagia, however, is an ominous sign, carrying, as it does, the risk of aspiration.

### Treatment

In addition to treating, if possible, the underlying cause, various medications may be used to reduce the severity of the emotional incontinence, including tricyclics and SSRIs. Among the tricyclics, both amitriptyline (in doses of 50–75 mg) and nortriptyline (in doses up to 100 mg) are effective, with nortriptyline generally better tolerated. Of the SSRIs, citalopram, in a dose of 20 mg, was effective, and there are also case reports of the effectiveness of paroxetine, sertraline and fluoxetine (Seliger and Hornstein, 1989). Overall, it is probably best to begin with an SSRI, and to hold nortriptyline in reserve.

### Klüver–Bucy Syndrome

#### Definition

In 1939, Klüver and Bucy (1939) noted some striking behavioral changes in monkeys which had been subjected to bilateral

temporal lobectomy, and in so doing described the syndrome that now bears their names. The full syndrome is characterized by hypermetamorphosis (excessive tendency to take notice and attend and react to every visual stimulus), agnosia, hyperorality, emotional placidity and hypersexuality. Some examples of the syndrome in humans follow.

The first example demonstrates hypersexuality, hyperorality, agnosia and emotional placidity. The patient was a 31-year-old woman, who, after recovering from a herpes simplex encephalitis, “made inappropriate sexual advances to female attendants, both manually and orally. At home, she was constantly chewing and swallowing, and all objects within reach were placed in her mouth...including toilet paper and faeces...Her affect was characterized by passivity and a pet-like compliance with those attending her” (Lilly *et al.*, 1983).

The second example provides examples of hypermetamorphosis, hyperorality, agnosia and hypersexuality. The patient, a 58-year-old man who had suffered from Alzheimer’s disease for 6 years, “spent much of his time examining ordinary objects such as the doorstep, ashtrays, or spots on the floor. He placed many objects in his mouth and occasionally ate soil from plant containers...he rubbed his genitals so frequently that he developed an excoriation on the shaft of his penis” (Lilly *et al.*, 1983).

Finally, there is the case of a 46-year-old man, who, during a complex partial seizure, “was observed grabbing for objects on his bedside table, and he masturbated in front of the nursing staff. He also placed objects in his mouth, chewed on tissue paper, and attempted to drink from his urine container” (Nakada *et al.*, 1984). Here, there are hypermetamorphosis, hypersexuality, hyperorality and agnosia.

## Etiology and Pathophysiology

The various causes of the Klüver–Bucy syndrome are listed in Table 33.11: in each case, bilateral damage or dysfunction of the temporal lobes has occurred. The mechanism of such bilateral damage in the case of precipitants is fairly straightforward. The neurodegenerative disorders listed have a predilection for the temporal lobes, and this is particularly the case in Pick’s dis-

ease and fronto-temporal dementia. Indeed, the appearance of the Klüver–Bucy syndrome early in the course of a dementia is a significant diagnostic clue to one of these two disorders; in the case of Alzheimer’s disease, the syndrome, if it does occur, is generally seen only late in the course. Of the miscellaneous causes, an ictal Klüver–Bucy syndrome is suggested by its exquisitely paroxysmal onset and by the occurrence of other symptoms typical for a complex partial seizure, such as confusion, and a postictal Klüver–Bucy syndrome by the history of an immediately preceding generalized seizure. Adrenoleukodystrophy, the last in the list, is an extremely rare cause of the Klüver–Bucy syndrome.

## Assessment and Differential Diagnosis

The combination of hyperorality and hypersexuality often brings the patient to medical attention: although the full syndrome presents little diagnostic difficulty, as it is not mimicked by any other condition, partial syndromes, consisting primarily of hypermetamorphosis and hypersexuality, may suggest mania. The differential rests on the presence or absence of pressured speech and activity, findings typical of mania but absent in the Klüver–Bucy syndrome.

## Epidemiology and Comorbidity

The full Klüver–Bucy syndrome is, overall, rare; in dementia clinics, however, full or partial Klüver–Bucy syndromes are commonly seen.

## Course

The course depends on the underlying cause; in some cases, the syndrome itself may have a fatal outcome, as in the following clinical vignette.

## Treatment

The underlying cause, if possible, is treated. In chronic cases, neuroleptics have been reported to be helpful; there are, however, no controlled studies.

## Comparison of DSM-IV/ICD-10 Diagnostic Criteria

The DSM-IV-TR Category Psychotic Disorder Due to a General Medical Condition is referred to in ICD-10 as “organic hallucinosis” or “organic delusional disorder” depending on the type of presenting symptom.

In contrast to DSM-IV-TR which requires clinically significant mood symptoms of any type, the ICD-10 Diagnostic Criteria for Research for Mood Disorder Due to a General Medical Condition require that the full symptomatic and duration criteria be met for a hypomanic, manic, or major depressive episode. This disorder is referred in ICD-10 as “organic mood disorder”. Also in contrast to DSM-IV-TR which requires anxiety symptoms of any type, the ICD-10 Diagnostic Criteria for Research for Anxiety Disorder Due to a General Medical Condition require that the clinical picture meet full symptomatic and duration criteria for panic disorder or generalized anxiety disorder.

For catatonic disorder due to a general medical condition, the ICD-10 Diagnostic Criteria for Research are more narrowly defined than the criteria in DSM-IV-TR by virtue of requiring both catatonic stupor/negativism “and” excitement and that there be a rapid alternation of stupor and excitement. In ICD-10, this disorder is referred to as “organic catatonic disorder”.

**Table 33.11** Causes of The Klüver–Bucy Syndrome

Secondary to Precipitants
Bilateral temporal lobectomy
Head trauma with bilateral damage to temporal lobes
Herpes simplex encephalitis
Status epilepticus
Heat stroke
Occurring as Part of Certain Neurodegenerative Disorders
Pick’s disease
Fronto-temporal dementia
Alzheimer’s disease
Miscellaneous Causes
Ictal
Postictal
Adrenoleukodystrophy

The DSM-IV-TR category of Personality Change Due to a General Medical Condition corresponds to two ICD-10 categories: “organic personality disorder” and “organic emotionally labile disorder”. The ICD-10 Diagnostic Criteria for Research for Organic Personality Disorder are probably more narrowly defined in that “at least three” features characteristic of a personality change are required.

# General Approaches to Substance and Polydrug Use Disorders

## Definition

### Substance Abuse and Dependence

The definitions of substance abuse and dependence are based on the dependence syndrome of Griffith Edwards (Edwards and Gross, 1976). Substance abuse is a maladaptive pattern of substance use leading to significant adverse consequences manifested by psychosocial, medical, or legal problems or use in situations in which it is physically hazardous that must recur during a 12-month period. Since a diagnosis of substance dependence preempts a diagnosis of abuse, tolerance, withdrawal and compulsive use are generally not present in individuals with a diagnosis of substance abuse. Since caffeine and nicotine generally do not cause psychosocial or legal problems and since it is not physically hazardous to use caffeine and nicotine, a diagnosis of abuse does not apply to these substances. The two abuse criteria focusing on legal and interpersonal problems are not among the dependence criteria. In the following chapters on substance abuse, readers will be referred to the DSM-IV TR criteria presented in this chapter as the outlines for specific disorders.

### Substance Intoxication

Substance intoxication is a reversible substance-specific syndrome with maladaptive behavioral or psychological changes developing during or shortly after using the substance. It does not apply to nicotine. Recent use can be documented by a history or toxicological screening of body fluids (urine or blood). Different substances may produce similar or identical syndromes and, in polydrug users, intoxication may involve a complex mixture of disturbed perceptions, judgment and behavior that can vary in severity and duration according to the setting in which the substances were taken. Physiological intoxication is not in and of itself necessarily maladaptive and would not justify a diagnosis of the DSM-IV-TR category substance intoxication. For example, caffeine-induced tachycardia with no maladaptive behavior does not meet the criteria for substance intoxication.

### Substance Withdrawal

Substance withdrawal is a syndrome due to cessation of, or reduction in, heavy and prolonged substance use. It causes clinically significant impairment or distress and is usually associated with substance dependence. Most often the symptoms of withdrawal

## DSM-IV-TR Criteria

### Substance Abuse

- A. A maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by one (or more) of the following, occurring within a 12-month period:
- (1) recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home (e.g., repeated absences or poor work performance related to substance use; substance-related absences, suspensions, or expulsions from school; neglect of children or household)
  - (2) recurrent substance use in situations in which it is physically hazardous (e.g., driving an automobile or operating a machine when impaired by substance use)
  - (3) recurrent substance-related legal problems (e.g., arrests for substance-related disorderly conduct)
  - (4) continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance (e.g., arguments with spouse about consequences of intoxication, physical fights)
- B. The symptoms have never met the criteria for substance dependence for this class of substance.

are the opposite of intoxication with that substance. The withdrawal syndrome usually lasts several days to 2 weeks.

### Etiology and Pathophysiology

The cause of substance addiction depends on a variety of biological, psychological and social factors. Biological factors can include genetic predisposition as well as neurobiological

### DSM-IV-TR Criteria

#### Substance Intoxication

- A. The development of a reversible substance-specific syndrome due to recent ingestion of (or exposure to) a substance. Note: Different substances may produce similar or identical syndromes.
- B. Clinically significant maladaptive behavioral or psychological changes that are due to the effect of the substance on the central nervous system (e.g., belligerence, mood lability, cognitive impairment, impaired judgment, impaired social or occupational functioning) and develop during or shortly after use of the substance.
- C. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

### DSM-IV-TR Criteria

#### Substance Withdrawal

- A. The development of a substance-specific syndrome due to the cessation of (or reduction in) substance use that has been heavy and prolonged.
- B. The substance-specific syndrome causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- C. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

substrates for positive and negative reinforcement by abused substances (Nestler, 2000). Family genetic studies have found rates of substance dependence three to four times higher in identical twins than in dizygotic twins (Cloninger, 1999). Although no single biological marker or specific genetic defect has been confirmed, work has suggested that some alleles associated with variations in the dopamine receptor may be more common in substance-dependent individuals than in those who are not dependent. Similarly, risk factor studies have found that the sons of individuals suffering from alcoholism have a general hyporesponsiveness to alcohol and sedative drugs, when compared with the sons of individuals without alcoholism.

Psychological factors related to etiology include high rates of depressive disorders and sensation seeking, which are found in substance addiction. The association of sensation seeking with substance addiction suggests not only that drugs enhance pleasant sensations, such as a high, but also that abused drugs may provide potential control of aggressive impulses. Whether abused drugs

serve as self-medication for individuals with these psychological disturbances (e.g., depression and impulsivity) has not been resolved clearly because the age at onset for major psychiatric disorders, such as depression, is older than the age at onset for substance abuse and dependence (Khantzian, 1985). Childhood precursors of substance abuse and dependence, including shy and aggressive behaviors, can also be precursors of later depressive disorders as well as of antisocial personality disorder – the adult expression of aggressive impulsivity.

Finally, social factors, including peer and family influences, which are not dependent on genetic inheritance, are important in leading to initial drug exposure. Kandel (1975) has conducted longitudinal studies of “gateway drug” usage by adolescents, and these original concepts have been expanded over the last 25 years to recognize their treatment implications. These gateway drugs are tobacco, alcohol and marijuana. Adolescents who begin using gateway drugs in their early teens are more likely to have substance dependence in their twenties than are adolescents who begin use in their late teens. Delaying the initiation of these gateway drugs and their associated intoxication by 1 to 2 years substantially decreases the later risk of the development of substance dependence. This association between early gateway drug use and later dependence may be related to the relatively higher rates of conduct disorder and failure to complete school in those who acquire a substance-related disorder in early adolescence. Life stressors related to peers and family are also possible causative factors in substance dependence and their associated comorbid psychiatric disorders.

### Special Issues in the Psychiatric Examination

Two special issues in the psychiatric examination of substance dependence include 1) the source of information when obtaining the history of the substance abuse, and 2) the management of aberrant behaviors. Information about a patient’s substance abuse history can be provided not only by the patient but also by employers, family members and school officials. When patients self-report the amount of substance abused, there is a tendency to underreport the severity and duration of abuse, particularly if the patient is being referred to treatment by an outside source such as the family, the employer, or the legal system. Objective verification of the exact amount of substance use is sometimes difficult but the critical issues in arriving at a diagnosis of substance dependence do not depend on the precise amount of substance abused. Tolerance and withdrawal can be assessed independently by using tests such as the naloxone challenge and the barbiturate tolerance test. In general, significant others’ estimates of the amount of drug use by the patient can be a good source of data. Thus, the initial evaluation of substance abuse and dependence may involve a wider range of interviews than would occur with many other types of psychiatric patients.

Aberrant behaviors potentially requiring management include intoxication, violence, suicide, impaired cognitive functioning and uncontrolled affective displays. The evaluation of an intoxicated substance abuser can address only a limited number of issues. These issues are primarily related to the safety of the substance abuser and other individuals who may be affected by his or her actions. Thus, a medical evaluation for signs of overdose or major cognitive impairment is critical, with consideration of detaining the patient for several hours or even days if severe complications are evident. Intoxication with sedating drugs such

## DSM-IV-TR Criteria

### Substance Dependence

A maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by three (or more) of the following, occurring at any time in the same 12-month period:

- (1) tolerance, as defined by either of the following:
  - (a) a need for markedly increased amounts of the substance to achieve intoxication or desired effect
  - (b) markedly diminished effect with continued use of the same amount of the substance
- (2) withdrawal, as manifested by either of the following:
  - (a) the characteristic withdrawal syndrome for the substance (refer to criteria A and B of the criteria sets for withdrawal from the specific substances)
  - (b) the same (or a closely related) substance is taken to relieve or avoid withdrawal symptoms
- (3) the substance is often taken in larger amounts or over a longer period than was intended
- (4) there is a persistent desire or unsuccessful effort to cut down or control substance use
- (5) a great deal of time is spent in activities necessary to obtain the substance (e.g., visiting multiple doctors or driving long distances), use the substance (e.g., chain-smoking), or recover from its effects
- (6) important social, occupational, or recreational activities are given up or reduced because of substance use
- (7) the substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance (e.g., current cocaine use despite recognition of cocaine-induced depression, or continued drinking despite recognition that an ulcer was made worse by alcohol consumption)

*Specify if:*

**With physiological dependence:** evidence of tolerance or withdrawal (i.e., either item 1 or 2 is present)

**Without physiological dependence:** no evidence of tolerance or withdrawal (i.e., neither item 1 nor 2 is present)

*Course specifiers* (see text for definitions):

**Early full remission**

**Early partial remission**

**Sustained full remission**

**Sustained partial remission**

**On agonist therapyIn a controlled environment**

as alcohol can lead to significant motor and cognitive impairment, which would have an impact on a patient's capacity to drive a motor vehicle. When a patient drives a car to an evaluation and is obviously intoxicated, the psychiatrist has an obligation to prevent the patient from getting back into the driver's seat of that vehicle until the effects of that drug intoxication have worn off. This may involve contacting the police to restrain the patient from driving at least temporarily. Similar issues of police restraint can arise when an intoxicated patient becomes violent and has threatened to harm his or her employers or family members. Judgment and impulse control may be substantially affected by abused drugs, but these effects may be temporary, and a short-term preventive intervention may be sufficient to avert substantial harm to the patient or others.

Temporary suicidal behavior may be encountered in a variety of substance addictions, particularly those with alcohol and

stimulants. Suicidal ideation may be intense but may clear within hours. During the evaluation session, it is important to elicit the precipitants that led the patient to seek treatment at this time and to keep the evaluation focused on specific data needed for the evaluation of substance dependence, its medical complications and any comorbid psychiatric disorders. Many patients spend a great deal of time detailing their drug-abusing careers, but in general these stories do not provide useful material for the evaluation or for future psychotherapeutic interventions. Similarly, the evaluation should not become focused on the affective aspects of a patient's recent life because affect is frequently used as a defense to avoid discussing issues of more immediate relevance such as precipitants or to act as a pretext for obtaining benzodiazepines or other anti-anxiety agents from the physician. Abused substances have generally been a way of managing affect and these patients need to develop alternative coping strategies.

## Course and Natural History

The natural history of substance dependence characteristically follows the course of a chronic relapsing disorder, although a large number of individuals who experiment with potentially abusable drugs in adolescence do not go on to acquire dependence. The initial phase of the natural history of experimenting with drugs has been well described in studies by Kandel (1975), who has used the concept of gateway drug use and its evolution into more serious drug dependence during adolescence and the early twenties. The later phases of dependence are characterized in the 20- to 30-year follow-up studies of individuals with alcoholism and those with opioid addiction by Vaillant (1988, 1983) and Laub and Vaillant (2000). He has documented the natural history after age 20 years in delinquent boys, which is most closely synonymous with having lifetime conduct disorder using DSM-IV-TR criteria, and found high mortality rates by age 40 years in those delinquent boys who later become substance users. In his most recent studies following 475 delinquent boys and 456 matched nondelinquent comparison boys from age 14 years until age 65 years he found that 13% of the delinquent and only 6% ( $N = 28$ ) of the nondelinquent subjects died unnatural deaths. These deaths were significantly associated with abuse of alcohol during adulthood and childhood delinquency, and these two factors completely accounted for the other associations of adult crime, dysfunctional home environment and poor education with the increased mortality. Thus, abusing substances may have a critical impact on later health, but having a conduct disorder as a child increases this risk, perhaps due to related behaviors such as unwillingness to seek out appropriate health care. Clearly, these studies open more questions about the interaction of substance abuse and childhood behaviors that may not include substance abuse.

Population surveys, such as the high school senior surveys and National Institute on Drug Abuse household survey (Wallace *et al.*, 1999), have provided repeated cross-sectional data on changing trends in substance use and its associated problems. These surveys have increasingly recognized cultural differences in the course of drug use. Individuals with substance dependence also have been followed up in a variety of longitudinal treatment studies such as the Drug Abuse Treatment Outcome Studies (DATOS) (Flynn *et al.*, 1999; Simpson *et al.*, 1999). These surveys and treatment follow-up studies provide indications of how the natural history of substance abuse changes over the course of several decades. In contrast to most medical disorders, substance abuse and dependence differs because the substances of abuse change over time as epidemics come and go and as new drugs, such as the “designer drugs”, are developed. The natural history of abuse and dependence on these new substances can be unique, with patterns of sustained low-level use, such as with methylenedioxyamphetamine (Ecstasy), or associated social phenomena, such as parkinsonism in abusers of fentanyl-related designer drugs. Thus, the natural history of substance abuse and dependence is determined by the type of substance used and, for polysubstance dependence, can be complicated by changing secular trends and epidemics lasting from months to decades.

## Other Substance Use Disorders: Anabolic Steroids

This group of substance-induced conditions most notably includes anabolic steroids and nitrite inhalants. Both have psychoactive

effects and can have consequences for the individual and broad public health, which suggest that future research may lead to their inclusion in DSM-V as separate disorders.

In 1988, a survey of male high school seniors showed that anabolic steroids had a lifetime use rate of 6.6% (Buckley *et al.*, 1988). Thus, by the late 1980s, widespread abuse of anabolic steroids was occurring among males as well as females. Multiple types of steroid derivatives were being used in order to make the lipid soluble steroids more water soluble and easier to administer than the intramuscular injections that were typically required. Because of this abuse, anabolic steroids were added to Schedule III of the Controlled Substances Act in 1990.

The clinical effects of anabolic steroids are related to a typical “cycle” 4 to 18 weeks on steroids and 1 month to 1 year off. While taking the steroids, the primary effects sought by abusers are increasing muscle mass and strength and not euphoria. In the context of an adequate diet and significant physical activity, these individuals appear quite healthy and they are unlikely to appear for treatment of their anabolic steroid abuse. However, some of the adverse cardiovascular, hepatic and musculoskeletal effects of steroids as well as virilization in women may bring these users to medical attention. Severe cases of acne can also bring some adolescents to medical attention. Abuse of other psychoactive drugs may occur in up to a third of these steroid users, but generally is relatively low compared with other substance abusers.

Heavy use can increase aggression, change libido and sexual functions, and induce mood changes with occasional psychotic features (Brower *et al.*, 1991; Su *et al.*, 1993). In studies comparing doses of 40 to 240mg/day of methyltestosterone in a double-blind inpatient trial, irritability, mood swings, violent feelings and hostility were greater during the high dose period than at baseline. The tendency of Androgenic steroids to provoke aggression and irritability has raised concerns about violence towards family members by abusers. Prospective trials have reported mood disturbances in over 50% of body builders using anabolic steroids, as well as cognitive impairment including distractibility, forgetfulness and confusion.

Dependence symptoms have included a withdrawal syndrome with common symptoms being fatigue, depressed mood and desire to take more steroids. Other common dependence symptoms are using the substance more than intended, continuing to use steroids despite problems worsened by its use and the excessive spending of time relating to obtaining steroids. Because few clinical laboratories are equipped to conduct steroid tests and these tests are quite expensive, these signs of dependence and some common laboratory abnormalities are usually used to access the diagnosis.

Anabolic steroid abuse leads to hypertrophied muscles, acne, oily skin, needle punctures over large muscles, hirsutism in females and gynecomastia in males. Heavy users can also develop edema and jaundice. Common laboratory abnormalities include elevated hemoglobin and hematocrit, elevated low density lipoprotein cholesterol, elevated liver function tests and reduced luteinizing hormone levels.

Mental health professionals may have these patients come to their attention due to the excessive aggression, loss of sexual ability, or mood disturbances. Treatment approaches are generally symptomatically oriented towards controlling the depressed mood and the psychotic features, but longer-term interventions such as peer counseling by former body builders and group support may be of value for these users.

## Comparison of DSM-IV/ICD-10 Diagnostic Criteria

The ICD-10 Diagnostic Criteria for Research for Substance Dependence are close, but not identical, to the DSM-IV-TR criteria. ICD-10 has included all seven of the DSM-IV-TR items but condenses these into five criteria and adds a sixth item tapping drug-craving behavior. Furthermore, the method for establishing clinical significance differs in the two systems. DSM-IV-TR specifies that there be a maladaptive pattern of substance use leading to clinically significant impairment or distress whereas the ICD-10 Diagnostic Criteria for Research indicate either a one month duration or repeated occurrences within a 12 month period.

The ICD-10 Diagnostic Criteria for Research corresponding to Substance Abuse is less specific than the criteria in DSM-IV-TR, requiring that there be “clear evidence that substance use was responsible for (or substantially contributed to) physical or psychological harm, including impaired judgment or dysfunctional behavior, which may lead to disability or have adverse consequences for interpersonal relationships”. In ICD-10, this disorder is referred to as “Harmful Use”.

The ICD-10 Diagnostic Criteria for Research for Intoxication are nearly equivalent to the DSM-IV-TR criteria. However, in contrast to the DSM-IV-TR definition of Withdrawal which specifies that the withdrawal symptoms cause clinically significant distress or impairment, the ICD-10 Diagnostic Criteria for Research for Withdrawal indicates only the presence of characteristic signs and symptoms.

# Substance Abuse: Alcohol Use Disorders

## Definition

Alcohol consumption occurs along a continuum, with considerable variability in drinking patterns among individuals. There is no sharp demarcation between “social” or “moderate” drinking and “problem” or “harmful” drinking. It is clear, however, that as average alcohol consumption and frequency of intoxication increase, so does the incidence of medical and psychosocial problems. The focus of this chapter is the alcohol use disorders which include alcohol abuse and alcohol dependence.

The most visible group of people affected by alcohol problems are those who have developed a syndrome of alcohol dependence and who are commonly referred to as alcoholics. In this chapter, the term alcoholic is applied specifically to those individuals with alcohol dependence. A less prominent group consists of those persons who experience problems with their drinking but who are not dependent on alcohol. These individuals are variously termed alcohol abusers, problem drinkers and harmful drinkers. These two “worlds” of alcohol problems may require different approaches to diagnosis and clinical management.

## Etiology and Pathophysiology

Alcoholism is a complex, multifaceted disorder which has long been recognized to run in families. There is substantial evidence from twin research and adoption studies that a major genetic component is operative in the development of alcoholism. Nonetheless, the disorder is etiologically complex, with a variety of other vulnerability factors. It has been estimated that there is a sevenfold risk of alcoholism in first-degree relatives of alcohol-dependent individuals, with male relatives of male alcohol-dependent individuals having the greatest risk for the disorder. However, the majority of alcohol-dependent individuals do not have a first-degree relative who is alcohol dependent. This underscores the fact that the risk for alcohol dependence is also determined by environmental factors, which may interact in complex ways with genetics. In addition to studying genetic contributions to alcoholism, another approach to understanding the etiology of alcoholism is to identify distinct subtypes of alcoholics. The best known of these typologies is the Type 1/Type 2 distinction developed by Cloninger and colleagues (1981) from studies of adopted sons of Swedish alcoholics (see Table 35.1).

Type 1 alcoholics are characterized by the late onset of problem drinking, rapid development of behavioral tolerance to alcohol, prominent guilt and anxiety related to drinking, and infrequent fighting and arrests when drinking. Cloninger also termed this

**Table 35.1** Cloninger’s Alcoholism Typology

	Type 1	Type 2
Onset of problem drinking	Late onset	Early onset
Tolerance	Rapid development of behavioral tolerance	Not specified
Mood issues	Prominent guilt and anxiety about drinking	Absence of guilt and anxiety about drinking
Personality traits	High reward dependence High harm avoidance Low novelty seeking	Low reward dependence Low harm avoidance High novelty seeking

Source: Adapted from Cloninger CR, Bohman M and Sigvardsson S (1981) Inheritance of alcohol abuse: Cross-fostering analysis of adopted men. *Arch Gen Psychiatr* 38, 861–868. Copyright 1981 American Medical Association

subtype “milieu-limited”, which emphasizes the etiologic role of environmental factors. In contrast, Type 2 alcoholics are characterized by early onset of an inability to abstain from alcohol, frequent fighting and arrests when drinking, and the absence of guilt and fear concerning drinking. Cloninger postulated that transmission of alcoholism in Type 2 alcoholics was from fathers to sons, hence term the **male-limited** alcoholism. Differences in the two subtypes are thought to result from differences in three basic personality (i.e., temperament) traits, each of which has a unique neurochemical and genetic substrate. Type 1 alcoholics are characterized by high reward dependence, high harm avoidance and low novelty seeking. In contrast, Type 2 alcoholics are characterized by high novelty seeking, low harm avoidance and low reward dependence.

Cloninger also hypothesized that specific neurotransmitter systems underlie personality structure. Specifically, dopamine is hypothesized to modulate novelty seeking, which is characterized by frequent exploratory behavior and intensely pleasurable responses to novel stimuli. Serotonin is hypothesized to modulate harm avoidance, which is a tendency to respond intensely to aversive stimuli and their conditioned signals. Finally, norepinephrine

is hypothesized to modulate reward dependence or the resistance to extinction of previously rewarded behavior. Although Cloninger's typology has generated substantial research, studies have failed to provide empirical support for this tridimensional personality scheme and other aspects of the classification (Glenn and Nixon, 1991; Schuckit *et al.*, 1990; Sannibale and Hall, 1998; Vaillant, 1994).

Implicit in the subtyping theories that have been developed to explain different clinical varieties of alcoholism is the notion that there are a variety of plausible etiological factors in addition to or mediated by genetic predisposition. Three such factors are pharmacological vulnerability, affective dysregulation and personality disorder. The evidence for pharmacological vulnerability as an etiological factor is based on studies showing reduced sensitivity to the effects of alcohol in adult children of alcoholics (Schuckit and Smith, 1996; Pollock, 1992). Other evidence comes from research on the effects of the alcohol metabolizing enzymes aldehyde dehydrogenase and alcohol dehydrogenase polymorphisms in individuals of Asian ancestry in which aversive reactions to the effects of alcohol are associated with reduced risk of alcohol dependence (Thomasson *et al.*, 1993). A second etiological factor is affect dysregulation, which proposes that alcoholism is caused by repeated use of alcohol to "self-medicate" negative affective states such as anxiety and depression. This theory is supported by research indicating strong associations between alcohol problems, mood disorders and life stress (Schuckit, 1985). The third etiological factor that has received considerable research support is deviance proneness or behavioral undercontrol, as indicated by hyperactivity, distractibility, sensation seeking, impulsivity, difficult temperament and conduct disorder. These conditions are hypothesized to contribute to school failure and association with deviant peers, which then provide a context for heavy drinking and drug use (Sher and Trull, 1994).

In summary, despite considerable progress in the identification of risk factors for alcoholism, the interactions among genetic, familial, psychological, interpersonal and environmental influences remain so complex that there is little consensus about etiology at this time.

## Pathophysiology

### Neuropharmacology

Taken in large doses, alcohol is considered to have anesthetic or depressive properties. It also has the ability to elicit euphoria when administered in small doses to susceptible persons (Beagleiter and Porjesz, 1999). This phenomenon appears to be mediated by direct activation by alcohol of the mesolimbic dopaminergic circuit, particularly the ventral tegmental area (VTA) and the nucleus accumbens (NAc). Anxiolysis and relaxation also appear to be part of the spectrum of the rewarding effects of alcohol, though these effects appear to be mediated by activation of the GABAergic neurotransmitter system.

In contrast to other addictive substances (e.g., nicotine, cocaine and opioids) and despite its significant effect on dopaminergic neurotransmission, the existence of specific alcohol binding sites on neuronal membranes has not been conclusively established. The lack of an alcohol receptor has led to the hypothesis that some alcohol effects, particularly those observed when it is administered at large doses, may be explained by disturbances in fluidity of the bi-layer lipid neuronal membrane. Changes in fluidity of neuronal membranes may affect the structure and function

of neurotransmitter receptors and ion channels. However, this hypothesis has failed to explain alcohol-rewarding effects that occur at lower doses.

On the other hand, alcohol administration appears to have effects across the major neurotransmitter systems (i.e., opioidergic, serotonergic, GABAergic and glutamatergic). These systems are affected by both acute and chronic alcohol administration. They appear to play a major role in mediating the rewarding effects of alcohol by modulating the firing of dopaminergic neurons in the VTA and the release of dopamine in the NAc.

## Assessment and Differential Diagnosis

### Phenomenology and Variations in Presentation

The DSM-IV-TR diagnosis of **alcohol dependence** is given when three or more of the seven criteria are present (see DSM-IV-TR for alcohol dependence). Because physiological dependence is associated with greater potential for acute medical problems (particularly acute alcohol withdrawal), the first criteria to be

#### DSM-IV-TR Criteria 303.90

##### Alcohol Dependence

A maladaptive pattern of drinking as manifested by three or more of the following during a 12-month period:

1. Tolerance, that is, either:
  - a. a need for markedly more alcohol to achieve intoxication
  - b. markedly diminished effect despite continued consumption of the same amount of alcohol
2. Withdrawal, that is, either:
  - a. two or more signs or symptoms (autonomic hyperactivity, tremor, insomnia, nausea or vomiting, transient illusions or hallucinations, psychomotor agitation, anxiety, grand mal seizures) within several hours of stopping or reducing heavy, prolonged drinking (consuming ) alcohol or a related substance (e.g., benzodiazepines) to relieve or avoid withdrawal symptoms
3. Alcohol is often consumed in larger amounts or over a longer period than was intended
4. There is a persistent desire to cut down or control drinking
5. A great deal of time is spent in drinking or recovering from drinking
6. Important social, occupational, or recreational activities are given up or reduced because of drinking
7. Drinking is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by alcohol.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

**DSM-IV-TR Criteria 305.00****Alcohol Abuse**

A maladaptive pattern of drinking as manifested by one or more of the following during a 12-month period:

1. Recurrent drinking resulting in a failure to fulfill major role obligations at work, school, or home
2. Recurrent drinking in situations in which it is physically hazardous
3. Recurrent alcohol-related legal problems
4. Continued drinking despite having persistent or recurrent social or interpersonal problems caused or exacerbated by drinking

**Note:** The individual must never have met criteria for alcohol dependence.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

considered are tolerance and withdrawal. The remaining criteria reflect behavioral and cognitive dimensions: a) impaired control (i.e., alcohol is consumed in larger amounts or over a longer period of time than was intended; there is a persistent desire or unsuccessful efforts to cut down or control drinking; the individual continues to drink despite knowledge of a persistent or recurrent physical or psychological problem), and b) increase salience of alcohol (i.e., a great deal of time spent drinking or recovering from its effects; important social, occupational, or recreational activities are given up or reduced due to drinking).

Once a diagnosis of alcohol dependence is given, a specification is made concerning course. **Early remission** is used if no criteria (**full remission**) or fewer than three symptoms (**partial remission**) of alcohol dependence are present for at least 1 month, but less than 12 months. **Sustained remission** is used if no symptoms (**full remission**) or fewer than three symptoms (**partial remission**) of alcohol dependence are present for at least 12 months. Finally, if the individual is in a setting in which he or she has no access to alcohol, the course specifier **in a controlled environment** is added.

**Alcohol abuse** is considered to be present only if the individual's drinking pattern has never met criteria for alcohol dependence and he or she demonstrates a pattern of drinking that leads to clinically significant impairment or distress, as evidenced by one or more of the four criteria in DSM-IV for alcohol abuse.

In addition to alcohol abuse and dependence, there is another important group of alcohol-related disorders described in DSM-IV as alcohol-induced disorders. These will be described briefly before returning to a discussion of assessment issues.

**Alcohol Intoxication**

A DSM-IV diagnosis of alcohol intoxication is given when, shortly after alcohol consumption, there are maladaptive behaviors such as aggression or inappropriate sexual behavior, or there are psychological changes such as labile mood and impaired judgment. Clinical signs indicative of alcohol intoxication include slurred

speech, lack of coordination, unsteady gait, nystagmus, impairment of attention and memory and, in the most severe cases, stupor and coma. Alcohol intoxication may also present with severe disturbances in consciousness and cognition (alcohol intoxication delirium), especially when large amounts of alcohol have been ingested or after alcoholic intoxication has been sustained for extended periods. Usually, this condition subsides shortly after alcohol intoxication ends. Physical and mental status examinations accompanied by analysis of blood and urine allow the clinician to rule out general medical conditions or psychiatric disorders mimicking this condition. In this regard, urine toxicology is a valuable tool in ruling out intoxication with benzodiazepines, barbiturates, or other sedatives that can present with a similar clinical picture. Collateral information from relatives or friends confirming the ingestion of alcohol is also useful, and should be actively pursued by the clinician. The blood alcohol level (BAL) is frequently used as a measure of alcohol intoxication, although this measure is less reliable in persons with a high degree of tolerance to alcohol. Alcohol is metabolized in the average adult at a rate of 1 oz or 7 to 10 g/hour. When this clearance rate is surpassed, signs of alcohol intoxication begin to appear. During the ascending limb of the BAL curve, euphoria, anxiolysis and mild deficits in coordination, attention and cognition can be observed at levels between 0.01 and 0.10%. Marked deficits in coordination and psychomotor skills, decreased attention, ataxia, impaired judgment, slurred speech and mood lability can be observed at a greater BAL. Severe intoxication, characterized by lack of coordination, incoherent thoughts, confusion, nausea and vomiting can be observed at BALs between 0.20 and 0.30. However, at these levels some heavy drinking individuals who have developed tolerance to the effects of alcohol may not appear intoxicated and may perform well on psychomotor or cognitive tasks. Stupor and loss of consciousness often occur when the BAL is between 0.30 and 0.40. Beyond this level, coma, respiratory depression and death are possible outcomes. It should also be noted that alcohol intoxication is often associated with toxicity and overdose with other drugs, particularly those with depressant effects on the CNS.

**Alcohol Withdrawal**

Alcohol withdrawal is a condition that follows a reduction in alcohol consumption or an abrupt cessation of drinking in alcohol-dependent individuals. In addition to significant distress, alcohol withdrawal is also associated with impairment of social, occupational and other areas of functioning. Uncomplicated cases of alcohol withdrawal are characterized by signs and symptoms of autonomic hyperactivity, and may include increased heart rate, increased blood pressure, hyperthermia, diaphoresis, tremor, nausea, vomiting, insomnia and anxiety. Onset of symptoms of uncomplicated alcohol withdrawal usually occurs between 4 and 12 hours following the last drink. Symptom severity tends to peak around the second day, usually subsiding by the fourth or fifth day of abstinence. After this period, less severe anxiety, insomnia and autonomic symptoms may persist for a few weeks, with some individuals experiencing a protracted alcohol-withdrawal syndrome up to 5 or 6 months after cessation of drinking. A small but significant number of alcohol-dependent individuals (10%) can experience complicated alcohol-withdrawal episodes. Alcohol-withdrawal delirium (also known as delirium tremens) can occur in 5% of the cases, usually between 36 and 72 hours following alcohol cessation. In addition to signs of autonomic hyperactivity, this condition is characterized by illusions, auditory, visual, or

tactile hallucinations, psychomotor agitation, fluctuating cloudiness of consciousness and disorientation. Grand-mal seizures associated with alcohol-withdrawal occur in 3 to 5% of the cases, typically within the first 48 hours following reduction or cessation of drinking. In both instances of complicated alcohol withdrawal, lack or delay in instituting proper treatment is associated with an increased mortality rate. Prior history of delirium tremens and/or alcohol-withdrawal seizures, older age, poor nutritional status, comorbid medical conditions and history of high tolerance to alcohol are predictors of increased severity of alcohol withdrawal.

### **Alcohol-induced Persisting Amnesic Disorder**

Continuous heavy alcohol consumption can lead to several neurological deficits caused by thiamin deficiency. Among them, alcohol-induced persisting amnesic disorder (AIPAD, also known as a Korsakoff's psychosis, due to the fantastic confabulatory stories described by patients suffering this condition) is prominent. Profound deficits in anterograde memory and some deficits in retrograde memory characterize this condition. Patients cannot retain or learn new information and experience profound disorientation to time and place. The severity of anterograde memory deficits typically leads Korsakoff's patients, who are unaware of their deficit, to reconstruct forgotten events by confabulating. Korsakoff's amnesic disorder is usually preceded by several episodes of Wernicke's encephalopathy, characterized by confusion, ataxia, nystagmus and gaze palsies. When this condition subsides, the characteristic memory deficits of Korsakoff's psychosis become prominent.

Cessation of drinking can lead to an improvement in memory with approximately 20% of the cases demonstrating complete recovery. However, in most cases memory deficits remain unchanged, and in some instances long-term care is needed despite sobriety.

### **Alcohol-induced Persisting Dementia**

Continuous heavy drinking is also associated with progressive and gradual development of multiple cognitive deficits characterized by memory impairment, apraxia, agnosia, or disturbances in executive functioning. These deficits cause serious impairment in social and occupational functioning and persist beyond the duration of alcohol intoxication and alcohol withdrawal. History, physical exam and laboratory tests should be utilized to determine whether these deficits are etiologically related to the toxic effects of alcohol use. Other factors associated with this condition are poor nutritional status and vitamin deficiencies, as well as history of head trauma. It is believed that this condition is associated with the repeated occurrence of Wernicke's encephalopathy. Atrophy of frontal lobes and increased ventricular size have been described in this condition. Continuous alcohol consumption exacerbates the dementia, whereas drinking cessation is associated with improvement and even recovery of cognitive deficits.

### **Alcohol-induced Mood Disorder**

Alcohol-induced mood disorder (AIMD), characterized by depressed mood and anhedonia, as well as elevated, expansive, or irritable mood, frequently develops as a consequence of heavy drinking. Onset of symptoms can occur during episodes of alcohol intoxication or withdrawal, and may resemble a primary

major depressive, manic, hypomanic, or a mixed episode. In contrast to the dysphoria and lack of energy observed during episodes of alcohol withdrawal, severity and duration of alcohol-induced mood symptoms is greater than is usually expected, warranting independent attention by the clinician. Although mood disturbances are common among alcoholic patients entering treatment (80%), alcohol-induced mood symptoms tend to subside within 2 to 4 weeks following alcohol cessation. Evidence that the mood disturbances are not better explained by a primary mood disorder should be sought by the clinician. Evidence suggesting a primary mood disorder includes onset of mood symptoms preceding onset of alcohol abuse and persistence of mood symptoms after alcohol cessation or during extended periods of abstinence. Regardless of the primary or secondary nature of mood symptoms, given the high prevalence of suicide among alcoholics, clinicians should closely monitor the patient for emerging suicidal thoughts, implementing more intensive treatment (discussed later) if necessary.

### **Alcohol-induced Anxiety Disorder**

Although alcohol has anxiolytic properties at low doses, heavy alcohol consumption can induce prominent anxiety symptoms. Alcohol-induced anxiety (AIA) symptoms more commonly include generalized anxiety symptoms, panic attacks and phobias. In order to establish this diagnosis, clinicians must rule out other general medical conditions or psychiatric disorders that can mimic this problem. AIA may develop during alcohol intoxication or withdrawal, but its severity and duration are typically worse than the anxiety normally observed during the course of these conditions. An onset of drinking preceding the anxiety syndrome, and improvement or remission of anxiety during periods of abstinence, suggest AIAD. Monitoring the course of these symptoms for several weeks after alcohol cessation can be useful in determining their nature. Usually, a substantial improvement of anxiety will be observed during this period, suggesting a direct relationship of anxiety to alcohol. In some cases, a full remission of symptoms is not observed until after 3 to 4 weeks of abstinence.

### **Alcohol-induced Psychotic Disorder**

This disorder is characterized by prominent hallucinations or delusions that are judged by the clinician to be due to the effects of alcohol. The psychotic symptoms usually occur within a month of an alcohol intoxication or withdrawal episode, and the patient is characteristically fully alert and oriented, lacking insight that these symptoms are alcohol-induced. Although onset of psychotic symptoms can occur during or shortly after alcohol intoxication, delirium or alcohol withdrawal delirium, alcohol-induced hallucinations, and/or delusions do not occur exclusively during the course of these conditions. Evidence that hallucinations and delusions are not part of a primary psychotic disorder include: atypical or late age of onset of psychotic symptoms, onset of alcohol drinking preceding the onset of psychiatric symptoms, and remission of psychotic episodes during extended periods of abstinence. Usually, alcohol-induced psychotic symptoms tend to subside within a few weeks of abstinence, although in a subset of patients psychotic symptoms can become chronic, requiring long-term treatment with antipsychotic medication. In these cases clinicians are obligated to consider a schizophrenic or a delusional disorder as part of the differential diagnosis.

### Alcohol-induced Sleep Disorder

Heavy alcohol consumption can be associated with a prominent disturbance of sleep. At intoxicating BALs, especially when blood alcohol levels are declining, sedation and sleepiness can be observed. Alcohol intoxication induces an increase in nonrapid eye movement (NREM) sleep, whereas rapid eye movement (REM) sleep density decreases. Subsequently, there is an increase in wakefulness, restless sleep, and vivid dreams or nightmares related to a reduction in NREM sleep and a rebound in REM sleep density. During alcohol withdrawal, sleep is fragmented and discontinuous with an increase in REM sleep. After withdrawal, patients frequently complain of sleep difficulties and may experience superficial and fragmented sleep for months or years.

In contrast to the primary sleep disorders (PSD), alcohol-induced sleep disorder (AISD) is characterized by an onset of drinking preceding the sleep disturbance and by remission of symptoms during the course of sustained abstinence. AISD can occur during the course of a typical alcohol intoxication or alcohol withdrawal episode. However, duration and severity of the sleep disturbances exceed those typically observed during these conditions. Given that protracted alcohol-withdrawal symptoms are frequent among abstinent alcoholics, onset of AISD can occur up to 4 weeks after initiation of alcohol abstinence. History of a previous PSD and/or persistence of sleep disturbances for more than 4 weeks following intoxication or acute withdrawal are highly suggestive of a PSD. Differential diagnosis is complicated by the fact that heavy alcohol consumption can cooccur and exacerbate other psychiatric disorders that present with sleep disturbances (e.g., mood disorders, anxiety). Alcohol consumption can also intensify other sleep problems such as narcolepsy or breathing-related sleep disorders BRSD.

### Alcohol-induced Sexual Dysfunction

Although small doses of alcohol in healthy individuals appear to enhance sexual receptivity in women and facilitate arousal to erotic stimuli in men, continuous and/or heavy drinking may cause significant sexual impairment. Alcohol-induced sexual dysfunction is characterized by impaired desire, impaired arousal and impaired orgasm, or sexual pain. It is also associated with marked distress or interpersonal conflicts. Onset of these impairments usually occurs during alcohol intoxication but duration of symptoms exceeds the uncomplicated course of alcohol intoxication. Symptoms usually subside after 3 to 4 weeks of alcohol abstinence. Persistence of symptoms beyond this time may suggest a primary sexual dysfunction (PSD) or a sexual dysfunction due to the medical complications of alcoholism (e.g., neuropathy, alcoholic-liver disease). Onset of a recurrent sexual dysfunction preceding the onset of alcohol abuse also suggests a primary disorder. Use of other substances, particularly those prescribed for the treatment of alcohol withdrawal such as benzodiazepines or barbiturates, should be ruled out as a cause of the sexual dysfunction.

### Assessment of Alcohol Use Disorders

Comprehensive assessment provides the basis for an individualized plan of treatment. Depending upon the severity of alcohol dependence, the nature of comorbid medical and psychiatric pathology, the presence of social supports, and evidence of previous response to treatment, decisions can be made concerning the most appropriate intensity, setting and modality of treatment.

Although denial of alcohol-related problems is legendary among alcoholics, there is substantial evidence that a valid alcohol history can be obtained, given adequate assessment procedures and the right conditions. A complete alcohol history should include specific questions concerning average alcohol consumption, maximal consumption per drinking occasion, frequency of heavy drinking occasions and drinking-related social problems (e.g., objections raised by family members, friends, or people at work), legal problems (including arrests or near-arrests for driving while intoxicated [DWI]), psychiatric symptoms (e.g., precipitation or exacerbation of mood or anxiety symptoms), and alcohol-related medical problems (e.g., alcoholic gastritis or pancreatitis).

It is crucial that questions concerning alcohol consumption and related problems be asked nonjudgmentally in order to enhance the likelihood of accurate reporting. The optimal approach to history-taking in the substance abuse patient includes reassuring the patient that information provided will be kept confidential. The interview begins with questions that are least likely to make the patient defensive (e.g., a review of systems or psychiatric symptoms, without relating these to alcohol use), and beginning questions with **How**, rather than with **Why**, to reduce the appearance of being judgmental (Schottenfeld, 1994).

### Screening

Systematic clinical assessment often begins with routine screening to identify active cases, as well as persons at risk. During the past 25 years a number of self-report screening tests have been developed to identify alcoholics as well as persons at risk of alcohol problems. The Michigan Alcoholism Screening Test (MAST), developed by Selzer (1971), is one of the most often cited instruments. It contains 25 items that ask about drinking habits, as well as social, occupational and interpersonal problems associated with excessive drinking. A total score is calculated, placing the individual along a continuum from “nonalcohol dependent” to “definitely alcohol dependent”. There are several shortened versions of the MAST (e.g., the 10-item Brief MAST, the 13-item Short MAST and the 35-item Self-Administered Alcohol Screening Test – SAAST). Perhaps the most widely used alcohol screening test is the CAGE (Ewing, 1984), which contains only four questions: 1) Have you ever felt you ought to **Cut** (the “C” in CAGE) down on your drinking? 2) Have people **Annoyed** (A) you by criticizing your drinking? 3) Have you ever felt bad or **Guilty** (G) about your drinking? 4) Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover that is, an **Eye opener** (E)? Reliability and validity studies of this test have been conducted in diverse samples (e.g., psychiatric inpatients, ambulatory medical patients, prenatal clinics), with generally acceptable levels of sensitivity. The Alcohol Use Disorders Identification Test (AUDIT) (Saunders *et al.*, 1993; Babor), a 10-item screening instrument, may be used as the first step in a comprehensive and sequential alcohol use history. The AUDIT (Table 35.2) covers the domains of alcohol consumption, symptoms of alcohol dependence and alcohol-related consequences. It has been shown to be sensitive and specific in discriminating alcoholics from nonalcoholics, and is superior to the MAST in identifying hazardous drinkers, that is, those heavy drinkers who have not yet experienced serious harm from their drinking (Bohn *et al.*, 1995). The AUDIT total score increases with the severity of alcohol dependence and related problems, and can be used as part of a comprehensive approach to early identification and patient placement. Because the misuse of both prescribed and illicit

**Table 35.2 Alcohol Use Disorders Identification Test**

1. How often do you have a drink containing alcohol?	Never (0)	Monthly or less (1)	Two to four (2) times a month	Two or three (3) times a week	Four or more (4) times a week
2.* How many drinks containing alcohol do you have on a typical day when you are drinking? [Code number of standard drinks]	1 or 2 (0)	3 or 4 (1)	5 or 6 (2)	7 or 8 (3)	10 or more (4)
3. How often do you have six or more drinks on one occasion?	Never (0)	Less than (1) monthly	Monthly (2)	Weekly (3)	Daily or almost (4) daily
4. How often during the last year have you found that you were not able to stop drinking once you had started?	Never (0)	Less than (1) monthly	Monthly (2)	Weekly (3)	Daily or almost (4) daily
5. How often during the last year have you failed to do what was normally expected from you because of drinking?	Never (0)	Less than (1) monthly	Monthly (2)	Weekly (3)	Daily or almost (4) daily
6. How often during the last year have you needed a first drink in the morning to get yourself going after a heavy drinking session?	Never (0)	Less than (1) monthly	Monthly (2)	Weekly (3)	Daily or almost (4) daily
7. How often during the last year have you had a feeling of guilt or remorse after drinking?	Never (0)	Less than (1) monthly	Monthly (2)	Weekly (3)	Daily or almost (4) daily
8. How often during the last year have you been unable to remember what happened the night before because you had been drinking	Never (0)	Less than (1) monthly	Monthly (2)	Weekly (3)	Daily or almost (4) daily
9. Have you or someone else been injured as a result of your drinking?	No (0)		Yes, but not in (2) the last year		Yes, during the (4) last year
10. Has a relative or friend or a physician or other health care worker been concerned about your drinking or suggested you cut down?	No (0)		Yes, but not in (2) the last year		Yes, during the (4) last year
Record sum of individual item scores here _____.					

\*In determining the response categories, it has been assumed that one “drink” contains 10 g of alcohol.

drugs is common among alcoholics, screening should include other psychoactive substances, including tobacco products.

### Psychiatric History and Examination

Diagnostic assessment in specialized treatment facilities, such as detoxification centers, residential programs, partial hospital programs and outpatient clinics, should be conducted with a standard interview schedule. If it is not possible to use a complete psychiatric interview, such as the Composite International Diagnostic Interview (CIDI) or the Structured Clinical Interview for DSM (SCID), then the alcohol sections of these interviews should be used. Given the lack of reliability in unstructured clinical diagnosis, it is imperative that programs specializing in the treatment of alcohol dependence use a structured interview to conduct and report their diagnostic evaluations.

An important purpose of clinical assessment is to obtain an estimate of illness severity. The number of DSM symptoms obtained using a structured interview can serve this purpose or the total score on the AUDIT screening test.

Assessment of psychological function should focus on measures of depression, anxiety and more global psychological distress. Instruments that are generally reliable, valid and accept-

able in a variety of health care settings include the Beck Depression Inventory and the Symptom Checklist 90-Revised. One subscale of the ASI assesses overall psychiatric severity, including number of inpatient and outpatient treatment episodes, medication status, and lifetime and current symptomatology.

There has been considerable attention devoted to the role of motivation and patient readiness to change, as critical ingredients in treatment planning for alcoholics. The University of Rhode Island Change Assessment Scale (URICA) is a 32-item questionnaire designed to measure the stages of change across diverse problem behaviors. The URICA score profiles have been used to predict treatment response in research on addictive behaviors such as smoking and alcoholism. The readiness to change questionnaire (RCQ) (I) is a short 12-item instrument developed for the same purpose.

### Relevant Physical Examination and Laboratory Findings

Medical illness is a common consequence of heavy drinking and may be present in the absence of physical dependence. Early in the course individuals with alcoholism may show no physical or laboratory abnormalities. But as it progresses, it is widely

manifested throughout most organ systems. A thorough physical examination is indicated if, in the history, there is evidence of medical problems. The physical examination provides essential information about the presence and extent of end-organ damage, and should be focused on the systems most vulnerable to developing alcohol-related pathology: the cardiovascular system, the gastrointestinal system, and the central and peripheral nervous systems. The physician should also be alert to other acute alcohol-related signs, including alcohol withdrawal or delirium, intoxication or withdrawal from other drugs, and the acute presentation of psychiatric symptomatology. Other systemic or nonspecific health problems associated with alcoholism include malnutrition, muscle wasting, neuritis, specific vitamin deficiencies, infectious diseases (such as tuberculosis, dermatitis, pediculosis, and hepatitis) and trauma secondary to fights and accidents.

Laboratory testing can assist the clinician in providing objective, nonjudgmental feedback to alcoholic patients on the negative physical consequences of excessive drinking. Laboratory determinations should be repeated biweekly at the initial phase of treatment, and monthly during the aftercare. Results should be graphically presented to the patient in an easy-to-comprehend format with reference to normal values. This allows the patient to appreciate the declining and eventual stabilization of laboratory indexes thereby enhancing his/her motivation to maintain sobriety.

Laboratory tests can also help to detect relapse to the extent they are sensitive to heavy drinking. Early identification of relapse can prevent the reinstatement of alcohol dependence. It can diminish adverse consequences of heavy drinking by promoting modifications to the original treatment plan and by prompting more aggressive therapeutic interventions. Finally, laboratory markers of drinking can be used to evaluate effectiveness of specific therapeutic interventions and provide funding agencies with objective treatment outcome information.

Several laboratory tests, particularly those related to hepatic function (e.g., serum transaminases, bilirubin, prothrombin time and partial thromboplastin time) have been commonly used by clinicians. Other laboratory tests (e.g., gamma-glutamyl transpeptidase [GGTP], mean corpuscular volume [MCV]) of erythrocytes can be used as objective indicators of heavy drinking. Elevation in GGTP occurs in approximately three-fourths of alcoholics before there is clinical evidence of liver disease. It is often considered to be the earliest indication of heavy alcohol consumption and is widely available clinically. GGTP levels usually return to normal limits after 4 to 5 weeks of abstinence. As with GGTP, elevations of the transaminases serum glutamic oxaloacetic transaminase (SGOT) and serum glutamic pyruvic transaminase (SGPT) are common in other liver diseases. However, elevations in the transaminases are less sensitive indicators of heavy drinking, with SGOT being elevated in 32 to 77% of alcoholics, while elevations in SGPT have been observed in 50% of alcoholics. In contrast to the use of absolute values of SGPT and SGOT, the ratio of SGPT to SGOT may provide a more accurate indicator of heavy drinking. A ratio greater than 2 is more likely to be related to heavy alcohol consumption whereas a ratio below 1 would suggest a different etiology. Elevation of MCV, which has also been associated with folate deficiency, is more prominent in alcoholics, especially among those who are smokers. Though MCV can assist clinicians in identifying patients who are drinking excessively, particularly when this marker is used in combination with GGTP or carbohydrate-deficient transferrin (CDT), this is not an efficient indicator of relapse because of the 2- to 4-month period of abstinence that is needed for its normalization.

CDT is more sensitive than most routine laboratory tests for the identification of heavy alcohol consumption. In contrast to GGTP, CDT elevations are associated with few conditions other than heavy drinking. CDT and GGTP appear to identify two different subsets of alcoholic patients. Elevations in GGTP values detect alcoholics with hepatic damage secondary to heavy drinking, whereas CDT appears to be more directly related to heavy drinking. Whenever possible, CDT and GGTP should be used together by classifying as a case individuals who have elevated scores in either test. This approach increases the likelihood of identifying individuals experiencing alcohol use disorders. CDT appears to detect relapse to heavy drinking among patients in alcohol treatment more accurately than other laboratory tests.

In a clinical setting where laboratory results are generally not immediately available, the alcohol breath test, which measures the amount of alcohol in expired air (providing an estimate of venous ethanol concentration), is valuable. Although its accuracy depends on the patient's cooperation (which in an intoxicated patient is often problematic), the alcohol breath test can be a reliable and inexpensive method for assessing recent alcohol consumption. Venous blood levels should be obtained if dangerously high levels of intoxication are suspected, when a patient is comatose, or for medical-legal purposes. A BAL greater than 150 mg/dL in a patient showing no signs of intoxication (i.e., no dysarthria, motor incoordination, gait ataxia, nystagmus, or impaired attention) can be interpreted to reflect physiological tolerance. In nontolerant individuals, a BAL in excess of 400 mg/dL can result in death, and 300 mg/dL indicates a need for emergency care.

Another laboratory evaluation that is indicated in alcoholics is a urine toxicology screen. To identify drug use that the patient may not recognize or which he or she denies is a problem, the screen should include opiates, cocaine, cannabis and benzodiazepines. Routine urinalysis, blood chemistries, hepatitis profile, complete blood count and serologic test for syphilis and (for the female patient) serum testing for pregnancy should also be obtained.

## Gender and Developmental Presentations

There are substantial differences in the prevalence of alcoholism among different gender, age and racial/cultural groups. Unfortunately, the high prevalence among young adult and middle-aged males often leads to inadequate consideration of the possibility that women and the elderly may drink excessively.

### Women

Women are more likely to abstain from alcohol, and if they do drink, they are more likely to consume less alcohol than men. Nevertheless, in comparison to men, problem drinking among women is more likely to be associated with negative mood states, particularly depression, anxiety and somatic symptoms. Alcoholic women identify negative emotions and interpersonal conflicts as antecedents of a relapse to drinking more frequently than men and substance-dependent women more frequently report depressive and anxiety symptoms as motivators for treatment. This is consistent with epidemiological and clinical studies which show that women who are diagnosed with alcohol or drug dependence experience higher rates of mood and anxiety disorders than their male counterparts. Furthermore, it is more common among women that mood and anxiety disorders precede the onset of substance use and dependence. Alcoholic women have a **Negative profile** of situations surrounding their alcohol use, characterized by solitary drinking and greater severity of alcohol de-

pendence, whereas alcoholic men tend to have a **Positive profile**, characterized by social drinking and drinking in the context of positive emotions. Studies comparing male and female alcoholics have found that women are significantly older than men when a variety of alcohol-related milestones occur, including regular drunkenness, loss of control over drinking, first drinking problems, drinking to relieve withdrawal symptoms, first attempt to stop drinking and realization that alcohol use is a problem. These studies have also found that women exhibit more rapid progression than men between the time of first regular intoxication and first treatment (Randall *et al.*, 1999).

Despite drinking for fewer years at lower levels, women have an increased sensitivity to toxic effects of alcohol on body organs. Alcoholic women are more likely to develop liver damage and, in general, alcoholic liver diseases tend to progress faster among women than men. The five-year mortality rate among alcoholic women is almost twice the mortality rate of alcoholic men. Alcoholic women diagnosed with alcoholic liver disease die almost a decade younger than alcoholic men. Alcoholic women appear to be more susceptible to alcohol-induced brain damage, evidenced by greater widening of the cerebral sulci and fissures in CT scans of the brain, as well as poorer performance in cognitive testing. The concept of “telescoping” has been used to describe the course of symptom progression observed among women who, despite beginning heavy drinking later than men, experience alcohol-related problems and seek treatment sooner than men.

Since alcohol is distributed in the aqueous phase, greater body fat composition among women reduces the volume of distribution. This, combined with smaller average body mass, translates into higher BALs for women in response to a specified level of alcohol consumption. In addition, less first-pass metabolism due to less gastric oxidation of ethanol may also contribute to the higher blood levels obtained by women following an equivalent dose of ethanol. Compared with men, women with alcohol problems are also at greater risk of comorbid drug abuse/dependence. Perhaps as a consequence of these differences, women alcoholics who seek treatment do so earlier in the course of the disorder than do men.

Since heavy drinking among women is most prevalent during the child bearing years, it has important public health implications for prenatal alcohol exposure and possible fetal alcohol effects. A variety of adverse outcomes have been related to heavy drinking in pregnant women, although the minimum amount of alcohol and the pattern of consumption necessary to produce such effects are not known. Heavy drinking in pregnant women may produce malnutrition in both the mother and the fetus, as well as spontaneous abortion, preterm delivery and intrauterine growth retardation. Alcohol-related birth defects (ARBDs) are estimated to occur in as many as 1 in 100 live births. The most severe manifestation of ARBDs is fetal alcohol syndrome (FAS), a constellation of morphological and developmental defects resulting from high-dose prenatal alcohol exposure. FAS is estimated to occur in 1 in 1000 to 1 in 300 live births. Prenatal or postnatal growth retardation, CNS involvement and characteristic facial dysmorphism are necessary for a diagnosis of FAS.

Since ARBDs can be avoided, the evaluation of pregnant patients should routinely include questions about alcohol and other substance use. Routine screening with an instrument such as the AUDIT, or the T-ACE (Chang, 2001), supplemented by questions concerning drug use, may also be useful with pregnant women. Those pregnant women who are identified as heavy drinkers or drug users should be designated as “high risk” and provided with specialized, comprehensive perinatal care, includ-

ing rehabilitation and appropriate attention to related psychosocial disabilities.

## Adolescents

There are a number of features that distinguish adolescents with alcohol abuse/dependence from adult alcoholics. As might be expected, adolescents have comparatively short histories of heavy drinking. A corollary to this is the rarity of physiological dependence on alcohol and alcohol-related medical complications among adolescents. Nonetheless, abuse of alcohol and drugs contributes in important ways to morbidity and mortality in adolescents, the leading causes of which are motor vehicle accidents, homicide and suicide. The values and behavior of the adolescent’s peer group are important elements in the evaluation of alcohol use and abuse in the adolescent. The evaluation of adolescents with an alcohol disorder must also take into account other prominent developmental issues that characterize adolescence, including the conflict inherent in asserting one’s independence from the family.

A number of instruments have been developed for the assessment of substance use symptoms and disorders in adolescents (Kaminer, 1994). As is generally true in dealing with adolescents, given their economic and emotional dependence, whenever possible a thorough family evaluation is important for understanding the adolescent’s substance use and related problems.

## The Elderly

Although heavy drinking is less prevalent in the elderly, it is nonetheless an important source of morbidity in this group. Elderly alcoholics suffer from more chronic medical problems and poorer psychosocial functioning than elderly nonalcoholics. The increased use of prescription medications in the elderly increases the potential for adverse pharmacokinetic interactions with alcohol. In addition, decreased cognitive functioning associated with heavy alcohol use can increase medication errors and noncompliance in this group.

The manifestations of alcoholism in the elderly are often more subtle and nonspecific than those observed in younger individuals. Because self-reported alcohol consumption may be particularly unreliable in the elderly, other sources of information such as family and neighbors should be used to identify heavy drinkers. The following areas should be systematically evaluated in the elderly when heavy drinking has been identified: untreated medical illness, prescription drug abuse, psychiatric comorbidity, cognitive impairment, functional assessment and need for social services.

Similar to the approach used with younger adults, alcoholism in the elderly has been classified by age of onset. It has been estimated that about two-thirds of elderly alcoholics began heavy drinking prior to age 60, while the remaining one-third began heavy drinking after the age of 60. Late-onset alcoholism appears to be more common among women and people of higher socioeconomic status and is less frequently associated with a family history of alcoholism. As might be expected, older alcoholics with early-onset alcoholism also have more alcohol-related medical and psychosocial problems and are more likely to require alcoholism treatment.

## Epidemiology and Comorbidity

### Patterns of Drinking and Types of Alcohol Problems in the USA

The majority (85.8%) of the US population aged 18 year and older has used alcohol in their lifetime, although only half (50.0%)

report current drinking. The highest rates of current use are among young adults aged 18 to 25 years, with males predominating. NonHispanic whites have the highest prevalence of drinking (89.3% lifetime use and 53.7% past month use), while Asians are least likely to drink (62.7% lifetime and 33.4% current). The prevalence of drinking is positively associated with education level; persons with less than a high school education are almost half as likely to report past month drinking as college graduates (33.5% compared with 62.6%).

More than 1 in 5 persons aged 18 years and older (21.4%) reported binge drinking in the past month, and more than 1 in 20 (6.1%) reported heavy alcohol use. Consistent with the prevalence of drinking, both binge and heavy drinking are more likely to be found among young adults and males. Compared with women, men are twice as likely to binge drink (defined as five or more drinks per occasion) and are four times more likely to be heavy drinkers. Asians, followed by blacks, have the lowest levels of binge drinking (11.6 and 18%, respectively); Hispanics and those reporting a mixed racial background have the highest prevalence of binge drinking (23.5 and 23.1% respectively). Heavy drinking is most often reported by those with multiple racial backgrounds (8.9%), followed by nonHispanic whites (6.5%). In contrast to the demographic correlates of any alcohol use, binge drinking and heavy alcohol use appear to have a curvilinear relationship with education level. The lowest levels of binge and heavy problem drinking are found among those with the least and most education.

Several large-scale community studies conducted since 1980 have provided estimates of the lifetime and past year prevalence of alcohol use disorders in the general population. For example, the National Comorbidity Study (NCS), a representative household survey of 8098 persons aged 15 to 54 years that was conducted between 1990 and 1992, assessed lifetime and past-year alcohol disorders using DSM-III-R criteria. The NCS estimated that the lifetime prevalence of alcohol abuse and alcohol dependence for adults 18 to 54 years old were 9.4 and 14.1%, respectively, indicating that more than one-in-five young to middle-aged adults in the USA have had a pattern of alcohol use that met criteria for lifetime alcohol disorder. The prevalences of alcohol abuse and dependence during the 12 months preceding the interview were 2.5 and 4.4%, respectively.

Narrow and colleagues (2002) applied “clinically significant” criteria to the NCS data to determine the percentage of the population who were in need of treatment, more in keeping with DSM-IV diagnostic guidelines. The revised estimates of the 12-month prevalence of clinically significant alcohol disorder is 5.2% for adults in the USA (including 6.5% of adults aged 18–54 years and 2% of adults aged 55 years or older).

Differences in the rates of disorder across the various studies have been attributed to differences in diagnostic criteria, age ranges of the samples and sampling approaches. Regardless of the differences, it should be noted that all of these studies are based on self-reports of drinking behavior and are likely to be conservative estimates of the prevalence of problem drinking due to underreporting.

Analyses of national prevalence data show that disorder rates vary by gender, age, race, ethnicity, socioeconomic status and geographic location. The prevalence of alcohol disorder is consistently found to be higher among men than women, often at a ratio of two to one or greater Substance Abuse and Mental Health Services Administration, 2000). Evidence suggests, however, that the gender differential has narrowed among more

recent cohorts of young adults, in part due to an increased likelihood of early onset drinking among women and the subsequent emergence of drinking problems. The highest prevalence rates of alcohol abuse and dependence occur among young adults, with a gradual decline associated with increasing age. The highest rates of past year dependence were found among those identifying their racial/ethnic background as “multiple race” (9%). There is a negative association between education level and alcohol dependence and 1-year alcohol dependence risk is highest among the unemployed). Urban residence is associated with higher rates of alcohol dependence.

Adverse consequences of drinking include a variety of social, legal and medical problems. Overall, alcohol-related mortality in 1988 totaled 107800 deaths, or about 5% of all deaths in the USA, putting it among the top four causes of death. Of alcohol-related deaths, approximately 17% were directly attributable to alcohol, 38% resulted from diseases indirectly attributable to alcohol and 45% were attributable to alcohol-related traumatic injury (US Department of Health and Human Service, 1994). Alcohol-related mortality declined during the last few decades of the 20th century.

Alcohol-related morbidity is manifested in virtually all organ systems. The primary chronic health hazard associated with heavy drinking is cirrhosis of the liver, which in 1988 was the ninth leading cause of death in the USA. Although the percentage of drivers in fatal crashes with BALs in excess of the legal limit has declined in recent years, alcohol intoxication remains a major contributor to this and other types of accidental injury, as well as to suicide and homicide. In addition, heavy drinking has been implicated in such health conditions as FAS, esophageal cancer, chronic pancreatitis, nutritional deficiencies, cardiomyopathy, hypertension and neurological problems. The social consequences of alcohol abuse and dependence are equally serious, with heavy drinking contributing to a variety of family, work and legal problems. The economic impact of alcoholism is substantial. Alcohol abuse and dependence contribute to unemployment, reduced productivity in the workplace and crime, as well as increased costs for health care. It has been estimated that the nonhealth related costs associated with alcohol abuse reached approximately \$13 billion in 1992, owing in part to costs associated with crime committed while under the influence of alcohol. In summary, the annual cost of heavy drinking and alcohol-related disorders in the USA (both in dollars and in suffering) is enormous. Successful efforts to reduce the burden of illness attributable to alcohol could produce substantial reductions in the social, economic and personal costs of alcohol-related problems.

### Psychiatric Comorbidity in Individuals with an Alcohol Use Disorder

High rates of comorbid psychiatric disorders have been found in both clinical and community samples of alcohol-dependent individuals. These studies show a consistent association between alcohol abuse/dependence and a variety of other psychiatric symptoms and disorders. The Epidemiological Catchment Area (ECA) study, for example, revealed that 36.6% of those with a lifetime alcohol use disorder received at least one other psychiatric diagnosis, which is nearly double the rate for community respondents with no lifetime alcohol disorder (Regier *et al.*, 1990). The evidence from the NCS study showed that cooccurring disorder is more likely with alcohol dependence than alcohol abuse (Kessler *et al.*, 1997). Among individuals with one or more

psychiatric disorders, 22.3% also had a lifetime alcohol disorder, substantially greater than the overall lifetime prevalence of alcohol abuse/dependence (13.5%). Women diagnosed with an alcohol disorder appear to be at greater risk for a comorbid psychiatric disorder. The NCS found that 72% of females with a lifetime alcohol abuse diagnosis had experienced one or more cooccurring psychiatric disorders, compared with 57% of men who had a lifetime history of alcohol abuse. While the prevalence of comorbid disorders was greater with alcohol dependence, the gender differential was smaller: 86% of women and 78% of men with lifetime alcohol dependency had had other lifetime DSM-III-R disorders.

The most frequent cooccurring diagnoses are for other drug use disorders, conduct disorder, antisocial personality disorder, anxiety disorders and affective disorders. The relative risks for different types of disorder vary somewhat by gender. Among women, anxiety and affective disorders are the most common cooccurring disorders. Among men with a history of alcohol abuse or dependence, drug disorders and conduct disorder account for the largest proportion of comorbid cases.

Both community and clinical studies underscore the importance of ASPD and drug abuse/dependence as comorbid diagnoses in individuals with an alcohol disorder. The odds ratios obtained for these disorders in community studies indicate that these associations are elevated not only as a function of greater treatment-seeking behavior in affected individuals, but also because of potential commonalities in the etiology and development of alcohol abuse/dependence. That is, genetic and/or psychosocial risk factors for the development of ASPD are likely to overlap with factors that increase risk for alcohol and drug use disorders. Similarly, the risk factors for alcohol and drug use disorders may overlap with those for schizophrenia and bipolar disorder. In contrast, although anxiety disorders and depression are highly prevalent in clinical samples of alcohol-dependent individuals, their association with alcohol dependence appears largely due to chance, since these disorders are also highly prevalent in the general population.

Given a high rate of psychiatric comorbidity, it is axiomatic that a careful psychiatric assessment be conducted in patients being seen for alcohol treatment, and that alcohol use and associated problems be evaluated in patients being seen primarily for other psychiatric conditions. Because the presence of comorbid disorders may have important implications for the development of alcoholism and its prognosis, the assessment of comorbid psychopathology is an essential element in the clinical evaluation. When comorbid diagnoses are present, an effort should be made to ascertain the order of onset of each disorder since treatment and prognosis may follow from such information.

### Course and Natural History

Schuckit and colleagues (1993) found that the symptoms of alcohol dependence appear in the following sequence in a sample of male veteran alcoholics: heavy drinking during the late twenties; interference with functioning in multiple life areas during their early thirties; loss of control, followed by an intensification of social and work-related problems, and onset of medical consequences in the mid- to late thirties; and severe long-term consequences by the late thirties and early forties. However, as mentioned above, women appear to experience many of these milestones at a later age than men. The study by Schuckit and colleagues showed no effect of onset age, family history of alcohol-

ism, or comorbid psychiatric diagnoses on the order of symptom appearance. However, other features defining the course of alcoholism, particularly the response to treatment, vary as a function of patient-related variables, including age of onset, severity of alcohol dependence and comorbid psychiatric disorders. There is consistent evidence that early age of onset is a predictor of greater severity of alcoholism and a poorer response to treatment.

Although a number of studies have shown that patients experience substantial improvement during the year following alcoholism treatment (Lindstrom, 1992), Vaillant (1983) found that treatment had minimal effects on long-term outcome. More long-term treatment outcome studies are needed to examine the impact of different kinds of alcoholism treatment on the course of the disorder. Additional studies are also needed to clarify both the prognostic significance of patient-related variables, including comorbid psychiatric disorders, and their interaction with different kinds of treatment.

## Treatment

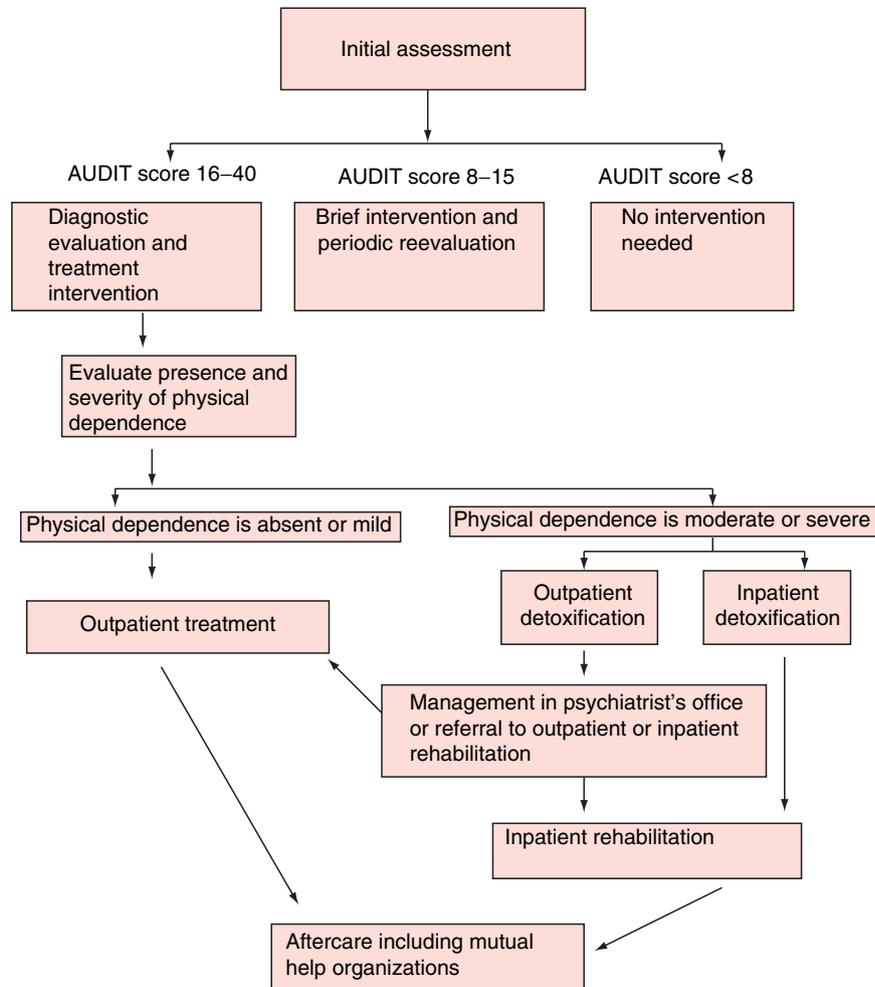

### Goals, Setting and Costs of Treatment

When a determination has been made that an individual is drinking excessively, the nature, setting and intensity of the intervention must be determined in order to address the specific treatment needs of the patient. Among heavy drinkers without evidence of alcohol dependence, a brief intervention aimed at the reduction of drinking may suffice. In contrast, among alcoholics, there are typically a variety of associated disabilities, so it is necessary to address both the excessive drinking **and** problems related to it. Consequently, alcoholism treatment is best conceived of as multimodal. Table 35.3 provides an overview of the goals of alcoholism treatment. It should be noted that while total abstinence is a primary goal of treatment for persons with alcohol dependence, moderate drinking can be considered as a goal for persons with alcohol abuse.

Figure 35.1 describes a process for the management of patients with alcohol abuse and dependence. The algorithm is written from the perspective of a community-based or consultation/liaison psychiatrist who does not necessarily have specialized training in addiction medicine. Following the initial

**Table 35.3** Goals of Alcoholism Treatment

Promote complete abstinence from alcohol.
Stabilize acute medical (including alcohol withdrawal) and psychiatric conditions, as needed.
Increase motivation for recovery.
Initiate treatment for chronic medical and psychiatric conditions, as needed.
Assist the patient in locating suitable housing (e.g., moving from a setting in which drinking is widespread), as needed.
Enlist social support for recovery (e.g., introduce to 12-step programs and, when possible, help the patient to repair damaged marital and other family relationships).
Enhance coping and relapse prevention skills (including social skills, identification and avoidance of high-risk situations).
Improve occupational functioning.
Promote maintenance of recovery through ongoing participation in structured treatment or self-help groups.

**Figure 35.1** Algorithm for the identification and management of patients with alcohol abuse and dependence.

assessment, using a screening test like the CAGE or AUDIT, the patient is referred to either a diagnostic evaluation with a likely treatment recommendation or a brief intervention with further monitoring. Brief interventions are characterized by their low intensity and short duration. They typically consist of one to three sessions of counseling and education. They are intended to provide early intervention, before or soon after the onset of alcohol-related problems. Brief interventions seek to motivate high risk drinkers to moderate their alcohol consumption, rather than promote total abstinence with specialized treatment techniques. They are simple enough to be delivered by primary care practitioners and are especially appropriate for psychiatric patients whose at-risk drinking meets criteria for alcohol abuse rather than dependence.

If the patient's screening results and diagnostic evaluation provide evidence of alcohol dependence, the next step is to differentiate between mild and more severe levels of physical dependence to determine the need for detoxification. If withdrawal risk is low, the patient may be referred directly to outpatient therapy. If the withdrawal risk is moderate or high, outpatient or inpatient detoxification is indicated.

There are a number of potentially life-threatening conditions for which alcoholics are at increased risk. The presence of any of the following requires immediate attention: acute alco-

hol withdrawal (with the potential for seizures and delirium tremens), serious medical or surgical disease (e.g., acute pancreatitis, bleeding esophageal varices) and serious psychiatric illness (e.g., psychosis, suicidal intent). In the presence of any of these emergent conditions, acute stabilization should be the first priority of treatment.

The presence of complicating medical or psychiatric conditions is an important determinant of whether detoxification and rehabilitation are initiated in an inpatient or an outpatient setting. Other considerations are the alcoholic's current living circumstances and social support network. Women with children are sometimes unwilling to enter residential treatment unless their family needs are taken care of. Homeless people may be eager to enter residential treatment even when their medical or psychiatric condition does not warrant it.

In the alcoholic patient whose condition is stabilized or in the patient without these complicating features, the major focus should be on the establishment of a therapeutic alliance, which provides the context within which rehabilitation can occur. The presence of a trusting relationship facilitates the patient's acknowledgement of alcohol-related problems and encourages open consideration of different treatment options. In addition to participation in structured rehabilitation treatment, the patient should be made aware of the widespread

availability of Alcoholics Anonymous (AA) and the wide diversity of its membership.

Residential settings include hospital-based rehabilitation programs, freestanding units and psychiatric units. With the growth of managed care in the 1990s, there has been a dramatic reduction in the average length of stay for residential treatment and a shift in emphasis to less costly outpatient treatment settings. There is no consistent evidence that intensive or inpatient residential treatment provides more benefit than less intensive outpatient treatment, but for certain kinds of patients residential treatment may have advantages (Finney and Monahan, 1996). In many populations, outpatient programs produce results comparable to those of inpatient programs.

Another approach to patient placement and treatment matching is based on the notion that patients should initially be matched to the least intensive level of care that is appropriate, and then stepped up to more intensive treatment settings if they do not respond.

Despite treatment, some alcoholics relapse repeatedly. For many emergency department personnel, the multiple recidivist alcoholic has come to personify the disorder. For clinicians involved in the delivery of alcoholism rehabilitation services, these individuals' apparent unresponsiveness to treatment may contribute to frustration and a sense of futility. Presently, long-term residential treatment appears to be the only option for alcoholics who do not respond to more limited efforts at rehabilitation. Unfortunately, the availability of such care in many states is limited as a consequence of the effort to deinstitutionalize psychiatric patients.

Finally, the importance of continuing care by means of aftercare groups, and other mutual help organizations cannot be overestimated. The value of these resources as well as the newer pharmacological and nonpharmacological interventions developed in the past two decades are discussed in subsequent sections of this chapter.

## The Management of Alcohol Withdrawal

An important initial intervention for a substantial number of alcohol-dependent patients is the management of alcohol withdrawal through detoxification. The objectives in treating alcohol withdrawal are the relief of discomfort, prevention or treatment of complications, and preparation for rehabilitation. Successful management of the alcohol withdrawal syndrome provides a basis for subsequent efforts at rehabilitation.

Careful screening for concurrent medical problems is an important element in detoxification. Administration of thiamine (50–100 mg by mouth or IM) and multivitamins is a low-cost, low-risk intervention for the prophylaxis and treatment of alcohol-related neurological disturbances. Good supportive care and treatment of concurrent illness, including fluid and electrolyte repletion, are essential.

Social detoxification, which involves the nonpharmacological treatment of alcohol withdrawal, has been shown to be effective. It consists of frequent reassurance, reality orientation, monitoring of vital signs, personal attention and general nursing care. Social detoxification is most appropriate for patients in mild-to-moderate withdrawal. Increasingly, detoxification is being done on an ambulatory basis, which is much less costly than inpatient detoxification. Inpatient detoxification is indicated for serious medical or surgical illness, and for those individuals with a past history of adverse withdrawal reactions or with current evidence of more serious withdrawal (e.g., delirium tremens).

A variety of medications have been used for the treatment of alcohol withdrawal. However, due to their favorable side-effect profile, the benzodiazepines have largely supplanted all other medications. Although any benzodiazepine will suppress alcohol withdrawal symptoms, diazepam and chlordiazepoxide are often used, since they are metabolized to long-acting compounds, which in effect are self-tapering. Because metabolism of these drugs is hepatic, impaired liver function may complicate their use. Oxazepam and lorazepam are not oxidized to long-acting metabolites and thus carry less risk of accumulation.

Although carbamazepine appears useful as a primary treatment of withdrawal the liver dysfunction that is common in alcoholics may affect its metabolism, which makes careful blood level monitoring necessary. Antipsychotics are not indicated for the treatment of withdrawal except in those instances where hallucinations or severe agitation are present, in which case they should be added to a benzodiazepine. In addition to their potential to produce extrapyramidal side effects, antipsychotics lower seizure threshold, which may be particularly problematic during alcohol withdrawal.

## Therapeutic Modalities: Nonpharmacological

A variety of treatment components are delivered within the context of rehabilitation services. In many programs a combination of therapeutic interventions is provided to all clients, based on the assumption that multiple components have a greater chance of meeting at least some of each client's needs. Therapeutic approaches most often employed in both residential and outpatient programs include behavior therapy, group therapy, family treatment and pharmacotherapy. Regarding specific treatment modalities, the weight of evidence suggests that behavioral treatments are likely to be more effective than insight-oriented or family therapies.

Nevertheless, recent research also indicates that Twelve Step Facilitation, which is based on the principles of AA, is as effective as more theory-based therapies.

Cognitive and behavior therapies are among the most investigated theory-based treatments. Behavioral elements most frequently employed in treatment programs are relapse prevention, social skills and assertiveness training, contingency management, deep muscle relaxation, self-control training and cognitive restructuring. Behavior therapists stress the importance of teaching new, adaptive skills designed to alter the conditions that precipitate and reinforce drinking, as well as developing alternative ways of coping with persons, events and feelings that serve to maintain drinking. A number of studies have demonstrated the benefits of teaching social and other coping skills. Patients who received skills training attended aftercare more regularly and they had less severe (though no less frequent) relapses than patients in control groups. These and other trials of cognitive-behavioral treatments have provided the empirical basis for elaboration of a generalized relapse prevention strategy.

In addition to specific treatment for alcoholic couples or families, self-help groups for family members of alcoholics have grown substantially. Al-Anon, although not formally affiliated with AA, shares the structure and many of the tenets of the 12 Steps of AA. Al-Anon and AA meetings are often held jointly. Alateen groups, sponsored by Al-Anon for children of alcoholics, are available as well.

## Therapeutic Modalities: Pharmacological

Although the benzodiazepines have played a key role in the treatment of alcohol withdrawal, pharmacotherapy has not yet had a demonstrable effect on other aspects of alcoholism treatment. Disulfiram, an alcohol-sensitizing drug, has been approved for clinical use in the USA since the 1940s, but it has not been widely prescribed. During the past decade, however, medications have begun to play a more important role both in the treatment of comorbid psychiatric disorders in alcoholics and in the rehabilitation of alcohol dependence. In dually diagnosed patients, medications that reduce psychiatric symptomatology may also reduce the risk of drinking. Independent of their effects on comorbid psychopathology, medications that reduce drinking may enhance the alcoholic's participation in psychosocial treatment. This rationale is similar to that underlying the combination of medications with psychotherapy in the treatment of depressive or anxiety disorders.

### Alcohol-sensitizing Drugs

Medications such as disulfiram or calcium carbimide cause an unpleasant reaction when combined with alcohol. The efficacy of such drugs in the prevention or limitation of relapse in alcoholics has not been demonstrated. However, these drugs may be of utility in selected samples of alcoholics with whom special efforts are made to ensure compliance.

Disulfiram (Antabuse) is the most commonly used alcohol-sensitizing medication and the only one approved for use in the USA. When given in a single daily dose of 125 to 500 mg, disulfiram binds irreversibly to ALDH, permanently inactivating this enzyme. When alcohol is consumed, it is metabolized to acetaldehyde which accumulates due to inhibition of the enzyme that metabolizes it. Elevated levels of acetaldehyde are responsible for the aversive effects associated with the disulfiram-ethanol reaction (DER).

In addition to its effects on ALDH, disulfiram inhibits a variety of other enzymes. Disulfiram also reduces clearance rates of a number of medications. Common side effects of disulfiram include drowsiness, lethargy and fatigue. More serious adverse effects, such as optic neuritis, peripheral neuropathy and hepatotoxicity are rare. The exacerbation of psychotic symptoms in patients with schizophrenia, and occasionally their appearance in other individuals as well as the development of depression, may be linked to inhibition of the enzyme dopamine-beta-hydroxylase. As with its neuropathic effects, the psychiatric effects of disulfiram are uncommon and may only occur at higher dosages of the medication.

Disulfiram is usually given orally. Although the daily dosage prescribed in the USA has been limited to 250–500 mg/day, some patients require in excess of 1 g/day of disulfiram to reach blood levels sufficient to produce the DER. The requirement that disulfiram undergo bioactivation before it can inhibit ALDH may explain the need for a higher dosage in some patients. At the dosage that is used clinically, faulty bioactivation in some individuals may yield too low a concentration of the active metabolite to inhibit ALDH.

Given the limited efficacy of disulfiram for the prevention of relapse, it should not be used as a first line treatment for alcohol dependence. However, if a patient has not responded to other pharmacological treatments and is motivated to take disulfiram, it may be beneficial. Whenever disulfiram is prescribed patients should be warned about its hazards, including the need to avoid over-the-counter (OTC) preparations with

alcohol and drugs that interact adversely with disulfiram, as well as the potential for a DER to result from alcohol used in food preparations.

## The Treatment of Psychiatric Comorbidity in Alcoholics

Comorbid psychiatric disorders may contribute to the development or maintenance of heavy drinking. Efforts to treat the comorbidity may have beneficial effects on drinking outcomes. Following detoxification, many alcoholics complain of persistent anxiety, insomnia and general distress. These symptoms may last for weeks or months and may be difficult to differentiate from the emergence of diagnosable psychiatric disorders. Irrespective of their etiology, negative emotional states, including frustration, anger, anxiety, depression and boredom, have been shown to contribute to relapse in a substantial proportion of alcoholics.

A variety of medications have been employed to treat comorbid psychiatric symptoms and disorders in alcoholics. Indications for the use of these medications in alcoholics are similar to those for nonalcoholic populations, but there is added potential for adverse effects due to comorbid medical disorders and the pharmacokinetic effects of acute and chronic alcohol consumption. The use of these medications in alcoholics therefore entails additional considerations that can only be arrived at through careful psychiatric diagnosis.

### Treatment of Depressive Symptoms/Disorders

Although it has been argued that most instances of postwithdrawal depression will spontaneously remit within a few days to several weeks there are still a substantial number of patients whose severe and persistent depression requires treatment. Given the superior safety profile of SSRIs, particularly in relation to risk of suicide by medication overdose, use of these drugs is preferable to the use of TCAs.

### Treatment of Anxiety Symptoms/Disorders

A number of studies have shown chlordiazepoxide to be effective in the maintenance of alcoholics in long-term outpatient treatment. However, the potential for additive CNS depression produced by the concurrent use of alcohol and benzodiazepines is well recognized.

Furthermore, the use of benzodiazepines may itself result in tolerance and dependence and may increase depressive symptoms. Although this concern may be exaggerated and all benzodiazepines may not be equal in their capacity to produce dependence in alcoholics the use of benzodiazepines in alcoholics is probably best limited to detoxification. Buspirone, a nonbenzodiazepine anxiolytic that is less sedating than diazepam or clorazepate, does not interact with alcohol to impair psychomotor skills, and has a low potential for abuse. When combined with appropriate psychosocial treatment, buspirone appears useful in the treatment of alcoholics with persistent anxiety. Currently, antipsychotics are indicated only in alcoholics with a coexistent psychotic disorder or for the treatment of alcoholic hallucinosis. Several placebo-controlled studies have found no advantage in the use of phenothiazines for treatment of anxiety, tension and depression following detoxification (Jaffe *et al.*, 1992). Because of their capacity to lower seizure threshold, antipsychotics should be used with caution in this population.

## Drugs that May Directly Reduce Alcohol Consumption

A number of specific neurotransmitter systems have been implicated in the control of alcohol consumption, including endogenous opioids, catecholamines, especially dopamine and serotonin. Although these systems appear to function interactively in their effects on drinking behavior, efforts to use medications to treat excessive drinking have increasingly focused on agents that have selective effects on specific neurotransmitter systems.

### Opioid Antagonists

An extensive literature supports the role of opioidergic neurotransmission in the pathophysiology of alcohol consumption and related phenomena. For example, small doses of morphine increase alcohol intake in experimental animals. In contrast, opioid antagonists, such as naltrexone, decrease ethanol consumption and self-administration. Effects similar to those in animals have been reported in some, but not all, studies of naltrexone for the treatment of alcohol dependence (Kranzler and Van Kirk, 2001). The considerable variability in findings concerning the efficacy of naltrexone underscores the need to identify the circumstances under which the medication exerts its therapeutic effects. Naltrexone appears to produce a modest effect on drinking behavior among alcoholics. However, given the comparatively small overall effect of the medication, a variety of other factors, including medication compliance, the severity and chronicity of alcohol dependence, and the choice of concomitant psychotherapy, may determine whether an effect of the medication is observed.

### Serotonergic Medications

5-HT has been shown consistently to exert an influence over alcohol consumption in preclinical models of drinking behavior. In contrast to this preclinical literature, data on the effects of serotonergic medications on human drinking behavior are more limited, and the results are less consistent. One explanation for the variable findings in studies of whether SSRIs reduce drinking is the diversity of study samples. The initial studies were conducted in nontreatment-seeking heavy drinkers. Subsequent studies, which have shown differential effects based on severity, suggest that SSRIs are efficacious only in subgroups of alcoholics.

### Acamprosate

Acamprosate, an amino acid derivative, affects both gamma-aminobutyric acid (GABA) and excitatory amino acid (i.e., glutamate) neurotransmission (the latter effect most likely being the one that is important for its therapeutic effects in alcoholism). Together, studies involving more than 4000 patients provide consistent evidence of the efficacy of acamprosate in alcoholism rehabilitation (Kranzler and Van Kirk, 2001). Based on these findings, and the benign side-effect profile of the medication, it appears to hold considerable value for the treatment of alcohol dependence.

### Summary

Considerable additional research is required before medications are likely to play a meaningful role in the postwithdrawal treatment of alcohol dependence. One currently useful strategy is the identification of comorbid psychopathology in alcoholics, with pharmacotherapy directed toward reducing both psychiatric symptoms and alcohol consumption. In addition, the opioid antagonist naltrexone, which is capable of yielding a modest effect overall in reducing drinking behavior, appears to be of consider-

able value in some individuals. Further research is required with naltrexone to determine the optimal dosage, duration of treatment and psychosocial treatment strategies with which to use the medication. The question of whether the medication is most efficacious for alcoholics with high levels of craving for alcohol remains an important one. The SSRIs fluoxetine, citalopram and sertraline may be of value in subgroups of heavy drinkers, particularly those with a later onset of problem drinking. In contrast, ondansetron may be useful in alcoholics with an early onset of problem drinking. Prospective replication of this serotonergic matching strategy is required, however, before it can be recommended for general clinical use. A camprosate could assume a prominent role in the pharmacological management of alcohol dependence in the USA.

## Alcoholics Anonymous (AA) and Mutual Help Organizations

Although mutual help societies composed of recovering alcoholics are not considered a formal treatment, they are often used as a substitute, an alternative and an adjunct to treatment. Mutual help groups based on the Twelve Steps of AA have proliferated throughout the world. To the extent that AA and other mutual help groups are more numerous than outpatient treatment, they may constitute a significant resource for problem drinkers who are attempting to reduce or stop drinking.

With an estimated 87000 groups in 150 countries, AA is by far the most widely utilized source of help for drinking problems in the USA and throughout the world. In addition, a number of self-help organizations have modeled themselves after AA, basing recovery from drug abuse, overeating, and other behavioral disorders on the 12 Steps of AA (see Table 35.4). Unfortunately, clinicians often refer patients to self-help groups such as AA without consideration of the patient's needs and without adequate monitoring of the patient's response. Not all people are willing to endorse the AA emphasis on spirituality and its disease concept of alcoholism, which requires lifelong abstinence as the only means to recovery. Greater familiarity with AA may help clinicians to identify those patients who might benefit from this approach.

Although it is regarded as one of the most useful resources for recovering alcoholics, the research literature supporting the efficacy of AA is limited. Attendance at AA tends to be correlated with long-term abstinence, but this may reflect motivation for recovery. The type of motivated alcoholic that persists with AA might do just as well with other forms of supportive therapy. In fact, the few random assignment studies that have been conducted (Walsh *et al.*, 1991) do not indicate that AA (or similar programs) is more effective than other types of treatment.

Infrequent attempts have been made to assess the efficacy of AA using controlled research designs because of methodological challenges, such as self-selection and ethical concerns about random assignment to treatment conditions. Nevertheless, several large-scale, well designed studies (Project MATCH Research Group, 1997, 1998) suggest that AA can have an incremental effect when combined with formal treatment, and AA attendance alone may be better than no intervention.

A study of long-term outcomes of treated and untreated alcoholics (Timko *et al.*, 2000) indicates that individuals who obtain help for a drinking problem, especially in a timely manner, have better outcomes over 8 years than those who do not receive help, but the type of help they receive (e.g., self-help or formal treatment) makes little difference in long-term outcomes.

**Table 35.4 The 12 Steps of Alcoholics Anonymous**

1. We admitted we were powerless over alcohol – that our lives had become unmanageable.
2. Came to believe that a Power greater than ourselves could restore us to sanity.
3. Made a decision to turn our will and our lives over to the care of God **as we understood Him**.
4. Made a searching and fearless moral inventory of ourselves.
5. Admitted to God, to ourselves, and to another human being the exact nature of our wrongs.
6. Were entirely ready to have God remove all these defects of character.
7. Humbly asked Him to remove our shortcomings.
8. Made a list of all persons we had harmed, and became willing to make amends to them all.
9. Made direct amends to such people wherever possible, except when to do so would injure them or others.
10. Continued to take personal inventory and when we were wrong, promptly admitted it.
11. Sought through prayer and meditation to improve our conscious contact with God **as we understood Him**, praying only for knowledge of His will for us and the power to carry that out.
12. Having had a spiritual awakening as the result of these steps, we tried to carry this message to alcoholics, and to practice these principles in all our affairs.

The 12 Steps are reprinted with permission of Alcoholics Anonymous World Services, Inc. Permission to reprint this material does not mean that AA has reviewed or approved the contents of this publication, nor that AA agrees with the views expressed herein. AA is a program of recovery from alcoholism. Use of the 12 Steps in connection with programs and activities that are patterned after AA but address other problems does not imply otherwise.

## Special Features Influencing Treatment

### Psychiatric Comorbidity

There is considerable evidence that links the outcome of alcoholism treatment to comorbid psychopathology. General measures of psychopathology, as well as the specific diagnoses of drug abuse, drug dependence, antisocial personality disorder and major depressive disorder have been shown to predict poorer outcomes in alcoholics. The extent to which treatment of concomitant psychopathology enhances alcoholism treatment outcome is unclear. Ries (1993) has distinguished among serial, parallel and integrated models for treating these disorders. The serial model involves the treatment of one disorder, followed by the treatment of the second disorder. For example, a psychotic alcoholic might first be treated on a general psychiatric unit and once his acute psychosis is controlled, transferred to an alcoholism rehabilitation program. The parallel treatment approach involves concurrent, but separate, treatment of both the psychiatric and the alcohol use disorder. The integrated model involves the treatment of both disorders in a single treatment setting at the same time. This approach requires that personnel with expertise in both the addictions and psychiatric treatment be available in a single location. Each of these approaches has advantages and disadvantages. For

example, the integrated model, while it provides the most comprehensive approach, is the most difficult and costly to configure and may, therefore, not be feasible for many treatment providers.

## Demographic Features

### Adolescents

Despite a paucity of controlled, age-specific treatment outcome studies of adolescents with alcohol use disorders, the need for prevention and specialized treatment for this group is clear. The literature indicates that in substance-abusing adolescents some treatment is better than no treatment, relapse rates are high, and there is no consistent support for the superiority of any single treatment modality. However, several factors have been associated with better treatment outcome: later onset of problem drinking, pretreatment attendance at school, voluntary entrance into treatment, active parental input and availability of ancillary adolescent-specific services, including those pertaining to school, recreation, vocational needs and contraception.

Because many adolescents have not yet fully developed formal operational thinking, treatment efforts should be concrete and goal-oriented. Furthermore, the clinician should consider the potential impact on treatment of other cognitive problems: learning disabilities, attention-deficit/hyperactivity disorder and other psychopathology which may previously have gone undiagnosed. Treatment of the adolescent with an alcohol use disorder also requires an appreciation of the importance of modeling, imitation and peer pressure, which are intrinsic to identity development. The use of age-appropriate support groups (e.g., Alateen) may be particularly useful in this regard.

### Geriatric Patients

In addition to the high prevalence of medical problems, pharmacokinetic and pharmacodynamic variables can affect treatment outcome in elderly alcoholics. For example, Liskow and colleagues (1989) found that elderly alcoholics, despite having drunk less than younger patients during the month prior to admission, had more severe alcohol withdrawal symptomatology and required a higher dosage of chlordiazepoxide. These investigators speculated that the observed differences might delay the entry of elderly alcoholics into rehabilitation.

An important question in treating elderly alcoholics is the extent to which specialized treatment services improve outcome. Kofoed and colleagues (1987) found that patients treated in special elderly peer groups remained in treatment longer and were more likely to complete treatment than those treated in mixed-age groups. These investigators concluded that elder-specific treatment has differential therapeutic value.

Recent shifts in the demographic features of AA participants suggest that the current cohort of elderly alcoholics has less experience with self-help groups at a time when AA is attracting younger members who are more likely to have comorbid drug abuse/dependence. As a consequence, the elderly can be expected to experience increased difficulty affiliating with AA. This, along with evidence indicating an advantage for age-specific treatment in the elderly, suggests that special efforts should be made to help the elderly alcoholic locate AA meetings that include a substantial proportion of older participants. Age-appropriate AA groups may be especially beneficial to the older alcoholic who is isolated and lonely and for whom the prospect of helping others may help to combat feelings of uselessness.

## Gender (Including Pregnancy)

As described above, epidemiological and clinical studies have shown that alcohol abuse and dependence have become quite common among women, as historical gender differences in drinking problems have diminished during the past 25 years. This trend has promoted greater awareness of the impact of alcohol use on women's health and the importance of gender as a potential determinant of treatment outcome. Nonetheless, the vast majority of studies related to alcohol use and its effects, including the diagnosis and treatment of alcohol dependence, have involved men.

To guide the treatment of alcoholism in women, Blume (1992) suggests that evaluation should include special attention to the identification of physical abuse, sexual abuse, medical problems, psychiatric comorbidity, the presence of alcoholism and drug abuse in spouses, and alcohol-related birth defects in children. To enable women with children to participate in treatment, the availability of child care services is critical, although it must generally be arranged independent of treatment. Blume (1992) also lists the following special treatment needs of women: information about the effects of substance use on the fetus, parenting skills, couples and family therapy, sober female role models, assertiveness training, and an awareness of sexism and its consequences. Special care must also be taken to avoid creating iatrogenic drug dependence in women (e.g., through the use of benzodiazepines to treat comorbid anxiety and depressive symptoms). While these are useful guidelines for treating alcoholic women, empirical research is needed to evaluate these and other issues more systematically.

## Ethnic and Cultural Issues and Treatment

In 1991 approximately two-thirds of patients in alcoholism treatment were white, 17% were black and 12% were Hispanic. Although socioeconomic and cultural issues should be addressed in alcoholism treatment, guidelines for such treatment are based largely on common sense, rather than systematic outcome evaluation. Obviously, where language barriers exist, special efforts must be made to ensure adequate communication. Treatment providers should also be aware of their patients' traditional patterns of drinking, how drinking may be influenced by acculturation, differences among ethnic groups in their perception of alcohol-related problems, the impact of sociocultural differences between patients and providers, and how prevailing social (e.g., family) relationships can affect treatment outcome.

## Conclusion

During the past 25 years significant progress has been made in the scientific study of alcoholism and its treatment. On the basis of evidence reviewed in this chapter, a number of conclusions appear warranted at this time:

1. Alcoholics are heterogeneous with respect to demographic features (e.g., age, gender, race/ethnicity), age of onset of heavy drinking, severity of alcohol dependence, comorbid psychopathology, genetic vulnerability and other prognostic factors.
2. The available evidence suggests that any treatment for alcoholism is better than no treatment. The majority of those treated demonstrate improvement, but many of these alcoholics may improve with minimal treatment.
3. The intensity of treatment has not been shown to produce pronounced differences in outcome (Moos and Moos, in press).

Similarly, medical inpatient treatment, while more costly, is not demonstrably more effective than nonmedical residential or outpatient treatment. For patients with serious comorbid medical and psychiatric disorders, medical inpatient treatment may, nonetheless, be necessary. Some evidence indicates that continuing aftercare helps to maintain abstinence following short-term intensive rehabilitation in inpatient settings.

4. There is little evidence that any one treatment approach is superior. There is some support for certain kinds of behavior therapy, but the effectiveness of AA and disulfiram seem to depend on patient characteristics and compliance. Several kinds of carefully specified and theoretically-derived therapeutic approaches show promise as a basis for a new generation of ambulatory treatments. These include the relapse prevention strategies that teach the alcoholic how to avoid high risk relapse situations, and new pharmacologic agents (e.g., naltrexone) that appear to reduce the alcoholic's risk of relapse by dampening the reinforcement potential of alcohol. Continued improvements in treatment outcome will depend upon successfully matching treatment settings and modalities to the specific needs of the individual patient.

## Comparison of DSM-IV/ICD-10 Diagnostic Criteria

The ICD-10 and DSM-IV-TR criteria sets are nearly identical except for the following: The ICD-10 Diagnostic Criteria for Research for Alcohol Intoxication also lists flushed face and conjunctival injection as symptoms but does not include the DSM-IV-TR item for impairment in attention; the ICD-10 Diagnostic Criteria for Research for Alcohol Withdrawal require three symptoms from a list of 10 which includes headache and splits tachycardia and sweating into two separate items.

# Substance Abuse: Caffeine Use Disorders

Caffeine is most widely consumed psychoactive substance in the world. In North America, it is estimated that more than 80% of adults and children consume caffeine regularly. Habitual consumption of coffee, tea, or caffeinated soda drinks with meals is extremely common and may not be readily recognized as caffeine consumption. This cultural integration of caffeine use can make the recognition of psychiatric disorders associated with caffeine use particularly difficult. However, it is important for the psychiatrist to recognize the role of caffeine as a psychoactive substance capable of producing a variety of psychiatric syndromes, despite the pervasive and well-accepted use of caffeine. In this chapter, five disorders associated with caffeine use are reviewed: caffeine intoxication, caffeine withdrawal, caffeine dependence, caffeine-induced anxiety disorder and caffeine-induced sleep disorder.

## Caffeine Intoxication

### Definition

The *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR) defines caffeine intoxication as a set of symptoms that develop during or shortly after caffeine use (American Psychiatric Association, 2000). There may be two kinds of presentation associated with caffeine intoxication. The first presentation is associated with the **acute** ingestion of a large amount of caffeine and represents an acute drug overdose condition. The second presentation is associated with the **chronic** consumption of large amounts of caffeine and results in a more complicated presentation.

The diagnosis of caffeine intoxication is based on the DSM-IV TR criteria of substance intoxication found in **Chapter 34**. Specifically, this disorder is diagnosed after the consumption of 250 mg of caffeine. Table 36.1 indicates the approximate caffeine content of numerous foods. This diagnosis is entertained when at least five of the following 12 signs are present and they produce significant distress not due to a general medical condition:

- nervousness
- restlessness
- insomnia
- periods of inexhaustibility
- diuresis
- excitement
- gastrointestinal disturbance
- muscle twitching

**Table 36.1** Typical Caffeine Content of Foods and Medications

Substance	Caffeine Content (mg)
Brewed coffee	100 mg/6 oz
Instant coffee	70 mg/6 oz
Espresso	40 mg/1 oz
Decaffeinated coffee	4 mg/6 oz
Brewed tea	40 mg/6 oz
Instant tea	30 mg/6 oz
Canned or bottled tea	20 mg/12 oz
Caffeinated soda	40 mg/12 oz
Cocoa beverage	7 mg/6 oz
Chocolate milk	4 mg/6 oz
Dark chocolate	20 mg/1 oz
Milk chocolate	6 mg/1 oz
Caffeinated water	100 mg/16.9 oz
Coffee ice cream or yogurt	50 mg/8 oz
Caffeinated gum	50 mg/stick
Caffeine-containing analgesics	32–65 mg/tablet
Stimulants	100–100 mg/tablet
Weight-loss aids	40–100 mg/tablet
Sports nutrition	100 mg/tablet

American Society of Addiction Medicine. *Source*: Griffiths RR, Juliano LM and Chausmer AL (in press) Caffeine pharmacology and clinical effects, in *Principles of Addiction Medicine* (eds Graham AN, Schultz TK, Mayo-Smith M *et al.*). Chevy Chase, Maryland.

- psychomotor agitation
- flushed face
- tachycardia or cardiac arrhythmia
- rambling flow of thought and speech

### Acquired Tolerance

In a person who regularly consumes caffeine, tolerance may occur to the acute effects of caffeine. Thus a sensitive person with no tolerance to caffeine might have signs and symptoms of caffeine intoxication in response to a relatively low dose of caffeine (such as 100 mg, the amount found in a typical cup of brewed coffee) (Table 36.1), whereas another person with a high daily consumption of caffeine would show no evidence of intoxication with a similar dose.

## Inadvertent Overdosing

Although caffeine intoxication can occur in the context of habitual chronic consumption of high doses, probably most often it occurs after inadvertent overdosing. Examples include overdosing of intravenous caffeine to children in medical settings (e.g., for respiratory stimulating effects), excessive caffeine consumption in tablet form by students who fail to appreciate the dose being ingested (e.g., to study through the night), and the person who unknowingly consumes a highly concentrated form of caffeine (e.g., caffeinated coffee brewed with caffeine-containing water to create an especially high dose of caffeine in the coffee).

## Pathophysiology

The principal cellular site of action of caffeine is the adenosine receptor, where caffeine functions as an antagonist. Adenosine produces a wide variety of physiological effects, including decreasing spontaneous electrical activity in brain, inhibiting neurotransmitter release in brain, decreasing spontaneous and operant motor activity, dilating central vasculature, producing antidiuresis, inhibiting renin release, and inhibiting gastric secretion and lipolysis. As an antagonist of adenosine many of caffeine's actions are opposite to those produced by adenosine (e.g., central nervous system stimulation, decreased cerebral blood flow, increased renin release and diuresis, increased gastric secretions and stimulation of respiration).

## Assessment

The primary features of caffeine intoxication can be found in the diagnostic criteria from DSM-IV. The diagnostic decision

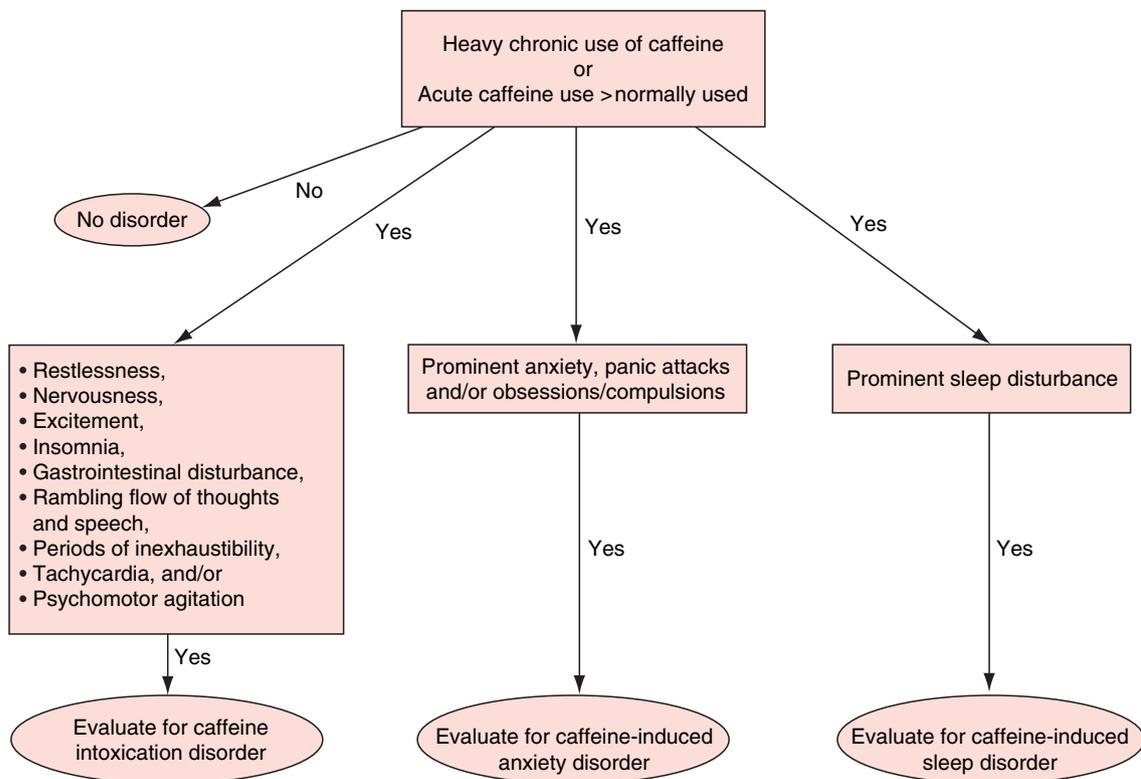

tree for caffeine intoxication disorder, caffeine-induced anxiety disorder and caffeine-induced sleep disorder is shown in Figure 36.1. The most common symptoms reported in decreasing order of frequency are frequent urination, restlessness, insomnia, nervousness and excitement (all which were at rates greater than 20%). In addition, nearly 25% of people report heart pounding in response to high caffeine use (although this is not one of the DSM-IV criteria).

## Differential Diagnosis

The diagnosis of caffeine intoxication is based on the history and clinical presentation of the patient. Ideally, the extent of caffeine exposure can also be assessed by a serum or saliva assay of the caffeine level. In the past, caffeine use has often been overlooked in patients presenting with symptoms consistent with a caffeine use disorder. However, it may be that there is presently a greater awareness of the deleterious effects of caffeine, making psychiatrists more sensitive to the inclusion of caffeine in a differential diagnosis (see Table 36.2), and patients more aware of the possible role of excessive caffeine in somatic and psychological symptoms.

## Epidemiology

Despite the long history of recognition of caffeine intoxication, there is little information available about the prevalence or incidence of caffeine intoxication either in the general community or in selected populations. It appears that the incidence of caffeine intoxication in the general community is about 7% per year, and it may be higher in selected populations at greater risk for caffeine intoxication (e.g., students).

**Figure 36.1** Diagnostic decision tree for caffeine intoxication disorder, caffeine-induced anxiety disorder and caffeine-induced sleep disorder.

**Table 36.2** Differential Diagnosis of Caffeine Intoxication

Manic episode	Panic disorder
Amphetamine/cocaine intoxication	Generalized anxiety disorder
Sedative, hypnotic or anxiolytic withdrawal	Medication-induced side effect (e.g., akathisia)
Nicotine withdrawal	Sleep disorders

### Course

In the patient who is not tolerant to caffeine, acute caffeine ingestion producing caffeine intoxication is a time-limited condition that will rapidly resolve with cessation of caffeine use, consistent with the relatively short half-life of caffeine (3–6 hours).

### Treatment

The first step in evaluating a patient with a possible diagnosis of caffeine intoxication is to obtain a careful history about all recent caffeine consumption. The possible use of beverages and medications – both prescription and over-the-counter (OTC) diet aids and energy pills – should be reviewed. Some beverages (e.g., caffeine-containing soft drinks) and medications (e.g., energy pills, aids to combat sleep, or diet pills) may not be recognized by the patient as containing caffeine. The amount of caffeine acutely consumed should help clarify the diagnosis of caffeine intoxication, although it is important to determine whether the patient has been chronically consuming high doses of caffeine. If this is the case, the patient may be tolerant and therefore less likely to be experiencing caffeine intoxication. However, some clinicians have reported that caffeine intoxication can occur even in the context of chronic caffeine use. The primary approach to the treatment of caffeine intoxication is to teach the patient about the effects of excessive caffeine consumption. In patients who

**Table 36.3** Signs and Symptoms Associated with Caffeine Withdrawal

Headache – most common symptom
Fatigue, lethargy, sluggishness
Sleepiness, drowsiness
Dysphoric mood
Difficulty concentrating
Work difficulty, unmotivated
Depression
Anxiety
Irritability
Nausea or vomiting
Muscle aches or stiffness

are resistant to accepting the role of caffeine in their presenting symptoms, it may be useful to suggest a trial-off of caffeine as both a diagnostic and a potentially therapeutic probe.

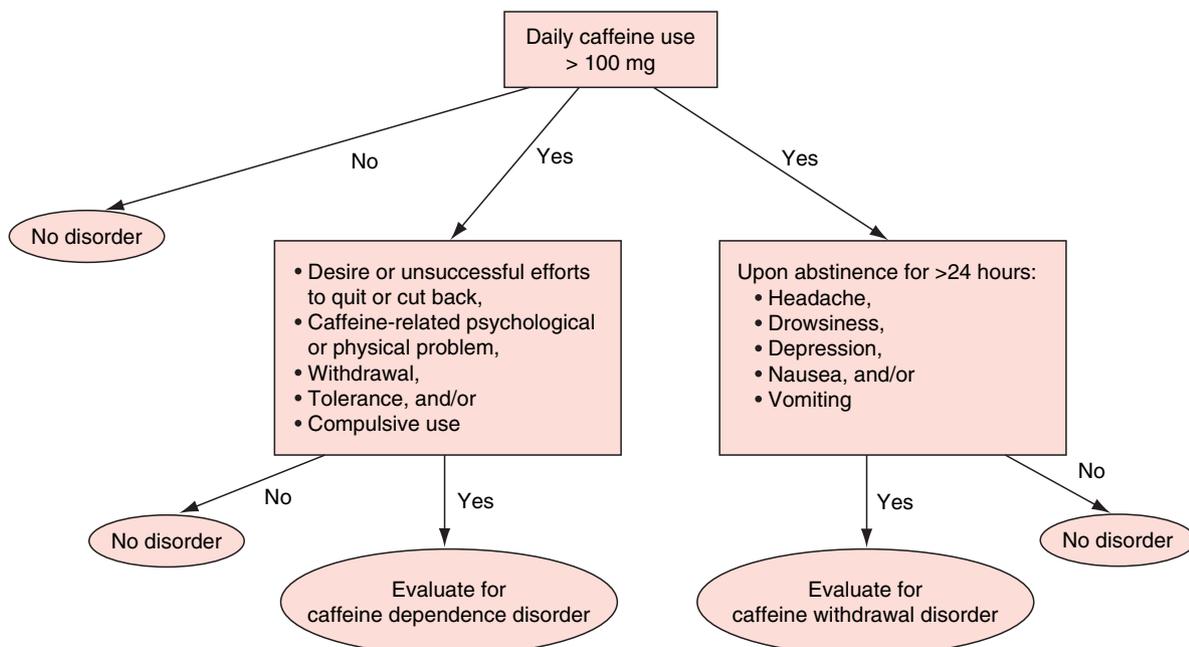

### Caffeine Withdrawal

#### Definition

Table 36.3 lists the signs and symptoms of withdrawal. As is the case with all DSM diagnoses, this disorder implies clinically significant distress or impairment and a general medical condition must be ruled out.

#### Assessment

The key steps in establishing a diagnosis of caffeine withdrawal are to determine the history of the person's caffeine consumption from all dietary sources, and then establish whether there has been a significant decrease in caffeine intake. The diagnostic decision tree for caffeine dependence disorder and caffeine withdrawal disorder is shown in Figure 36.2. Caffeine withdrawal

**Figure 36.2** Diagnostic decision tree for caffeine dependence disorder and caffeine withdrawal disorder.

is probably more common than is generally recognized, and it seems there is a tendency for people to attribute the symptoms of caffeine withdrawal to other etiologies besides caffeine (e.g., having the flu, or a bad day). Caffeine withdrawal may be particularly common in medical settings where patients are required to abstain from food and fluids, such as before surgical procedures and certain diagnostic tests. In addition, caffeine withdrawal may occur in settings where the use of caffeine-containing products is restricted or banned, such as inpatient psychiatric wards.

### Differential Diagnosis

Caffeine withdrawal should be considered when evaluating individuals presenting with headaches, fatigue, sleepiness, mood disturbances or impaired concentration. The differential diagnosis of caffeine withdrawal includes: viral illnesses; sinus conditions; other types of headaches such as migraine, tension, postanesthetic; other drug withdrawal states such as amphetamine or cocaine withdrawal; and idiopathic drug reactions.

### Course

Caffeine withdrawal generally begins within 12 to 24 hours after discontinuing caffeine use. The peak of caffeine withdrawal generally occurs within 24 to 48 hours, and the duration of caffeine withdrawal is generally 2 days to about 1 week.

### Treatment

There have been few studies attempting to address the treatment of caffeine withdrawal, although it has frequently been observed that the symptoms of caffeine withdrawal can be alleviated with the consumption of caffeine and this approach is probably best. If the medical recommendation is made to eliminate or substantially reduce caffeine consumption, then it may be useful to recommend a tapering dose schedule rather than abrupt discontinuation. Caffeine tapering (or “fading”) is described in more detail in the section on “caffeine dependence”.

## Caffeine Dependence

### Definition

This diagnosis is predicated on the DSM-IV TR criteria of substance dependence found in **Chapter 34**.

The clinical features of individuals with caffeine dependence were described in a series of 16 cases described by Strain and colleagues (1994). Most of these individuals reported physical or psychological problems from caffeine use which had prompted multiple unsuccessful attempts to cut down or quit caffeine use, often in response to physicians' recommendations. Most reported tolerance to caffeine and withdrawal when attempting to abstain completely. A double-blind withdrawal trial showed functional impairment in most cases. For the group, median daily caffeine intake was 357 mg with a wide range of 129 to 2548 mg. The preferred vehicle was almost equally divided between soft drinks and coffee.

### Etiology

It is known that the consumption of caffeine may be influenced by several different factors, which are summarized below.

### Caffeine Subjective Effects

Many studies have shown that caffeine in low to moderate doses (20–200 mg) produces mild positive subjective effects of increased feelings of well-being, alertness, energy, concentra-

tion, self-confidence, motivation for work and desire to talk to people. The profile of positive effects with caffeine is qualitatively similar to that produced by *d*-amphetamine and cocaine, which may reflect a common dopaminergic mechanism of action. High doses of caffeine (e.g., 800 mg) produce negative subjective effects such as anxiety and nervousness, especially in people who are not tolerant to caffeine.

### Caffeine Reinforcement

Consistent with its ability to produce mild positive subjective effects, low to moderate doses of caffeine have also been shown to function as a reinforcer in humans, that is, when given the choice under experimental conditions, some people will consistently choose to consume caffeine rather than placebo.

### Caffeine Tolerance

Survey data indicate 17% of current caffeine users reported tolerance (Hughes *et al.*, 1998), whereas 75% of a group of caffeine dependent individuals reported tolerance (Strain *et al.*, 1994). Although tolerance is one of the criteria for making a diagnosis of caffeine dependence (see DSM-IV-TR criteria for substance dependence), it is not clear what role the development of tolerance may have in the development of clinical dependence upon caffeine.

### Genetics and Caffeine Use

Genetic studies suggest that caffeine use problems have an underlying biological basis, part of which may be shared with other commonly abused substances. Twin studies comparing monozygotic and dizygotic twins showed heritabilities of heavy caffeine use, caffeine tolerance and caffeine withdrawal which ranged between 35 and 77% (Kendler and Prescott, 1999).

### Caffeine Use and Alcoholism

The conclusion suggested by the genetic studies described above is that a common genetic factor underlies joint use of caffeine, alcohol and cigarettes. This is consistent with findings of studies on the cooccurrence of use of these three substances (Kozlowski *et al.*, 1993). A study of individuals whose pattern of caffeine use fulfilled DSM-IV diagnostic criteria for substance dependence on caffeine found that almost 60% had a past diagnosis of alcohol abuse or dependence (Strain *et al.*, 1994).

### Caffeine Use and Nicotine/Cigarette Smoking

Epidemiological studies have shown that cigarette smokers consume more caffeine than nonsmokers (Swanson *et al.*, 1994).

### Caffeine Use in Psychiatric Patients

Surveys of psychiatric patients (typically inpatients) have found high rates of caffeine consumption, particularly among patients with schizophrenia. Other groups at risk may include substance abusers (Russ *et al.*, 1988; Hays *et al.*, 1998) and patients with anorexia nervosa (Sours, 1983). While preliminary work suggests there may be some factors (such as heritability) that contribute to the predisposition to use caffeine, there are no studies that have examined the possible etiologic role of such factors in the development of caffeine dependence as a specific diagnosis. Caffeine dependence, like other drug dependence syndromes, in all likelihood represents the interaction of social and cultural forces, and individual histories and predispositions, operating in the context of a psychoactive substance that produces pleasant subjective effects and is reinforcing.

## Assessment

Caffeine dependence may be an unrecognized condition with a higher prevalence than is generally appreciated (see Figure 36.2). Clinicians do not typically think to inquire about caffeine use and about problematic use consistent with a diagnosis of caffeine dependence. However, probing for evidence of caffeine dependence may be useful, and it would be reasonable to focus upon the DSM-IV criteria for dependence that are more appropriate for a substance that is widely available and generally culturally accepted. Thus, the clinician should probe for evidence of tolerance, withdrawal, continued use despite a doctor's recommendation that the person cut down or stop using caffeine, use despite other problems associated with caffeine, often using larger amounts or over a longer period than intended, or persistent desires and/or difficulties in decreasing or discontinuing use.

## Differential Diagnosis

The diagnosis of caffeine dependence includes symptoms that can also contribute to a diagnosis of caffeine intoxication and caffeine withdrawal, and both of these conditions should be included in the differential diagnosis of a patient with possible caffeine dependence. Since intoxication and withdrawal symptoms can contribute to the diagnosis of dependence, conditions that overlap with these caffeine-related disorders should also be considered. When considering a patient for a possible diagnosis of caffeine dependence, the clinician should also consider other substance dependence syndromes – especially those related to stimulants – in the differential diagnosis.

## Epidemiology

Caffeine is the most widely used mood-altering drug in the world. In North America, dietary surveys indicate that weekly or more frequent consumption of caffeine-containing foods occurs in 80 to 90% of children and adults (Gilbert, 1984; Hughes and Oliveto, 1997). In the USA, average daily caffeine consumption among caffeine consumers is 280 mg (Barone and Roberts, 1996). There is only one study of the prevalence of caffeine dependence in the general population based upon standardized diagnostic criteria (Hughes *et al.*, 1998). In this random telephone survey of residents of Vermont, 162 out of the 202 surveyed participants reported current caffeine use. Employing the generic DSM-IV criteria for dependence, 30% of the 162 current caffeine users fulfilled criteria for a diagnosis of caffeine dependence by endorsing three or more dependence criteria, with 56% endorsing the diagnostic criterion of persistent desire or unsuccessful efforts to cut down or control caffeine use, 28% endorsing using more than intended, 14% endorsing caffeine use continued despite knowledge of a physical or psychological problem likely to have been caused or exacerbated by caffeine use, 18% endorsing withdrawal and 9% endorsing tolerance. These results suggest there may be a large number of people who demonstrate symptoms consistent with a DSM-defined diagnosis of caffeine dependence.

## Course

While there are no studies that have specifically examined the course and natural history of caffeine dependence, like other drug dependence syndromes caffeine dependence appears to be a chronic relapsing disorder. In the study described above by Strain and colleagues (1994), caffeine dependence participants reported

recurrent efforts to discontinue caffeine use, with failures to discontinue use or frequent relapses.

## Treatment

In a survey of physicians' practices, it was found that over 75% of medical specialists recommend that patients reduce or eliminate caffeine for certain conditions including anxiety, insomnia, arrhythmias, palpitations and tachycardia, esophagitis/hiatal hernia and fibrocystic disease (Hughes *et al.*, 1988). However, stopping caffeine use can be difficult for some people. For example, in the diagnostic study of caffeine dependence (Strain *et al.*, 1994), subjects reported physical conditions such as acne rosacea, pregnancy, palpitations and gastrointestinal problems that led physicians to recommend that they reduce or eliminate caffeine; all reported that they were unable to follow their doctors' recommendations.

## Caffeine-induced Anxiety Disorder

### Definition

In addition to the symptom of anxiety that can be a component of caffeine intoxication and caffeine withdrawal, caffeine can also produce anxiety disorder, caffeine-induced anxiety disorder (American Psychiatric Association, 2000) (see DSM-IV-TR (criteria). Although there has been no work using this specific set of diagnostic criteria, there have been several studies examining the relationship between caffeine in general, and this work is reviewed here.

### Etiology and Pathophysiology

Caffeine-induced anxiety disorder by definition is etiologically related to caffeine. Caffeine's primary cellular site of action appears to be the adenosine receptor, where it functions as an antagonist.

### Caffeine's Anxiety-inducing Effects in Persons with Anxiety Disorders

Several studies have examined caffeine consumption in patients with an independent anxiety disorder. Interestingly, patients with anxiety disorders generally have lower levels of caffeine consumption compared with patients without an anxiety disorder (Boulenger *et al.*, 1984; Rihs *et al.*, 1996). After the acute consumption of caffeine, self-reports by patients with anxiety disorders versus control subjects show greater anxiety scores. This suggests that some people (such as patients with an anxiety disorder) may avoid caffeine use because of anxiety effects produced by caffeine.

### Assessment and Differential Diagnosis

The diagnosis of caffeine-induced anxiety disorder is based on evidence of an anxiety disorder etiologically related to caffeine (see previous diagnostic decision tree for caffeine intoxication disorder, caffeine-induced anxiety disorder and caffeine-induced sleep disorder). Other diagnostic considerations besides caffeine-induced anxiety disorder include caffeine intoxication and caffeine withdrawal, a primary anxiety disorder, and an anxiety disorder due to a general medical condition. Caffeine-induced anxiety disorder can occur in the context of caffeine intoxication or caffeine withdrawal, but the anxiety symptoms associated with the caffeine-induced anxiety disorder should be excessive

**DSM-IV-TR Criteria 292.89****Substance-induced Anxiety Disorder**

- A. A prominent anxiety, panic attacks, or obsessions or compulsions predominate in the clinical picture.
- B. There is evidence from the history, physical examination, or laboratory findings of either (1) or (2):
  - (1) the symptoms in Criterion A developed during, or within 1 month of, substance intoxication or withdrawal
  - (2) medication use is etiologically related to the disturbance
- C. The disturbance is not better accounted for by an anxiety disorder that is not substance induced might include the following: The symptoms precede the onset of the substance use (or medication use); the symptoms persist for a substantial period of time (e.g., about a month) after the cessation of acute withdrawal or severe intoxication, or are substantially in excess of what would be expected given the type or amount of the substance used or the duration of use; or there is other evidence suggesting the existence of an independent nonsubstance-induced anxiety disorder (e.g., a history of recurrent nonsubstance-related episodes).
- D. The disturbance does not occur exclusively during the course of a delirium.
- E. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

**Note:** This diagnosis should be made instead of a diagnosis of substance intoxication or substance withdrawal only when the anxiety symptoms are in excess of those usually associated with the intoxication or withdrawal syndrome and when the anxiety symptoms are sufficiently severe to warrant independent clinical attention.

Reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

relative to the anxiety seen in caffeine intoxication or caffeine withdrawal. In addition to these conditions, substance-induced anxiety disorder can be produced by a variety of other psychoactive substances (e.g., cocaine).

**Epidemiology and Comorbidity**

There are no specific data on the prevalence or incidence of caffeine-induced anxiety disorder, and there is no information known about comorbid conditions.

**Course**

There is no known information on the course or natural history of caffeine-induced anxiety disorder.

**Treatment**

Although there are no studies on the treatment of caffeine-induced anxiety disorder, guidelines for treatment should generally follow those recommended for the treatment of caffeine

dependence (see earlier). Thus, an initial, careful assessment of caffeine consumption should be conducted, and a program of gradual decreasing caffeine use should be instituted. Abrupt cessation of caffeine use should be avoided to minimize withdrawal symptoms and to increase the likelihood of long-term compliance with the dietary change. Given the etiological role of caffeine in caffeine-induced anxiety disorder, the prudent course of treatment would avoid the use of pharmacological agents such as benzodiazepines for the treatment of the anxiety disorder until caffeine use has been eliminated. A temporary caffeine-free trial may be useful in persuading skeptical patients about the role of caffeine in their anxiety symptoms.

**Caffeine-induced Sleep Disorder****Definition**

Psychoactive substances can produce sleep disorders distinct from the sleep disturbances associated with intoxication or withdrawal produced by that substance. It has long been recognized that caffeine-containing products can produce sleep disturbances, primarily in the form of insomnia. The primary feature of a substance-induced sleep disorder is a sleep disturbance directly related to a psychoactive substance (see DSM-IV-TR criteria). The form of the disorder can be insomnia, hypersomnia, parasomnia, or mixed, although caffeine typically produces insomnia. In general, sleep disturbance can often be a feature of substance intoxication or withdrawal (although sleep disturbance does not typically occur with caffeine withdrawal), and caffeine-induced sleep disorder should be diagnosed in patients who are having caffeine intoxication only if the symptoms of the sleep disturbance are excessive relative to what would typically be expected.

**Etiology and Pathophysiology**

Caffeine's effects on sleep can depend on a variety of factors, such as the dose of caffeine ingested, the individual's tolerance to caffeine, the time between caffeine ingestion and attempted sleep onset, and the ingestion of other psychoactive substances. The effects of caffeine on various measures of sleep quality are an increasing function of dose. Caffeine administered immediately prior to bedtime or throughout the day has been shown to delay onset of sleep and rapid eye movement sleep, reduce total sleep time, alter the normal stages of sleep and decrease the reported quality of sleep.

**Assessment and Differential Diagnosis**

The diagnosis of a caffeine-induced sleep disorder is based on evidence of a sleep disorder etiologically related to caffeine (see diagnostic decision tree for caffeine intoxication disorder, caffeine-induced anxiety disorder and caffeine-induced sleep disorder). Although caffeine consumption may decrease with age, the elderly commonly report increased sleeping problems which may be exacerbated by caffeine (Curless *et al.*, 1993). Occult caffeine consumption in the form of analgesic medication may produce sleep problems in the elderly (Brown *et al.* 1995).

**Epidemiology, Comorbidity, Course and Treatment**

There are no specific data on the prevalence, incidence, course, treatment, comorbidity or patterns of caffeine-induced sleep disorder.

**DSM-IV-TR Criteria** 292.89**Substance-induced Sleep Disorder**

- A. A prominent disturbance in sleep that is sufficiently severe to warrant independent clinical attention.
- B. There is evidence from the history, physical examination, or laboratory findings of either(1) or (2):
- (1) the symptoms in Criterion A developed during, or within 1 month of, substance intoxication or withdrawal
  - (2) medication use is etiologically related to the sleep disturbance
- C. The disturbance is not better accounted for by a sleep disorder that is not substance induced. Evidence that the symptoms are better accounted for by a sleep disorder that is not substance induced might include the following: the symptoms precede the onset of the substance use (or medication use); the symptoms persist for a substantial period of time (e.g., about a month) after the cessation of acute withdrawal or severe intoxication, or are substantially in excess of what would be expected given the type or amount of the substance used or the duration of use; or there is other evidence that suggests the existence of an independent nonsubstance-induced sleep disorder (e.g., a history of recurrent nonsubstance-related episodes).
- D. The disturbance does not occur exclusively during the course of a delirium.
- E. The sleep disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

**Note:** This diagnosis should be made instead of a diagnosis of substance intoxication or substance withdrawal only when the sleep symptoms are in excess of those usually associated with the intoxication or withdrawal syndrome and when the symptoms are sufficiently severe to warrant independent clinical attention.

**Comparison of DSM-IV/ICD-10 Diagnostic Criteria**

ICD-10 includes caffeine-related disorders in its “Other Stimulant” class which also includes amphetamines. This results in the ICD-10 Diagnostic Criteria for Research for Caffeine Intoxication being the same as those for amphetamine intoxication.

# Substance Abuse: Cannabis-related Disorders

## Definition

As with other substances of abuse, the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (DSM-IV-TR) distinguishes a number of different cannabis-related diagnoses, which are shown in Table 37.1. These fall into two basic groups. The first group is defined by adverse effects resulting from cannabis use; these include cannabis abuse and cannabis dependence. The category of cannabis dependence includes a number of specifiers that indicate the presence or absence of physiological dependence, type of remission, and whether or not the individual has been in a controlled environment. The second set of cannabis-related disorders in DSM-IV-TR includes psychiatric syndromes presumed to be induced by cannabis. This group includes: cannabis intoxication, which is almost certainly induced by cannabis and consists of the common signs and symptoms that normally follow cannabis use; cannabis intoxication delirium, a degree of disturbance beyond that normally expected with ordinary intoxication; cannabis-induced psychotic disorder which is subdivided into categories of psychosis with delusions and psychosis with hallucinations; and cannabis-induced anxiety disorder which is also subdivided into several types as shown in Table 37.1.

Throughout the remainder of this chapter, we discuss cannabis abuse and dependence under the general heading of cannabis use disorders; cannabis intoxication, cannabis intoxication delirium, cannabis-induced psychotic disorder and cannabis-induced anxiety disorder are discussed as cannabis-induced disorders.

## Cannabis: Botany and Pharmacology

Cannabis preparations, derived from the female *Cannabis sativa* plant, have been widely used for their psychotropic effects since the beginning of history. The drug is prepared in different ways in different parts of the world. The flowering tops and resin secreted by the female plant contain the highest concentrations of  $\Delta$ -9-tetrahydrocannabinol ( $\Delta$ -9-THC), the primary psychoactive component. Marijuana, the most common preparation, is made by drying and shredding the upper leaves, tops, stems, flowers and seeds of the plant. Hashish is a more potent preparation made by extracting and drying the resin and sometimes also the compressed flowers. Hashish oil, which is even more potent, is distilled from hashish. Marijuana and hashish can be smoked either in the form of cigarettes or by using a pipe. Hashish, hashish oil and, less commonly, marijuana can be mixed with tea or food and taken orally (Ashton, 2001; Hall and Solowij, 1998). For the

292.89	Cannabis intoxication With perceptual disturbances
292.81	Cannabis intoxication delirium
292.11	Cannabis-induced psychotic disorder, with delusions With onset during intoxication
292.12	Cannabis-induced psychotic disorder, with hallucinations With onset during intoxication
292.89	Cannabis-induced anxiety disorder With onset during intoxication With generalized anxiety With panic attacks With obsessive-compulsive symptoms With phobic symptoms
292.9	Cannabis-related disorder not otherwise specified

remainder of this chapter we will refer to these preparations collectively as “cannabis”.

Selective breeding and improved growing methods have produced cannabis plants that contain significantly higher  $\Delta$ -9-THC concentrations than naturally occurring plants. Thus, although there is a great deal of variation, the potency of illicit cannabis available in the USA has increased substantially, on average, over the last 30 years (Ashton, 2001; Hall and Solowij, 1998).

Intoxication occurs within minutes after smoking cannabis and typically persists for several hours. After eating foods

containing cannabis, intoxication occurs after approximately an hour and can persist for 8 to 24 hours. The onset of intoxication after drinking cannabis steeped in tea is shorter, but not as rapid as after smoking, and has an intermediate duration of intoxication. Smoking cannabis induces intoxication more quickly than ingesting cannabis because first-pass metabolism in the liver is avoided and the combustion causes enhanced release of  $\Delta$ -9-THC from pyrolysis of acids in cannabis preparations. Smoking is the predominant method of taking cannabis in most parts of the world, including the USA, probably because of the more rapid onset of action and because the potency of the drug when it is smoked is about three times that experienced when an equivalent amount is eaten (Ashton, 2001; Hall and Solowij, 1998).

$\Delta$ -9-THC and other cannabinoids are highly lipophilic and are quickly and widely distributed throughout the body.  $\Delta$ -9-THC can cross the placenta and enter breast milk; it may interact with other drugs by inducing liver enzymes and competing for plasma binding sites.  $\Delta$ -9-THC is metabolized in the liver by hydroxylation to at least 20 different metabolites. Some, such as 11-hydroxy-THC, are psychoactive and have half-lives exceeding 2 days.  $\Delta$ -9-THC may also be conjugated to more water-soluble metabolites that are excreted predominantly into the gut where they may be reabsorbed, and also into the bile, urine, sweat and hair.  $\Delta$ -9-THC is stored in adipose tissue from which it is released slowly; in regular users it can often be detected more than 30 days after the individual's last exposure to cannabis (Johnson, 1990). If an individual uses cannabis regularly, the stores of  $\Delta$ -9-THC in the adipose tissue result in a constant supply of cannabinoids to the body including the brain (Ashton, 2001).

There are two types of G-protein-coupled cannabinoid receptors.  $CB_1$  receptors are found in the lipid membranes of neurons in the central nervous system, including the cerebral cortex, basal ganglia, thalamus and brain stem, with high densities in the hippocampus, cerebellum and striatum.  $CB_2$  receptors are found in the lipid membranes of various types of cells in the immune system.  $\Delta$ -9-THC is a partial agonist, activating both  $CB_1$  and  $CB_2$  receptors (Hall and Solowij, 1998). Activation of cannabinoid receptors mediates the inhibitory effect of adenylate cyclase, decreasing cyclic adenosine monophosphate, and also inhibits calcium and potassium transport. Receptor activation also mediates the excitatory effect of mitogen-activated protein kinase (Ameri, 1999). The cannabinoid system plays a modulatory role in regulating many different functions including mood, motor control, perception (including pain perception), appetite, sleep, memory and cognition, reproductive function and immune response (Hall and Solowij, 1998).  $\Delta$ -9-THC can potentiate the effects of alcohol, barbiturates, caffeine and amphetamines (Solomons and Neppe, 1989).

## Etiology and Pathophysiology

### Cannabis Use Disorders

Cannabis dependence develops as a result of repeated use of the drug, and frequency of use is one of the most important predictors of developing dependence (Chen and Kandel, 1998; Kandel and Chen, 2000). Like most other dependence-producing drugs, cannabis produces its reinforcing effects by activating the mesolimbic dopaminergic "reward" pathway, which consists of dopaminergic neurons in the ventral tegmental area (VTA) that project to the nucleus accumbens, increasing dopamine levels in the shell of the nucleus accumbens (Diana *et al.*, 1998a; Gardner,

1999; Tanda *et al.*, 1997). Naloxone, an opiate antagonist at the  $\mu_1$  opioid receptor in the VTA, blocks this increase in dopamine, which suggests that  $\Delta$ -9-THC and opiates share the same mechanism of activating this pathway (Tanda *et al.*, 1997). Studies have shown that people choose higher-potency cannabis preparations over lower-potency preparations, a finding which suggests that increased potency may result in an increased risk of progression to addiction and dependence (Chait and Burke, 1994; Harder and Reitbrock, 1997).

Regular use of cannabis for periods as short as 1 to 3 weeks can produce tolerance to many of its acute physiological and psychological effects (Jones *et al.*, 1976, 1981; Jones, 1983). Such tolerance may cause some individuals to increase their use in order to continue to experience desired effects. As with other addictive drugs, discontinuation of cannabis use increases corticotropin-releasing factor (CRF) in the central amygdala and decreases dopaminergic transmission in the limbic system, resulting in withdrawal symptoms (Diana *et al.*, 1998b; Rodriguez *et al.*, 1997).

The core symptoms of cannabis withdrawal are irritability, anxiety, physical tension, and decreases in mood and appetite. Restlessness, tremors, sweating, insomnia, increased aggressiveness and very vivid dreams have also been reported (Budney *et al.*, 1999; Haney *et al.*, 1999; Kouri *et al.*, 1999; Kouri and Pope, 2000; Kaymakcalan, 1973, 1981; Tennant, 1986; Compton *et al.*, 1990; Jones *et al.*, 1976, 1981; Jones, 1983; Wiesbeck *et al.*, 1996). The symptoms of cannabis withdrawal are similar to those of opiate withdrawal, except that their intensity is milder and their course is delayed and prolonged due to the fact that cannabis is cleared from the body gradually as it is released slowly from storage in adipose tissue. Symptoms typically begin the day after last use, do not reach maximal intensity until the third day, and then resolve over the following week. The severity of the withdrawal syndrome varies considerably among individuals. In a recent study of 108 chronic, long-term cannabis users, the authors observed a number of individuals who experienced severe withdrawal symptoms which precluded their completion of the month-long abstinence period required by the study protocol, suggesting that, for at least some individuals, the withdrawal syndrome is an important factor in the development and persistence of dependence (Pope *et al.*, 2001a; Gruber *et al.*, in press). The two clinical vignettes provided at the end of the chapter describe individuals who experienced withdrawal effects from their use of cannabis.

Environment appears to play a major role in determining whether an individual will initiate cannabis use, but only a minor role in determining whether an individual will go on to develop cannabis dependence. Genetic factors, on the other hand, appear to play only a moderate role in determining whether an individual will initiate cannabis use, but a major role in determining whether an individual who initiates use will subsequently develop cannabis dependence. A study of female twins reported that genetic factors accounted for 60 to 80% of the variance in liability for cannabis dependence (Kendler and Prescott, 1998). A study of male twins reported that genetic factors contributed significantly to progression from first exposure or opportunity to use cannabis to initial use of cannabis, from initial use to use more than five times, and from use more than five times to regular use (Tsuang *et al.*, 1999). A second study of male twins reported that genetic factors were responsible for 44% and common environmental factors for only 21% of the variance in risk of developing cannabis dependence (True *et al.*, 1999).

In addition to the addictive properties of cannabis and the genetic predisposition of individuals, another possible etiology for cannabis dependence is that some individuals may be “self-medicating” themselves for underlying psychiatric symptoms. Some patients with depression, anxiety, or negative symptoms of schizophrenia report that marijuana use alleviates their symptoms (Peralta and Cuesta, 1992; Dixon *et al.*, 1991; Estroff and Gold, 1986; Warner *et al.*, 1994; Gruber *et al.*, 1996). In addition, a large portion of adolescents and young adults with cannabis dependence have reported using marijuana to self-treat anger, boredom, or lack of direction (Chen and Kandel, 1998; Gruber *et al.*, in press; Johnston *et al.*, 2001; Newcombe and Bentler, 1988). An interesting finding of a longitudinal study of chronic cannabis users is that prescriptions for psychoactive medications increased as cannabis use decreased when the subjects were in their late twenties and early thirties, raising the possibility that for some individuals the prescription medications were serving the same purpose as the cannabis (Chen and Kandel, 1995, 1998). We have observed this apparent self-medication phenomenon in a number of patients with underlying depressive illness or bipolar disorder.

However, contrary to the beliefs of the users, cannabis may also contribute to the symptoms enumerated above (Miller *et al.*, 1989; Lex *et al.*, 1989; Mirin *et al.*, 1971; Chen and Kandel, 1998; Baigent *et al.*, 1995; Green and Ritter, 2000).

### Cannabis-induced Disorders

The mechanism causing the euphoria experienced during cannabis intoxication is activation of the mesolimbic dopaminergic “reward” pathway, and is described in detail in the botany and pharmacology section (Diana *et al.*, 1998a; Gardner, 1999; Tanda *et al.*, 1997). The mechanisms causing the physiological signs and symptoms associated with cannabis intoxication are thought to result from the action of the cannabinoid system on other major neurotransmitter systems including the noradrenergic, cholinergic, serotonin and opioid systems (Ameri, 1999).

There are no adequate data regarding the mechanism by which cannabis intoxication delirium, cannabis-induced psychotic disorder, or cannabis-induced anxiety disorder can occur *de novo* in individuals without preexisting medical or psychiatric disorders. In a review of studies of patients with cannabis-induced psychotic disorder, it was found that most of the studies had not excluded individuals with a preexisting Axis I disorder, such as schizophrenia or a major mood disorder, which would render the individual vulnerable to psychotic symptoms even in the absence of cannabis use. At present, therefore, it seems possible that the majority of cannabis-induced psychotic or anxiety disorders represent exacerbations of preexisting DSM-IV Axis I psychiatric disorders in individuals who become intoxicated with the drug (Gruber and Pope, 1994).

## Assessment and Differential Diagnosis

### Cannabis-related Disorders

To diagnose any of the cannabis-related disorders, it is important to obtain a detailed history of the individual’s pattern of substance abuse (including abuse not only of cannabis but of other substances) and to attempt to substantiate this report with toxicology screening for drugs of abuse. Individuals who smoke cannabis regularly can have substantial accumulations of THC in their fat stores. Thus, for weeks after cessation of smoking, de-

tectable levels of cannabinoids may be found in urine (Johnson, 1990). However, a positive response on toxicology screening for cannabinoids cannot establish any of the cannabis-related diagnoses; it is useful only as an indicator that these diagnoses should be considered.

### Cannabis Dependence

It is uncommon to see patients who exhibit cannabis dependence as their only diagnosis because such individuals rarely seek treatment as they generally do not acknowledge that they have a problem and are unaware that treatment is available. However, some patients with this disorder will respond to offers for treatment because they realize that they are unable to stop use on their own and because they notice the deleterious effect of compulsive use (Roffman and Barnhart, 1987). Therefore, the diagnosis of cannabis dependence will most often be made in patients who present with other psychiatric problems, such as mood and anxiety disorders, and other substance use disorders. Another manner in which individuals with cannabis dependence may come to the attention of psychiatrists is when they are arrested for possession of the substance or some crime related to cannabis abuse, such as driving under the influence of the drug. Nevertheless, cannabis dependence is probably underdiagnosed in both psychiatric and general medical populations because it is not considered.

The diagnosis of cannabis dependence cannot be made without obtaining a history indicating that the cannabis use is impairing the patient’s ability to function either physically or psychologically. Areas to inquire about include the patient’s performance at work, ability to carry out social and family obligations, and physical health. It is also important to find out how much of the patient’s time is spent on cannabis-related activities and whether the patient has tried unsuccessfully to stop or cut down on use in the past. Although it has been our experience that people who have used cannabis daily over a period of years almost invariably report tolerance to many of the effects of cannabis and to experience an unpleasant withdrawal state if use is discontinued, neither tolerance nor withdrawal is necessary for the diagnosis of cannabis dependence. When this diagnosis is made, it can be described further by the following specifiers: with or without physiological dependence, early full or partial remission, sustained full or partial remission, or in a controlled environment. These diagnostic distinctions must be based on the pattern of use reported by the patient.

### Cannabis Abuse

Most individuals who are diagnosed with cannabis abuse have only recently started using cannabis. As with cannabis dependence, cannabis abuse is unlikely to be diagnosed unless some additional condition or circumstance brings the individual to medical attention. Teenagers often fall into this category because they spend time in supervised environments like school and home where responsible adults may intervene. Also, teenagers are more likely to have motor vehicle accidents while intoxicated because they are inexperienced drivers, and are more likely to be arrested for possession because they have a greater tendency to participate in risky behaviors of all types.

Although virtually all individuals with cannabis dependence meet the inclusion criteria for cannabis abuse, they cannot be given this diagnosis because the presence of cannabis dependence is an exclusion criterion. Undoubtedly, the vast majority of people with cannabis dependence would have been given the diagnosis of cannabis abuse until they developed dependence.

It is probable that individuals qualifying for a diagnosis of cannabis abuse will either cease use (see course section) or develop cannabis dependence. The criteria for cannabis abuse focus on adverse consequences of cannabis use that could potentially result from just a single use such as failure to fulfill obligations at work, school, or home, participating in potentially dangerous activities like driving while intoxicated with cannabis, having cannabis-related legal problems, or social or interpersonal difficulties. Even though these adverse consequences can occur following a single episode of cannabis use, the consequences must be recurrent, requiring multiple episodes of use. Since the number of episodes necessary for “recurrent” is not defined, and the pattern of use is often dependent on patient self-report, it is often difficult to distinguish between abuse and dependence. This difficulty is easier to recognize if one looks at the extremes. On one end of the continuum, a high school student who actually has only used cannabis twice, but who was unfortunate enough to be caught and suspended from school on both occasions, would appropriately be diagnosed with cannabis abuse. At the other end of the continuum, a high school student who had actually been using cannabis every day for three years and met the criteria for dependence, who was also caught and suspended from school twice but denied symptoms of dependence, would incorrectly be diagnosed with cannabis abuse.

The difference between people with cannabis abuse and those with cannabis dependence is that the people with dependence have been using more regularly (one or more times per day) and for a longer duration (one or more years), and the acute problems associated with abuse have turned into the chronic problems associated with dependence. For example, what started as failure to fulfill obligations at work or school has resulted in dropping out of school or working at jobs with extremely low expectations. Multiple car accidents or arrests have led to chronic injuries (often associated with obtaining SSDI), loss of licenses, probation and even periods of time in prison. Social or interpersonal problems have resulted in isolation or at least separation from people who are not regular cannabis users. If there is a committed relationship where the partner is typically cannabis dependent, and if children are involved, chronic neglect is present if caring for children while intoxicated with cannabis represents neglect.

## Cannabis Intoxication

There are four criteria necessary to make this diagnosis (see DSM-IV criteria for intoxication). The first is that recent use of cannabis must be established. This cannot be done with toxicology screening because the result may be negative after a single episode of smoking or, alternatively, may be positive even if the individual has not used the drug for a time much longer than the period of intoxication (see section on Cannabis botany and pharmacology). Thus, the recent use of cannabis must be reported by the patient or another person who witnessed the patient’s use. In addition, the symptoms resulting from cannabis use must produce “clinically significant maladaptive behavioral or psychological changes”. Thirdly, the patient must exhibit some physical signs of cannabis use. DSM-IV-TR requires the patient to have at least two of four signs – conjunctival injection, increased appetite, dry mouth and tachycardia – within 2 hours of cannabis use. Fourthly, symptoms cannot be accounted for by a general medical condition or another mental disorder. There is a specifier, “with perceptual disturbances”, that can be used if the patient is experiencing illusions or hallucinations while not delirious and while maintaining intact reality testing.

**Table 37.2 Physiological Effects of Cannabis Intoxication**

Common and Transient
Tachycardia
Hypertension
Thirst
Increased appetite
Constipation
Decreased intraocular pressure
Mydriasis
Mild bronchoconstriction followed by bronchodilation
Increased reaction time
Impaired coordination
Distorted time perception
Decreased libido
Mild analgesia
Mild anti-emetic effects
Uncommon and Transient
Ataxia
Ptosis
Miosis
Drowsiness
Bradycardia
Hypotension
Peripheral vasoconstriction
Hypothermia

There has been extensive research on the effects of acute cannabis intoxication. In addition to the symptoms and signs required for a DSM-IV-TR diagnosis, many psychological and physiological effects have been reported. Awareness of these may enhance the psychiatrist’s ability to recognize cannabis intoxication. Physiological effects are listed in Table 37.2, and are divided into commonly observed effects and rare effects that have been described only after the use of very high doses of cannabis (Hall and Solowij, 1998; Ameri, 1999; Perez-Reyes, 1999). Cannabis has low toxicity, and to our knowledge, no deaths from cannabis overdose have been reported (Hall and Solowij, 1998). Similarly, psychological effects are listed in Table 37.3, divided into commonly observed effects and uncommon effects. Most people find the commonly experienced psychological effects enjoyable. However, some individuals, especially women (Thomas, 1996)

**Table 37.3 Psychological Effects of Cannabis Intoxication**

Common and Transient
Euphoria
Distortions in perception, including time perception
Enhancement of sensations
Uncommon and Transient
Dysphoria
Anxiety, and less commonly panic reactions
Restlessness
Depersonalization
Derealization
Paranoid ideation

and inexperienced users in an unfamiliar environment, find them frightening and experience anxiety and even have panic reactions (Hall and Solowij, 1998; Johns, 2001; Thomas, 1996). Although all of these effects typically persist only for the period of acute intoxication, some reports have described individuals who report “flashbacks” of cannabis intoxication long after use, and depersonalization persisting long after acute intoxication (Keeler *et al.*, 1968, 1971; Levi and Miller, 1990; Annis and Smart, 1973; Stanton and Bardoni, 1972). At this time there is insufficient evidence to ascertain whether these reports are attributable to cannabis itself, to confounding factors such as the concomitant use of other drugs, or the presence of other Axis I disorders (Johns, 2001).

In addition, cannabis use produces deficits in a number of neuropsychological functions, both during acute intoxication and after up to a week or more of abstinence in chronic, long-term users. These tasks include short-term memory, sustained or divided attention, and complex decision-making (Ehrenreich *et al.*, 1999; Pope *et al.*, 1995, 1997, 2001a; Pope and Yurgelun-Todd, 1996; Schwartz *et al.*, 1989; Solowij *et al.*, 1991, 1995; Solowij, 1995, 1998). A study of chronic, long-term users found that these deficits were reversible after 28 days of abstinence (Pope *et al.*, 2001a). However, a few studies have found that subtle electrophysiologic changes, of uncertain clinical significance, may persist even after years of abstinence (Solowij, 1995, 1998; Struve *et al.*, 1998).

### Cannabis Intoxication Delirium

We have not located any original reports of this entity, although it is mentioned in various reviews and is included in DSM-IV. Thus, if cannabis intoxication delirium does occur in neurologically intact individuals, it is probably a rare complication. If the delirium does not resolve within 24 to 48 hours, it is almost certainly a result of an underlying neurological or medical condition. Therefore, in a patient with delirium, even if recent cannabis use has been reported, a full diagnostic work-up should be performed to rule out a concomitant, treatable neurological condition (Halikas, 1974; Johns, 2001).

The following two substance-induced conditions are not generally diagnosed unless the symptoms are in excess of those usually associated with the intoxication or withdrawal state and are sufficiently severe to warrant independent clinical attention.

### Cannabis-induced Psychotic Disorder

There are two subtypes of cannabis-induced psychotic disorder: one featuring delusions, the other hallucinations. The diagnosis of this disorder is readily made in individuals who have psychotic symptoms that appear immediately after ingestion of cannabis. However, a careful history is required to establish whether the individual has a preexisting psychotic disorder (as is often the case in such situations) or whether the symptoms arose *de novo* after cannabis consumption. There is little evidence that cannabis-induced psychotic disorders can arise in previously asymptomatic individuals (Gruber and Pope, 1994). Therefore, if psychotic symptoms persist for 24 to 48 hours after the period of acute intoxication, they are likely due to an underlying psychiatric disorder which must be diagnosed and treated (Hall and Degenhardt, 2000; Johns, 2001; Gruber and Pope, 1994).

### Cannabis-induced Anxiety Disorder

This disorder may be further described by the following specifiers: with generalized anxiety, with panic attacks, with

obsessive–compulsive symptoms and with phobic symptoms. The literature contains papers that report individuals who have anxiety, panic reactions and paranoid ideation during the period of acute intoxication, but we are unaware of any papers that report obsessive–compulsive or phobic symptoms. People who experience anxiety after using cannabis are typically inexperienced users who react to the novel experiences of perceptual distortions and intensified sensations with anxiety and even panic reactions, rather than enjoyment (Thomas, 1996; Johns, 2001; Szuster *et al.*, 1988). Women are more likely than men to experience cannabis-induced anxiety (Thomas, 1996). As with cannabis-induced psychotic disorders, we have been unable to find clear cases of cannabis-induced anxiety disorders in individuals without a preexisting Axis I disorder. Again, if symptoms of severe anxiety or panic persist for 24 to 48 hours after the period of acute intoxication, they are likely due to an underlying psychiatric disorder that must be diagnosed and treated (Johns, 2001).

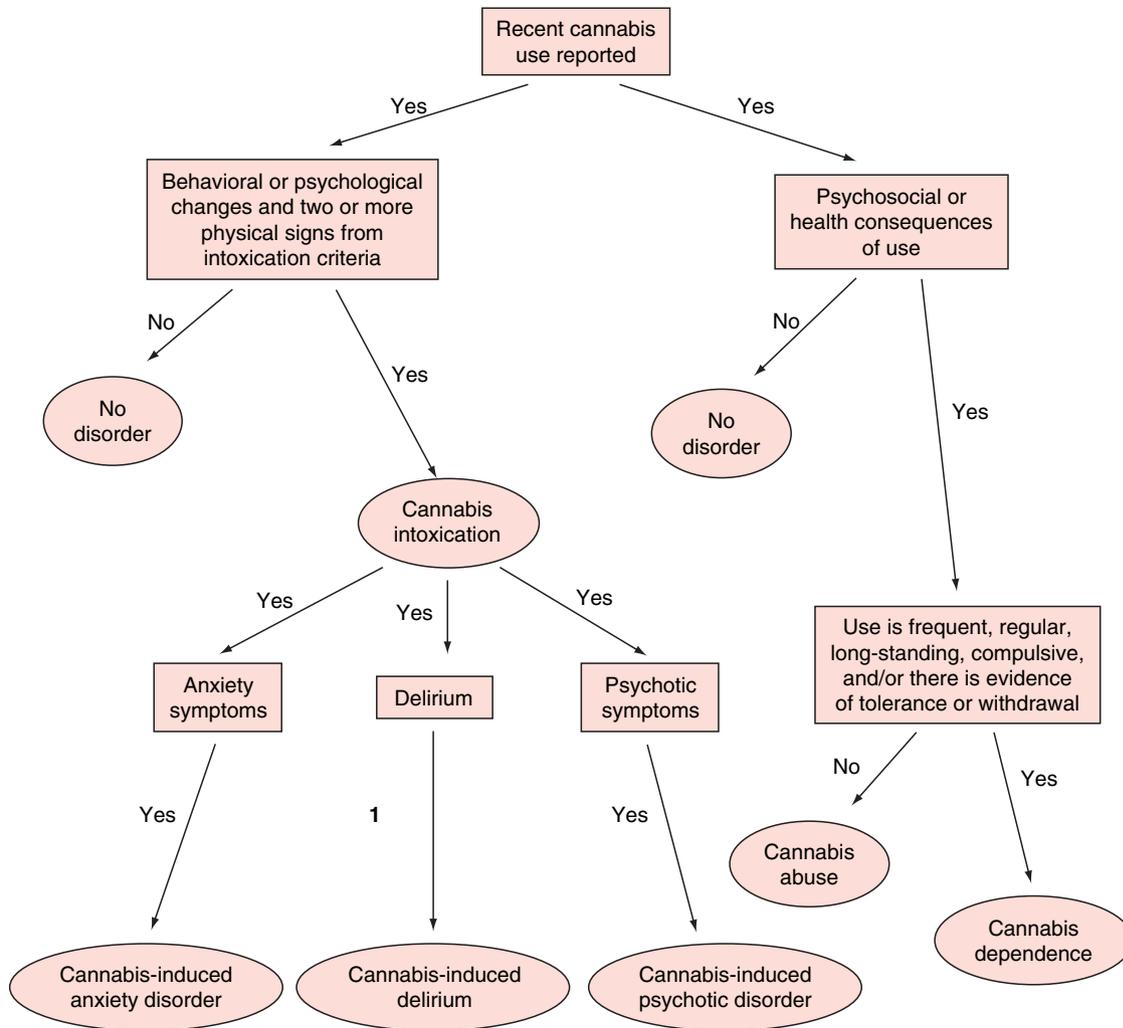

A diagnostic decision tree for cannabis use disorders is presented in Figure 37.1.

## Epidemiology and Comorbidity

### Cannabis Use Disorders

Cannabis is probably the most commonly used illicit substance in the world, with an estimated 200 to 300 million regular users (Johnson, 1990). In the USA, cannabis is generally thought to be the most widely used illicit drug, with more than 50% of Americans reporting at least one episode of use (Johnson, 1990; Mueser *et al.*, 1992; Chen and Kandel, 1998; Hubbard *et al.*, 1999). As with most other illicit drugs cannabis use occurs more often in men though the difference between the sexes is decreasing (Greenfield and O’Leary, 1999). Also, like other illicit drugs cannabis use typically begins in adolescence and is most prevalent in people between the ages of 18 to 30 years (Chen and Kandel, 1995, 1998; Johnston *et al.*, 2001; Kandel and Chen, 2000). The age of first cannabis use in America has been decreasing; in 1997 the average age of first use was reported to be 14 by the National Household Survey on Drug Abuse (NHSDA) (SAMHSA, 1997). The annual, monitoring the future study of high school students, reported that in 2000, 15.6% of 8th graders, 32.2% of 10th graders and 36.5% of 12th graders reported using cannabis in the past year. Approximately 20% of 12th grade cannabis users reported daily use (Johnston *et al.*, 2001).

Adolescents appear more vulnerable to developing cannabis dependence than adults, becoming dependent after using cannabis at a lower dose and frequency of use (Chen *et al.*, 1997). Although earlier onset of use during adolescence is a predictor for continued use and the development of dependency, frequency of use is a stronger predictor (Chen and Kandel, 1998; Kandel and Chen, 2000; DeWit *et al.*, 2000; SAMHSA, 2000). Of those adolescents who use cannabis more than once, about a third will subsequently use cannabis regularly for some period of time, with 20% using daily, and an additional 10 to 20% using near daily (Hall and Solowij, 1998; Johnston *et al.*, 2001; Zoccollilo *et al.*, 1999). It is estimated that a third of those who use cannabis daily meet the criteria for cannabis dependence, and that of all adolescents who use cannabis at least once, approximately 9% will develop dependence (Anthony *et al.*, 1994; Chen *et al.*, 1997). However, most adolescents who use cannabis regularly will have stopped use by the time they are 30 (Chen and Kandel, 1995, 1998).

**Figure 37.1** Diagnostic decision tree for cannabis use disorders.

Studies have reported that individuals with cannabis use disorders have high rates of other substance abuse disorders (Miller *et al.*, 1990) as well as other types of Axis I disorders (Regier *et al.*, 1990; Troisi *et al.*, 1998). It is possible, however, that these findings reflect “spurious comorbidity” (Smoller *et al.*, 2000) because individuals with cannabis dependence and other Axis I disorders are probably more likely to present for treatment or research studies than those with cannabis dependence alone.

Conversely, studies of several psychiatric populations (Brady *et al.*, 1991; Alterman *et al.*, 1982; Miller *et al.*, 1989; Cantwell *et al.*, 1999; Menezes *et al.*, 1996; Johns, 2001) with a number of different Axis I diagnoses other than panic disorder (Szuster *et al.*, 1988) have found high rates of cannabis use. The course of the Axis I illnesses is often adversely affected by cannabis use; cannabis may exacerbate psychotic symptoms in patients with schizophrenia, possibly precipitate schizophrenia in predisposed individuals (Andreasson *et al.*, 1987, 1989), precipitate hypomanic or manic episodes in bipolar patients (Gruber and Pope, 1994) and trigger panic reactions in patients with panic disorder (Szuster *et al.*, 1988). Cannabis use, abuse and dependence are also commonly comorbid with conduct disorder in children and adolescents and with antisocial personality disorder in adults (Weller and Halikas, 1985; Henry *et al.*, 1993; True *et al.*, 1999; Crowley *et al.*, 1998). Despite these findings of

comorbidity, cannabis use has not been shown to induce any psychiatric disorders *de novo* in nonpredisposed individuals (Hall and Degenhardt, 2000; Johns, 2001).

### Cannabis-induced Disorders

The prevalence of cannabis intoxication should be approximately the same as the prevalence of cannabis use described at the beginning of this section. No formal epidemiological data exist regarding the prevalence of cannabis intoxication delirium, cannabis-induced psychotic disorder, or cannabis-induced anxiety disorder. In fact, it is not entirely certain that any of these three entities actually occurs in individuals free of preexisting DSM-IV-TR Axis I disorders (Hall and Degenhardt, 2000; Johns, 2001).

For example, no original reports of cannabis-induced delirium in the literature were found except for comments about it in review articles. Whereas cannabis use occasionally causes anxiety, or even panic reactions, especially among inexperienced users, there is again no known published study exhibiting a cohort of previously asymptomatic subjects who developed clinically significant cannabis-induced anxiety disorder. One investigator (Pillard, 1970) observed that there were five to seven cases of cannabis-associated anxiety reactions reported to a university health service per year; he hypothesized that more cases

occurred but were not reported. However, he noted that reassurance was all the treatment necessary, suggesting that these patients had not developed clinically significant anxiety disorders. Finally, although anecdotal reports and even case series of cannabis-induced psychotic disorder have appeared, many of these have been collected outside the USA and most provide insufficient evidence to assess whether the subjects studied were suffering from preexisting psychotic disorders before their ingestion of cannabis (Gruber and Pope, 1994). In one US study, the investigators reviewed approximately 10 000 discharges from two psychiatric units. All cases of possible cannabis-induced mental disorders were investigated by chart review. No cases of clear-cut cannabis-induced psychotic disorder or cannabis-induced anxiety disorder were found. Thus, it appears that these disorders, at least of sufficient magnitude to prompt a psychiatric admission, are rare or do not exist at all (Gruber and Pope, 1994; Hall and Degenhardt, 2000; Johns, 2001).

## Course

### Cannabis Use Disorders

As discussed in the epidemiology section, about a third of those adolescents who try cannabis will use it regularly for some period of time, whereas only about 10% will go on to develop long-term dependence lasting into adulthood (Hall and Solowij, 1998). Even among these persistent users, the majority will stop use by age 30 years. Thus, it is possible to extrapolate from these figures that less than 2% of adults will exhibit cannabis dependence during their twenties and probably less than 1% of adults will continue use into their thirties, suggesting a good prognosis for the majority of cannabis-dependent patients under age 30 years. However, for the small minority who continue to suffer from cannabis dependence into their thirties, most follow a chronic or relapsing course similar to those who suffer from dependence on other substances (Miller *et al.*, 1989; Hall and Solowij, 1998; Johnston *et al.*, 2001; Zoccolillo *et al.*, 1999; Anthony *et al.*, 1994; Chen and Kandel, 1995, 1998; Chen *et al.*, 1997; Kandel and Chen, 2000; Stephens *et al.*, 1993a, 1993b, 1994, 2000; Baer *et al.*, 1998; Hser *et al.*, 2001; Hubbard *et al.*, 1985).

Cannabis abuse and dependence appear to pursue a benign course in many individuals; many studies have suggested that individuals suffering from these disorders do not differ in ability to function in society from matched control subjects who are not users (Kouri *et al.*, 1995; Simon *et al.*, 1974; Pope *et al.*, 1990, 2001b; Zinberg and Weil, 1970; Comitas, 1976; Hochman and Brill, 1973; Boulougouris *et al.*, 1976; Robins *et al.*, 1970; Mendelson *et al.*, 1976; Brill and Christie, 1974; Pope and Yurgelun-Todd, 1996). However, a few studies have described an “amotivational syndrome” associated with chronic cannabis use, characterized by subjective reports of lack of direction, motivation and ambition (Mellinger *et al.*, 1976; Lessin and Thomas, 1976; Kupfer *et al.*, 1973; Burdsal *et al.*, 1973; Campbell, 1976; Hendin and Haas, 1985; Musty and Kaback, 1995; Gruber *et al.*, in press). This “amotivational syndrome” appears to result from the effects of continuous intoxication and resolves when cannabis is discontinued (Johns, 2001). In the context of a recent study involving 108 chronic, long-term cannabis users (Pope *et al.*, 2001a; Gruber *et al.*, in press), the authors encountered a number of chronic long-term cannabis users who reported lack of direction, motivation and ambition while using cannabis heavily, but

then reported increased productivity and success in their work and social lives after discontinuing use.

### Cannabis-induced Disorders

Cannabis intoxication is a self-limiting state that remits as cannabis is metabolized and eliminated from the body. If symptoms suggestive of cannabis intoxication persist, other diagnoses should be considered. Similarly, although there are few data regarding the course of the other cannabis-induced disorders, it appears that cannabis-induced psychotic and anxiety disorders, as well as cannabis intoxication delirium, rarely persist beyond the period of acute intoxication with the drug. For example, although there have been reports of cannabis-induced psychoses persisting for days or even weeks beyond the time of acute intoxication, a review of the literature (as discussed earlier) was unable to exhibit a series of unequivocal cases in which such symptoms persisted in the absence of an underlying Axis I disorder. Therefore, symptoms of delirium, psychosis, or anxiety persisting more than 24 to 48 hours after acute cannabis intoxication suggest that another Axis I disorder, rather than cannabis itself, is responsible for the symptoms (Gruber and Pope, 1994; Hall and Degenhardt, 2000; Johns, 2001).

## Treatment

### Cannabis Use Disorders

#### Standard Approaches to Treatment

Up until the last few years, the prevailing opinion was that cannabis use did not produce addiction and dependence and that cannabis users could discontinue use without the help of treatment programs. In fact, this was the prevailing attitude even amongst users, many of whom had tried unsuccessfully to discontinue use (Weiner *et al.*, 1999). Although it is undeniably true that the majority of cannabis users are able to stop without assistance, it is also becoming apparent that many cannabis-dependent individuals cannot stop without help. The generally held opinion among cannabis users is that there are few substance abuse programs that will accept them if their primary substance is cannabis and that those programs that do exist are not effective for cannabis users (Weiner *et al.*, 1999).

However, mounting evidence documents the existence of a population of cannabis-dependent individuals who desire treatment (Roffman and Barnhart, 1987; Budney *et al.*, 1999; Stephens *et al.*, 1993a, 1993b, 1994, 2000; Weiner *et al.*, 1999). For example, a survey of 335 adolescent cannabis users reported that 80% had considered quitting, 52% had tried unsuccessfully to quit, and only 24% believed that they would never quit (Weiner *et al.*, 1999). In one investigation, a public service announcement directed at chronic marijuana users resulted in interviews of 225 people who responded. It was found that 74% reported negative consequences of their marijuana use and 92% wanted to be treated (Roffman and Barnhart, 1987). In 1998, 48% of adolescent admissions to state-funded substance abuse programs were for primary cannabis dependence, indicating a significant need for treatment programs for cannabis dependence (SAMHSA, 1999).

With the recognition that cannabis use produces dependence and withdrawal, and that cannabis-dependent individuals may benefit from treatment, many substance abuse programs have started offering treatment to people whose primary drug

of abuse or dependence is marijuana. Unfortunately, these programs are not generally designed specifically for cannabis dependence and they have not achieved high success rates (Baer *et al.*, 1998; Hser *et al.*, 2001; Hubbard *et al.*, 1985; SAMHSA, 2000). Similarly, many nonprofessional organizations that offer support groups, such as Alcoholics Anonymous (AA), Narcotics Anonymous (NA) and Self-Management and Recovery Training (SMART), have also begun to welcome people whose primary drug is cannabis. In addition, there is now a nonprofessional support organization, Marijuana Anonymous (MA), started by and run for cannabis-dependent individuals.

We are aware of only four controlled studies of treatment of cannabis-dependent individuals. In three of the studies, the subjects were seeking treatment specifically for cannabis dependence, whereas the fourth study involved schizophrenic patients undergoing treatment for marijuana dependence. The first study found no difference in the outcome between a cognitive-behavioral relapse prevention group and a support group – overall, 16% of subjects had decreased use and 15% were abstinent when assessed 12 months after treatment (Stephens *et al.*, 1994). Higher quantity and frequency of marijuana use prior to treatment were strongly correlated with poorer outcome (Stephens *et al.*, 1993b). A second study compared a motivational enhancement group, a motivational enhancement plus cognitive-behavioral therapy group, and a motivational enhancement plus cognitive-behavioral therapy group combined with a voucher-based incentive program that rewarded bi-weekly urine screens that were negative with vouchers for retail items. The group that received the voucher-based incentive program achieved a higher rate of abstinence during the study period and at the end of the study than either of the other two treatment groups (Budney *et al.*, 2000). Similar success using monetary rewards for negative urines was also reported in a small trial of schizophrenic patients undergoing treatment for marijuana dependence (Sigmon *et al.*, 2000). The last study compared brief motivational therapy with a cognitive-behavioral relapse prevention support group and a control group consisting of subjects put on a waiting list. Although no difference was found between the two active-treatment groups, subjects in both treatment groups were using significantly less marijuana and reported significantly fewer symptoms of dependence and fewer marijuana-related problems than subjects in the control group. Nevertheless, only 22% of the subjects in the active-treatment groups remained abstinent throughout a 16-month follow-up period (Stephens *et al.*, 2000).

The strongest predictor of successful outcome is longer retention in treatment programs (Simpson, 1981). Predictors of dropping out of an outpatient treatment program and presumably continuing use, were found to be young age, financial difficulties and psychological stress (Crits-Christoph and Siqueland, 1996; Grella *et al.*, 1999; Hser *et al.*, 2001; Simpson *et al.*, 1997; Roffman *et al.*, 1993). More research is clearly required to discover effective ways to retain cannabis-dependent patients in treatment.

Currently, there are few substance abuse programs specifically designed to treat cannabis dependence. Most programs are designed to treat all types of substance abuse, so that cannabis-dependent patients typically receive the same treatment as patients with other types of substance abuse. Since many cannabis-dependent patients are also dependent on other substances, this is often a satisfactory treatment strategy. Also, a number of basic principles of treatment of substance use disorders are equally applicable to cannabis dependence and other types of substance dependence.

One of these principles, critical for selecting the most appropriate intervention, is the importance of assessing an individual's stage in the recovery process (Prochaska and Velicer, 1997). Individuals in early stages, such as “precontemplation” and “contemplation”, benefit most from strategies aimed at using reliable sources to convey accurate information about cannabis that will help individuals identify personal reasons for discontinuing use. Individuals in later stages, such as “action” and “maintenance”, benefit most from cognitive-behavioral relapse-prevention strategies (Botvin, 2000; Prochaska and Velicer, 1997).

As with all other drugs of abuse, the ultimate goal in the treatment of cannabis dependence is abstinence. In a phenomenon similar to that seen in alcohol-dependent people, many cannabis-dependent people have exposure to others who are able to use cannabis in a nonproblematic manner, and will often insist that their goal is to moderate their use, rather than cease use altogether. Unfortunately, if a person is susceptible to cannabis dependence, the most frequent outcome of trying to use moderately after a period of abstinence is that within a few weeks or months they have returned to their preabstinence pattern of use. Although physicians can tell cannabis-dependent people that this is the likely outcome, only after going through this process one or more times do people whose goal is moderation rather than abstinence recognize that like alcoholics, moderation is not an option for them. The process of treatment begins with detoxification followed by maintenance. As discussed in the section on etiology and pathophysiology, chronic users usually experience a withdrawal syndrome during detoxification. Since the cannabis withdrawal syndrome is not life-threatening, detoxification generally does not require hospitalization unless it is complicated by detoxification from other drugs or by comorbid Axis I disorders that do require hospitalization for safe treatment. The intensity of the cannabis withdrawal syndrome varies widely, with some individuals reporting very mild symptoms and others reporting more severe symptoms (Budney *et al.*, 1999; Haney *et al.*, 1999; Kouri and Pope, 2000; Kaymakcalan, 1973, 1981; Tennant, 1986; Compton *et al.*, 1990; Jones *et al.*, 1976, 1981; Jones, 1983; Wiesbeck *et al.*, 1996).

To help a patient tolerate the 7- to 10-day withdrawal period, practitioners should provide psychological support (e.g., reassurance that the symptoms will resolve in a little over a week) and in some cases, provide pharmacological support (Miller *et al.*, 1989; Haney *et al.*, 2001a, 2001b). Research into possible pharmacological interventions is just getting underway. One author suggested the use of long-acting benzodiazepines if the level of discomfort is high or there are abnormal vital signs (Miller *et al.*, 1989). A small placebo-controlled, crossover study of 10 subjects showed that the antidepressant bupropion (Wellbutrin, Zyban) worsened irritability, restlessness, depression and insomnia associated with marijuana withdrawal (Haney *et al.*, 2001a). A second small placebo-controlled, crossover study of seven subjects showed that the antidepressant nefazodone (Serzone) decreased anxiety, muscle aches and restlessness associated with marijuana withdrawal, but not irritability or insomnia (Haney *et al.*, 2001b).

The foundation of maintenance treatment, as with other types of substance use disorders, is regular attendance at groups that provide education and support. It is hypothesized that such groups are effective because fellow group members are best able to confront each other's denial and minimization of the substance abuse problem and the rationalizations put forth by the substance abuser for continued use despite negative consequences. Also,

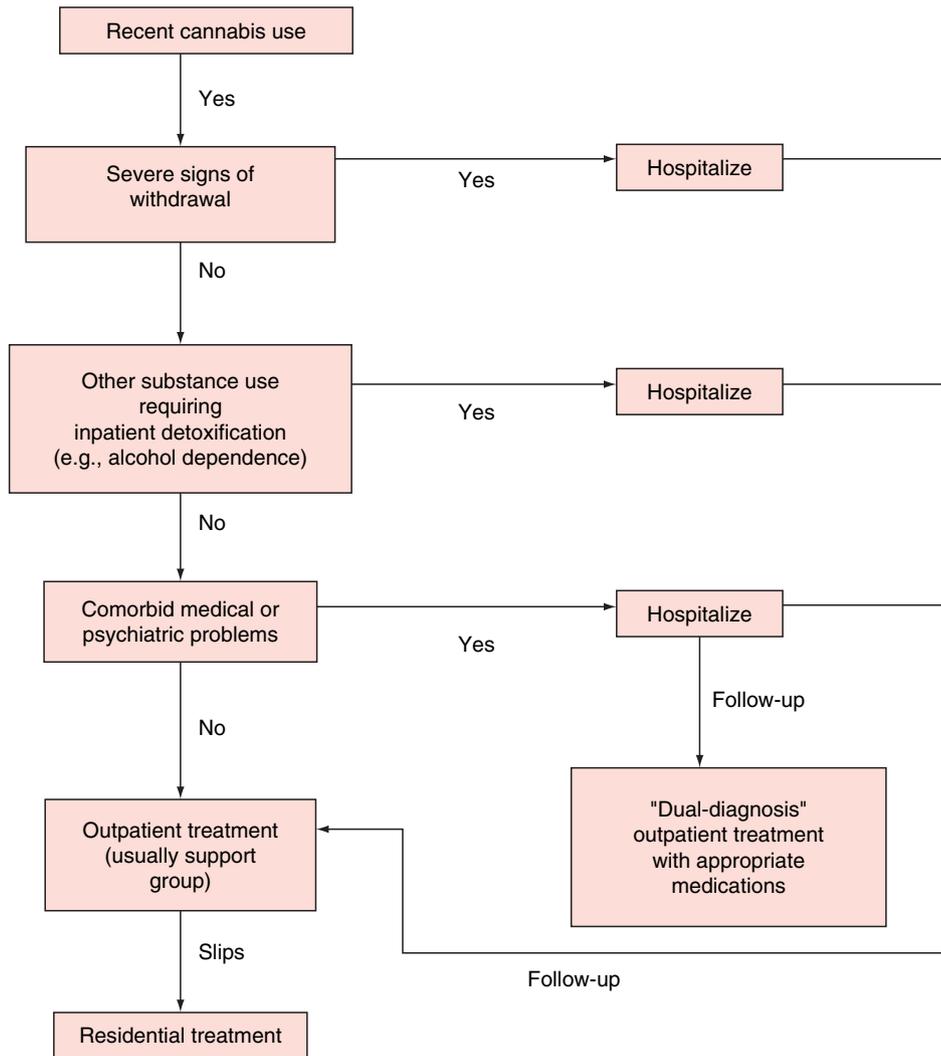

substance users typically report that they are most likely to believe information if it is provided by former users (Weiner *et al.*, 1999). Since cannabis dependence, like other types of substance abuse, is characterized by a chronic, relapsing course, these groups provide an important function by addressing issues around relapse prevention and provide support for dealing with relapses when they do occur.

### Special Features Influencing Treatment

Several approaches that are more important to the treatment of cannabis dependence should be employed in addition to the basic, general substance abuse program. Recent studies examining reasons for cannabis use have provided information to guide treatment strategies. For example, both adolescent and adult cannabis users frequently report that they use cannabis to relax, or as a stress reduction or coping mechanism. This observation suggests that treatment programs should teach healthier and more effective coping mechanisms and cognitive-behavioral strategies for relaxation and stress reduction (Botvin, 2000; Hendin and Haas, 1985; Weiner *et al.*, 1999).

The most salient feature of cannabis abuse or dependence is that it is often comorbid with other Axis I disorders as discussed earlier. Toxicology screening for other drugs of abuse is imperative because the most common comorbid Axis I disorders are other types of substance abuse. Even in the absence of an obvious Axis I diagnosis, psychological reasons for cannabis use should be investigated. For example, use of cannabis for relaxation or improving mood may be indicative of efforts to “self-medicate” underlying anxiety or mood disorders (Chen and Kandel, 1998; Latimer *et al.*, 2000). Thus, treatment programs for cannabis dependence should include a dual-diagnosis component. Because of the high frequency of comorbidity among cannabis-dependent individuals, diagnosing and treating the underlying disorder or symptomatology may be a necessary condition for the individual to stop using marijuana (Brady *et al.*, 1991; Cantwell *et al.*, 1999; Crits-Christoph and Siqueland, 1996; Johns, 2001; Menezes *et al.*, 1996; Regier *et al.*, 1990; Rounds-Bryant *et al.*, 1999; Simpson, 1981; Simpson *et al.*, 1997; Troisi *et al.*, 1998).

Another treatment situation frequently encountered is that of an individual with a known Axis I disorder that is being exacerbated by cannabis use. Some studies, performed in popu-

Note: Most of these patients will not be comittable and will have to voluntarily seek treatment

**Figure 37.2** Treatment decision tree for cannabis use disorders.

lations of patients with schizophrenia, have found that cannabis use worsens the course of the illness, whereas others have found that it does not affect the course (Negrete *et al.*, 1986; Treffert, 1978; Cuffel *et al.*, 1993; Linszen *et al.*, 1994). It is a reasonable assumption that at least some patients with Axis I disorders are adversely affected by cannabis use even if they use the drug only occasionally. In such cases, the role of cannabis as an exacerbating factor must be assessed and discussed with the patient. These patients may or may not be suitable for support groups directed primarily at substance abuse because cannabis may represent a relatively minor portion of the patient's overall clinical picture.

### Refractory Patients and Nonresponse to Initial Treatment

Like alcohol, the most common problem in managing cannabis use disorders is the high rate of relapse due to the wide availability of the drug and the large number of people who are users. Users are therefore tempted to resume use soon after a period of treatment when they find themselves in situations where they are surrounded by people using the substance. It is often useful for families and other people important in the patient's life to get involved in treatment to understand the role that they play in the patient's substance abuse. Some treaters advocate periodic random urine testing, which is an inexpensive and reliable method of monitoring abstinence, because THC remains present for such a long time and can be detected with infrequent testing (Miller *et al.*, 1989).

A difficult treatment situation arises when it is hypothesized that the patient is using cannabis to self-medicate a primary Axis I disorder such as depression or an anxiety disorder. In these individuals, abstinence is difficult to achieve because the patient believes that cannabis will alleviate his or her symptoms. Relapse may occur repeatedly until the underlying Axis I disorder is effectively treated (Peralta and Cuesta, 1992; Dixon *et al.*, 1991; Estroff and Gold, 1986; Warner *et al.*, 1994).

### Cannabis-induced Disorders

Uncomplicated cannabis intoxication rarely comes to clinical attention and, if it does, it does not require treatment other than reassurance, as it is a self-limiting condition. Similarly, as suggested in the previous sections, symptoms of delirium, psychosis, or anxiety associated with cannabis use typically resolve promptly after the period of acute intoxication is past. Again, no treatment is necessary other than keeping the patient safe and providing reassurance that symptoms caused by the drug will stop, as these are also self-limiting conditions. If the symptoms continue after more than 24 to 48 hours of abstinence from the drug, the possibility of another Axis I diagnosis must be considered. In such cases, treatment should then be directed at the primary Axis I disorder.

In the given treatment decision tree a diagnosis of cannabis use disorders is presented Figure 37.2.

### Comparison of DSM-IV/ICD-10 Diagnostic Criteria

The ICD-10 criteria and DSM-IV-TR criteria for Cannabis Intoxication are equivalent.

# Substance Abuse: Cocaine Use Disorders

## Definition

Cocaine, a central nervous system stimulant produced by the coca plant, is consumed in several preparations. Cocaine hydrochloride powder is usually snorted through the nostrils, or it may be mixed in water and injected intravenously. Cocaine hydrochloride powder is also commonly heated (“cooked up”) with ammonia or baking soda and water to remove the hydrochloride, thus forming a gel-like substance that can be smoked (“freebasing”). “Crack” cocaine is a precooked form of cocaine alkaloid that is sold on the street as small “rocks”. Abundant supplies and falling prices for cocaine (the equivalent of 1 gram of cocaine can be purchased for as little as \$25 to \$50 and a vial of crack [two or three small “rocks”] can be had for about \$10) have contributed greatly to the prevalence of cocaine abuse and dependence as well as other related cocaine use disorders.

Cocaine intoxication produces a state of intense euphoria that is a powerful reinforcer and can lead to the development of cocaine use disorders in many individuals, although only 10 to 16% of those who try the drug go on to develop these disorders (Van Etten and Anthony, 1999). Some experience the stimulant effects of cocaine as anxiogenic; others discontinue use because of lack of easy drug availability, fear of loss of control over use, or apprehension regarding possible legal consequences of cocaine abuse. The route of administration is strongly correlated with the development of cocaine use disorders, in that the intravenous and smoked routes of administration allow rapid transport of the drug to the brain, producing intense effects that are short-lived. Rapid tolerance to euphoria occurs and plasma concentrations are not correlated with peak euphoria, producing a need for frequent dosing to regain euphoric effects (binge use) that can place the cocaine abuser at risk for medical and psychiatric complications of cocaine abuse.

Cocaine abuse is characterized by a maladaptive pattern of substance use demonstrated by recurrent and significant adverse consequences related to repeated drug use. Such consequences include family discord, legal and employment problems and interpersonal problems. The person diagnosed with cocaine abuse may have significant periods during which no cocaine-related problems are experienced, but the initiation of cocaine abuse usually heralds the onset of psychosocial difficulties. Cocaine dependence is characterized by a more pervasive pattern of frequent cocaine use and a chronic cycle of psychosocial problems. In addition, medical and psychiatric adverse events associated with cocaine use can result in serious morbidity and, in some cases, mortality.

While the question of whether cocaine is physiologically addictive is not completely clear, the psychological addiction alone is powerful and can completely dominate the life of the cocaine abuser. Binge use of cocaine may be followed by what has been described as a mild withdrawal syndrome characterized by dysphoria and anhedonia. Cocaine withdrawal may resemble a depressive disorder, in some cases requiring emergent psychiatric treatment. Some combination of these consequences of cocaine abuse are usually responsible for the identification and diagnosis of individuals with cocaine use disorders and referral to substance abuse treatment.

## Epidemiology

The National Household Survey on Drug Abuse (NHSDA) reported that in 2000, 1.2 million Americans were current cocaine users representing 0.5% of the population over the age of 12 (SAMHSA, 2001a). Since 1975, the monitoring the future (MTF) study has annually examined the extent of drug abuse among 8th to 12th graders. Use of cocaine decreased significantly among 12th graders, from 6.2% in 1999 to 5.0% in 2000; crack cocaine use in the year 2000 decreased from 2.7 to 2.2% for 12th graders. While cocaine use has shown a downward trend, several statistics indicate that cocaine abuse is still a serious threat to the public. For example, cocaine-related emergency department visits constituted 29% of all drug related visits in 2000, more than for any other illicit substance (SAMHSA, 2001b).

## Gender Differences in Cocaine Use Disorders

While men continue to have a higher rate of current cocaine use than women, the gap is narrowing (Van Etten and Anthony, 1999; SAMHSA, 1996). Some studies have reported that women cocaine abusers differ from men in several respects, including responses to the direct administration of cocaine.

Much of the research on substance abuse treatment efficacy is based predominantly on male samples. Cocaine dependence in women is as severe as that in men, however women often receive less treatment for their substance abuse (McCance-Katz *et al.*, 1999). Studies have also suggested that cocaine dependence can develop more rapidly in women than in men. Cocaine is one of the most frequently abused illicit drugs during pregnancy (SAMHSA, 1999). It has been estimated that 0.1% of pregnant women are cocaine users (SAMHSA, 1999). The risks of cocaine

and other substance abuse during pregnancy are significant not only for women but also for their unborn children who may be at increased risk of vascular injury to the central nervous system. Abuse of cocaine has been linked to placental abruption, preterm labor, and low birth weight. Abuse and neglect of children are also common consequences of parental addiction. Recent studies have suggested that children exposed to cocaine *in utero* do not appear to have permanent sequelae attributable to maternal cocaine abuse.

### Relationship of Psychiatric Disorders to Cocaine Abuse and Dependence

Several studies have documented the high rate of comorbid psychiatric disorders in cocaine abusers entering treatment. These disorders include mood disorders (major depressive disorder, bipolar disorders), schizophrenia, post traumatic stress disorder, attention-deficit hyperactivity disorder, anxiety disorders and antisocial personality disorder. Mood disorders often temporally follow the onset of cocaine abuse in patients presenting for treatment, while attention-deficit hyperactivity disorder and antisocial personality disorder precede the onset of cocaine abuse (McMahon *et al.*, 1999; Clure *et al.*, 1999). However, while high levels of depressive symptoms during treatment were associated with greater craving for cocaine, alcohol and other substances, only limited evidence exists regarding the influence of depression on treatment course and outcome (Carroll *et al.*, 1995; Brown *et al.*, 1998; Simpson *et al.*, 1999).

It is important to note that comorbid psychiatric illnesses are common among cocaine users. Furthermore, the diagnosis of a comorbid primary psychiatric disorder can be challenging to make in cocaine abusers because psychiatric symptoms may be the result of cocaine abuse or acute abstinence. When psychiatric disorders cooccur with cocaine use disorders, it is important to provide treatment for both disorders. Cocaine use disorders will not generally resolve with treatment of the psychiatric disorder alone, nor will substance abuse treatment resolve a comorbid psychiatric disorder.

### Course and Natural History

Cocaine produces a sense of intensified pleasure in most activities and a heightened sense of alertness and well-being. Anxiety and social inhibition are decreased. Energy, self-esteem and self-perception of ability are increased. There is enhancement of emotion and sexual feeling. Pleasurable experiences, although heightened, are not distorted and hallucinations are usually absent. The person engaging in low-dose cocaine use often receives positive feedback from others responding to the user's increased energy and enthusiasm. This, in combination with the euphoria experienced by the user, can be reinforcing, and cocaine use is perceived as free of any adverse consequences. The duration of cocaine's euphoric effects depends on the route of administration. Cocaine and alcohol are often consumed together. In addition to the synergistic effects of cocaine and alcohol in humans, an active metabolite, cocaethylene, with cocaine-like pharmacological properties is formed and users of both drugs simultaneously report enhanced euphoria.

Cocaine users quickly learn that higher doses are associated with intensified and prolonged euphoria, resulting in increasing use of the drug and progression to cocaine dependence. The abuser is focused on the cocaine-induced euphoria and begins compulsively to pursue this effect. These behaviors become

pivotal in the lives of cocaine abusers who continue drug abuse despite the presence of increasing personal and social consequences. Uncontrolled use of cocaine often begins with either increased access and resultant escalating dosages and frequency of administration or a change from intranasal use to a route of administration with more rapid onset of effects (i.e., intravenous or smoked). Such binges produce extreme euphoria and vivid memories. These memories are later contrasted with current dysphoria to produce intense craving, which perpetuates the binge use pattern. Addicts report that during binge use, thoughts are focused exclusively on the cocaine-induced effects. Normal daily needs, including sleep and nourishment, are neglected. Responsibilities to family and employer and social obligations are given up. This continues until the supply of cocaine is exhausted.

Binges are often separated by several days of abstinence; cocaine-dependent individuals average one to three binges per week. This is in contrast to use patterns for opiate and alcohol dependence which often produce physiological dependence necessitating daily consumption to prevent withdrawal symptoms. This differentiation is crucial to an understanding of the syndrome of cocaine dependence. Newly abstinent cocaine abusers may experience a triphasic abstinence pattern, although this varies by individual, that includes a period of acute abstinence, sometimes referred to as the "crash", lasting several hours to several days consisting of dysphoria, fatigue, insomnia or hypersomnia, increased appetite, and either psychomotor agitation or retardation, subsequent to the more intensive "crash" phase. A more chronic withdrawal period sometimes occurs characterized by minor depressive symptoms and cocaine craving lasting 2 to 10 weeks. This may then be followed by an extinction phase characterized by intermittent drug craving that becomes increasingly manageable with continued abstinence.

Like other drug and alcohol use disorders, cocaine use disorders are chronic relapsing illnesses that present substantial challenges in the treatment process. Cocaine abusers are at high risk for relapse, particularly in the first few months of treatment related to acute craving often in the context of ongoing psychosocial stressors that result from or have been exacerbated by cocaine abuse. Newly abstinent cocaine abusers often lack adequate coping skills necessary to avoid cocaine use, which take time to acquire in the treatment process. Although the ability to cope with cocaine craving improves with continued abstinence, relapse to cocaine abuse or other drug and alcohol abuse will continue to be a risk for those with a history of a cocaine use disorder who relapse to cocaine abuse. Repeated treatments may be required for those with cocaine use disorders. Treatment modalities include inpatient hospitalization for medical or psychiatric complications of cocaine abuse, partial hospital programs, self-help groups, psychotherapy (usually group or family therapy for patients with primary cocaine use disorders), or some combination of these treatments according to the clinical presentation of the patient.

### Neurobiological Changes Related to Cocaine Use

Cocaine has effects on multiple neurotransmitters, including release and reuptake blockade of dopamine, serotonin (5-hydroxytryptamine [5-HT]) and norepinephrine. The most widely accepted explanation of cocaine-induced euphoria is that dopamine reuptake inhibition results in increased extracellular dopamine concentration in the mesolimbic and mesocortical reward pathways in the brain. Another important phenomenon related

to acute cocaine administration is that of “acute tolerance”. A single dose of cocaine has been shown experimentally to reduce the response to a second identical dose given 100 minutes later as measured by extracellular dopamine levels and motor activity (Bradberry, 2000). The finding of “acute tolerance” is consistent with the binge pattern of cocaine use in which abusers consume escalating doses of cocaine in an attempt to recapture the intense euphoria of the initial cocaine dose (Bradberry, 2000). A growing body of evidence indicates that chronic cocaine administration can result in sustained neurophysiological changes in brain systems that regulate psychological processes, specifically pleasure and hedonic responsivity. This has been postulated to underlie a physiological addiction to cocaine with associated withdrawal phenomena that are manifested clinically as a psychological syndrome (Koob and Nestler, 1997).

### Diagnosis of Cocaine Use Disorders

The initial evaluation period should include the collection of a complete history of all substance abuse, which is essential to accurate diagnosis and appropriate treatment. The history includes the circumstances under which each drug was used, the psychoactive effects sought and obtained, the route of administration, and the frequency and amount of each drug used. Cocaine abusers frequently abuse other drugs and alcohol to enhance euphoria or to alleviate dysphoric effects associated with cocaine abuse (agitation, paranoia). A thorough history with diagnosis of other substance use disorders is important to treatment planning. Patients may need detoxification from other substances prior to initiation of cocaine abuse treatment. It is also important to monitor clinically for relapses to any substance abuse during treatment for cocaine use disorders because the use of other drugs and alcohol often leads to resumption of cocaine abuse. In addition, a thorough history of current and previous substance abuse is important so that treatment can be individualized and patients can be helped to develop coping skills that will assist them in specific situations that they identify as placing them at high risk for relapse.

A complete physical examination is necessary to determine whether medical complications of substance abuse are present. Common medical problems seen in those with cocaine use disorders include poor nutrition, vitamin deficiencies, anemia, human immunodeficiency virus (HIV) infection and sexually-transmitted diseases. In those who self-administer the drug by injection or who abuse other drugs in addition to cocaine by the intravenous route, endocarditis, abscesses, cellulitis, and Hepatitis B and C occur with regularity. The clinical evaluation should include blood studies to determine the presence of abnormalities and urine toxicology screen to determine recent drug use.

### Cocaine Dependence

Cocaine has a short half-life requiring frequent dosing to maintain the “high” (binge use). Persons with cocaine dependence often spend large amounts of money for the drug and may be involved in illegal activities to obtain cocaine. Binges may be separated by several days while the individual recovers or attempts to obtain more money for drug purchase. Illegal activities such as theft and prostitution are often engaged in to obtain cash for cocaine. Obligations such as employment and childcare are often neglected. Tolerance to cocaine effects develops quickly, resulting in larger amounts of drug use with time. This is often associated with mental or physical complications of use including

paranoia, aggressive behavior, anxiety and agitation, depression and weight loss. Withdrawal symptoms, most prominently dysphoric mood, may be seen but are usually short-lived and clear within several days of abstinence. The criteria of cocaine dependence is identical to that of substance dependence and may be found on p. 411.

### Cocaine Abuse

Substance abuse is described by DSM-IV-TR as a maladaptive pattern of substance use demonstrated by recurrent and significant adverse consequences related to repeated use (see p. 409). For example, there may be neglect of obligations to family or employer, repeated use in hazardous situations, legal problems and recurrent social or interpersonal problems. These problems must recur within the same 12-month period. The intensity and frequency of use are less in cocaine abuse than in cocaine dependence. Episodes of abuse may occur around paydays or special occasions and may be characterized by brief periods (hours to days) of high-dose binge use followed by longer periods of abstinence or nonproblem use.

### Cocaine Intoxication

The clinical effects of cocaine intoxication are characterized initially by euphoria (referred to as “high”) and also include agitation, anxiety, irritability or affective lability, grandiosity, impaired judgment, increased psychomotor activity, hypervigilance or paranoia, and sometimes hallucinations (visual, auditory, or tactile) may occur. Physical symptoms that can accompany cocaine intoxication include hypertension, tachycardia, hyperthermia, pupillary dilatation, nausea, vomiting, tremor, diaphoresis, chest pain, arrhythmia, confusion, seizures, dyskinetic movements, dystonia and, in severe cases, coma. These effects are more frequently seen in high-dose binge users of cocaine. Cardiovascular effects are probably a result of sympathomimetic properties of cocaine (i.e., release of norepinephrine and blockade of norepinephrine reuptake). The DSM-IV criteria of cocaine intoxication are based on the general criteria for substance intoxication (see p. 410).

### Cocaine Withdrawal

The principal feature of substance withdrawal is development of a substance-specific maladaptive behavioral change, which may have associated physiological and cognitive components, resulting from the cessation of or reduction in heavy and prolonged substance use. Depression and suicidal ideation are the most serious complications and require individualized assessment and treatment. The syndrome may last up to several days but generally resolves without treatment. The diagnosis of cocaine withdrawal is predicated on the general DSM-IV criteria for substance abuse withdrawal (see p. 410). Specifically it requires the presence of dysphoria and two of the following symptoms developing as short as a few hours after discontinuation of the drug: insomnia, fatigue, increased appetite, psychomotor agitation or retardation, and vivid, unpleasant dreams.

### Medical Complications of Cocaine Abuse

Cardiac toxicity is one of the leading causes of morbidity and mortality associated with cocaine use. The risk of myocardial

infarct is well established in cocaine use and is not related to dose, route, or frequency of administration. The risk of acute myocardial infarction is increased 24-fold in 1 hour immediately following cocaine use in persons who are otherwise at relatively low risk for such events (Mittleman *et al.*, 1999). Detection of recent cocaine use by urine toxicology screen has been observed in 25% of those reporting to urban emergency departments and 7% of those evaluated at suburban hospitals and found to have evidence of myocardial infarct (Hollander *et al.*, 1995). About half of the patients with cocaine-related myocardial infarction have no evidence of atherosclerotic coronary artery disease (Hollander *et al.*, 1997a, 1997b). Identifying and diagnosing cocaine-related myocardial infarction can be difficult. The hallmarks of myocardial infarct are a constellation of physical symptoms including chest pain, electrocardiogram (ECG) abnormalities and elevated creatine kinase. Cocaine abusers with chest pain may have ECG abnormalities that are not specific for myocardial infarct (Weber *et al.*, 2000). Cocaine abusers are also often found to have nonspecific elevations in creatine kinase without myocardial infarction. Therefore, the diagnosis of cocaine-related myocardial infarction is often based on the physician's clinical judgment. Evaluation of serum troponin I, a cardiac marker that is not affected by recent cocaine use, can be helpful in determination of whether a myocardial infarct has occurred.

The pathophysiology of cocaine-related myocardial infarction is probably multifactorial. The sympathomimetic effects of cocaine increase myocardial oxygen demand by increasing heart rate, systemic blood pressure and left ventricular contractility while reducing oxygen supply through its coronary artery vasoconstriction effects (Baumann *et al.*, 2000). According to new treatment guidelines for emergency cardiovascular care, nitroglycerine and benzodiazepines are first line agents and phenolamine is a second line agent for patients with cocaine-related myocardial ischemia or infarction. Propranolol is contraindicated as it exacerbates cocaine-induced vasoconstriction of coronary arteries. Thrombolysis is not recommended unless evidence of evolving myocardial infarction persists despite medical therapy and an occluded coronary artery is shown to be present on angiography.

Cocaine use is associated with a wide range of cardiac dysrhythmias including sinus tachycardia, sinus bradycardia, supraventricular and ventricular tachycardia, ventricular premature contractions, ventricular tachycardia and fibrillation, torsades de pointes and asystole. Life-threatening dysrhythmia caused by cocaine in the absence of myocardial ischemia is rare. In many instances, cardiac dysrhythmias have occurred in the context of profound hemodynamic or metabolic disturbances (Wang, 1999). Intranasal abuse of cocaine has been associated with a number of medical complications including chronic sinusitis, septal perforation, subperiosteal abscess, pneumomediastinum, pneumothorax and pulmonary edema (Gendeh *et al.*, 1998). The presence of pulmonary edema in a young, otherwise healthy patient, without predisposing risk factors, should alert the physician to the possibility of cocaine abuse.

Cerebrovascular accidents related to cocaine use have been well documented in the medical literature. Cerebral infarct, subarachnoid hemorrhage, intraparenchymal hemorrhage and intraventricular hemorrhage have been observed as acute complications of cocaine use. Seizures were one of the earliest known complications of cocaine abuse. While anticonvulsants have not been helpful in preventing cocaine-related seizures, intravenous diazepam has been effective in acute management.

### Clinical Vignette 1

Mr B is a 34-year-old divorced man with a 10-year history of freebase cocaine abuse characterized by weekly binge use of up to 6 g of cocaine and alcohol use reported as five beers several times per week with cocaine, but no other illicit drug use. He was admitted to the hospital emergency department with a chief complaint of visual hallucinations and paranoid ideation that developed during the course of several hours of binge cocaine use. On physical examination, he was noted to be agitated with mild tachycardia and hypertension, but there were no other concurrent medical illnesses.

Haloperidol 5 mg and lorazepam 2 mg were administered by intramuscular injection for treatment of psychosis and agitation, with rapid abatement in symptoms. The patient was transferred to a dual-diagnosis inpatient unit for further evaluation. Resolution of visual hallucinations and paranoia occurred within 24 hours. After 2 days of hypersomnia, intermittent anxiety and mild depressive symptoms, he reported feeling better and began to engage in substance abuse treatment. He was discharged to an outpatient clinic for further treatment of cocaine and alcohol use disorders.

#### Final DSM-IV Diagnoses

Axis I: Cocaine dependence, alcohol abuse, cocaine intoxication, cocaine withdrawal

Axis II: Deferred

Axis III: None

### Assessment and Treatment Overview

The two primary goals of cocaine treatment are: 1) the initiation of abstinence through disruption of binge cycles and 2) the prevention of relapse. Treatment planning to achieve these goals must be considered in the context of the individual clinical presentation of the patient. Initial assessment to determine immediate needs is necessary to determine the most appropriate level of care (inpatient or outpatient treatment) as well as other psychiatric and medical considerations important to the development of the treatment plan.

The majority of those with cocaine use disorders are most appropriately treated in an outpatient setting. Outpatient treatment may vary by provider but generally includes multiple weekly contacts for the initial months of treatment because less frequent contact is not effective in the initiation or maintenance of abstinence these sessions consist of some combination of individual drug counseling, peer support groups, family or couples therapy, urine toxicology monitoring, education sessions, psychotherapy and psychiatric treatment that may include pharmacotherapy for cocaine addiction or comorbid psychiatric disorders. Inpatient treatment is reserved for those who have been refractory to outpatient treatment, whose compulsive use of cocaine represents an imminent danger (e.g., suicidality associated with cocaine toxicity or acute abstinence), who have other comorbid psychiatric or medical disorders, or who are dependent on more than one substance and require monitored detoxification.

### Cocaine Use Disorders: Clinical Course

Cocaine use is characterized by binge use that can occur over extended periods of time and is limited only by the supply of drug

or money to purchase the drug. Cocaine toxicity may occur with repeated use of the drug over the course of a binge. Symptoms can include hypervigilance, psychomotor agitation, hyperawareness and psychosis. While these symptoms generally resolve within 24 hours of cessation of cocaine use, prolonged symptoms may be indicative of an underlying bipolar disorder that will need further assessment. Another facet of cocaine toxicity that may be manifested as psychiatric symptoms is that of a syndrome of hyperthermia and agitation resembling neuroleptic malignant syndrome. An additional serious complication of cocaine intoxication is that of stimulant delirium characterized by confusion, disorientation and agitation. This should be treated as a medical emergency since such symptoms may be indicative of cocaine overdose. Cocaine abstinence symptoms occur with the cessation of binge use (Margolin *et al.*, 1996; Foltin and Fischman, 1998; Milby *et al.*, 2000). The abstinence syndrome is characterized by extreme exhaustion after a binge. Initial depression, agitation and anxiety are a common experience, followed by craving for sleep. Prolonged hypersomnolence and hyperphagia are usually followed by a return to normal mood, although some dysphoria may remain.

Cocaine abusers may present to urgent care settings in the context of cocaine toxicity or severe psychiatric symptoms associated with acute abstinence including anxiety, depression, or psychosis. Symptoms may be of a severity that require emergent use of benzodiazepines or antipsychotics. Lorazepam is a good choice for treatment of anxiety, agitation, or psychosis because it can be administered orally; it is also well-absorbed by the intramuscular route. The use of benzodiazepines in the severely agitated patient may decrease the need to employ the use of restraints. Antipsychotics should be used sparingly because, like cocaine, these drugs may lower the seizure threshold. In considering the choice of an antipsychotic, low-potency antipsychotics may be more likely than high-potency neuroleptics to lower seizure threshold and therefore should be avoided. Psychiatric management must also include clinical observation because suicidal ideation is not uncommon. Symptoms resembling those of a major depressive episode occur frequently in newly abstinent cocaine abusers. The occurrence of major depressive disorder must be excluded by observation over several days following the initiation of abstinence.

Individuals with cocaine use disorders will experience a withdrawal syndrome upon cessation of binge cocaine abuse that can last for as long as 10 weeks. Cocaine withdrawal is marked by decreased energy, lack of interest and anhedonia. These symptoms fluctuate and are usually not severe enough to meet diagnostic criteria for a major depressive episode. However, this subjective state experienced by the cocaine abuser is contrasted with vivid memories of cocaine-induced euphoria and constitutes a strong inducement to resume cocaine use. It is during this time that relapse is most likely. Withdrawal symptoms generally diminish over several weeks if abstinence is maintained.

The withdrawal phase is followed by what has been termed “extinction”, an indefinite period during which evoked craving can occur, placing the individual at increased risk for relapse. Craving is evoked by moods, people, locations, or objects associated with cocaine use (money, white powder, pipes, mirrors, syringes) that act as cues to conditioned associations with drug use and drug-induced euphoria.

## Treatment of Cocaine Use Disorders

One of the greatest challenges in the early stages of cocaine treatment is to prevent early drop out. It has been estimated that up to

80% of patients drop out of treatment programs (Higgins *et al.*, 1994). Frequent clinical contacts, especially in the early weeks of treatment, can help to establish a therapeutic alliance that will assist in engaging the patient in the treatment process. Many programs offer 3 to 6 days per week of substance abuse treatment sessions within outpatient partial hospital programs or intensive outpatient chemical dependency programs. Assessments by the program physician and counseling staff can identify other areas requiring specific interventions (comorbid medical or psychiatric disorders) and can expedite the initiation of appropriate pharmacotherapies. These interventions will increase treatment retention. Often patients must be helped to realize that their drug use is having a significant and adverse impact on their lives. Many patients come to treatment because of family, legal, or social pressures. They can be ambivalent about the need for treatment and require education about their addiction and assistance in reviewing the consequences of cocaine use in their lives. This inventory should occur in the initial visits to the substance abuse treatment program.

Initial treatment should include the encouragement of abstinence from all drug and alcohol use. Patients who abuse alcohol and marijuana often do not perceive these drugs as problems. Education regarding the use of such drugs as conditioned stimuli to the use of cocaine should be emphasized. The “disease model” of chemical dependency may be used to assist in the initiation of abstinence. Emphasis is placed on the patients recognizing chemical dependency as a disease needing treatment to control, but one for which there is no cure. Comprehensive drug education should also be provided in the initial treatment phase. Frequent contact with a drug counselor is an important part of treatment. Individual, group and (where clinically indicated) family or marital therapy should be available. Attendance at 12-step or other self-help groups is often a useful adjunct to treatment and can be particularly helpful during the early stages of treatment when support for sobriety is essential.

The early recovery phase of treatment varies in duration from 3 to 12 months and is characterized by multiple weekly contacts and participation in therapeutic modalities with the goal of initiation and maintenance of abstinence. The focus during early recovery should be on relapse prevention and development of new and adaptive coping skills, healthy relationships and lifestyle changes that will facilitate abstinence.

Relapses are common during early recovery. Patients often feel pleased about their progress in treatment, become overly confident about their ability to control use, and test themselves by deliberately encountering what they know to be a high-risk situation for their drug use. Experimentation with cocaine to prove that drug use can be controlled often results in relapse and is associated with guilt. Patients should be informed about the potential for relapse from the start of the treatment process. Relapse should be reviewed with the patient in a supportive way with an emphasis on helping the patient to gain an understanding of the events leading to relapse. Relapse should, however, also trigger a review of the treatment plan and consideration of the need for additional interventions or whether a higher level of care is needed to assist the patient in the recovery process.

Success with initiating and maintaining abstinence over several months is followed by a reduced frequency of contact (e.g., a decrease to weekly group or individual therapy sessions). The focus should be on maintaining a commitment to abstinence, addressing renewed denial and continued improvement of interpersonal skills. Participation in self-help groups should continue to be encouraged. Self-help groups based on 12-step principles

**Table 38.1 Psychotherapies: The Mainstay of Treatment for Cocaine Use Disorders**

Interpersonal therapy  
 Supportive expressive therapy  
 Cognitive–behavioral therapy/Relapse prevention therapy  
 Voucher based treatment alternative reinforcement behavioral therapy  
 Individual and group drug counseling  
 Systematic cue exposure  
 Self-help groups (e.g., Cocaine Anonymous)

encourage patients to continue to view themselves as addicts in recovery – a cognitive structuring that many recovering drug abusers find helpful in maintaining sobriety.

### Psychotherapies for Cocaine Use Disorders

A variety of psychotherapeutic strategies for the treatment of cocaine use disorders have been adopted (Table 38.1). In contrast to opiate addiction, for which psychotherapies alone are insufficient, there appear to be at least some subpopulations of cocaine abusers for whom psychotherapy alone may be adequate (Crits-Christoph *et al.*, 1997, 1998, 1999). Behavioral therapies, in particular cognitive–behavioral therapy and contingency management approaches, have been demonstrated to be effective treatments for some cocaine-dependent patients.

The lack of a medically dangerous withdrawal syndrome from cocaine also suggests that some cocaine abusers may respond to psychotherapy alone in an outpatient treatment setting, compared with opiate- or alcohol-dependent persons for whom hospitalization may be required for detoxification. Another important reason for the development of psychotherapies for the

treatment of cocaine use disorders is that no medication is currently approved for the treatment of these disorders. Psychotherapies are also important platforms on which any pharmacological treatment may be supported.

### Physician–Patient Relationship Considerations

The treatment of cocaine use disorders should be undertaken in the context of a thorough understanding of the disease (Table 38.2). The physician should develop individual treatment plans for patients based on the presenting complaints and symptoms related to cocaine abuse and any abstinence syndrome. Treatment plans include assessment for psychiatric and medical illnesses, pharmacological interventions, psychotherapy and other psychosocial interventions.

The physician is the provider who will make decisions regarding pharmacotherapy for cocaine dependence. This is an important consideration because there are currently no medications for cocaine use disorders that are approved by the US Food and Drug Administration. Therefore, any decision to provide medication to assist with the maintenance of abstinence from cocaine abuse must be carefully considered with documentation of the rationale for medication choice, risks and benefits of treatment and informed consent from the patient.

### Pharmacotherapies for Cocaine Use Disorders

The development of pharmacological treatments for cocaine abuse has been based on the premise that an altered neurochemical substrate underlies the chronic, high-intensity (binge) use and acute abstinence/withdrawal that follows binge use. This neuroadaptation model has also served as a basis for a number of studies that have evaluated the clinical utility of psychotropic

**Table 38.2 Cocaine Use Disorders: Recovery and Treatment**

Parameter	Acute Abstinence	Withdrawal Phase	Extinction Phase
Duration	Several hours to 4 d	2–10 wk	3–12 mo
Treatment	Symptomatic May need hospitalization for medical or psychiatric care and assessment	Initiate psychotherapy Individual/group therapy Self-help groups, other therapies, e.g., family, marital, individual, as needed	Continue psychotherapy, decrease intensity with continued abstinence; self-help groups and additional interventions developed for individual patients as needed
Pharmacotherapy	Benzodiazepines for anxiety, agitation, paranoia. Antipsychotics (sparingly) for severe psychosis or agitation	None approved specific for cocaine use disorders Consider disulfiram for cocaine- or alcohol abuse previously refractory to treatment; psychotropics for comorbid psychiatric disorders or cocaine-related disorders; pharmacotherapies for other substance use disorders	Unusual to initiate in this phase Taper and discontinue pharmacotherapy for cocaine abuse and monitor clinically

agents that, based on their pharmacological profile, might possess anticraving properties, block euphoria, or decrease cocaine abstinence symptoms. To date, no medication has emerged as an accepted effective pharmacotherapy.

### Common Problems in Management

Several common problems are encountered in the treatment of patients with cocaine use disorders. These include: 1) relapse to cocaine use, 2) comorbid psychiatric disorders, 3) comorbid substance use disorders, 4) premature treatment termination and 5) treatment refractoriness.

### Comparison of DSM-IV/ICD-10 Diagnostic Criteria

The ICD-10 and DSM-IV-TR Criteria sets for Cocaine Intoxication and Withdrawal are almost the same except that ICD-10 criteria set for Withdrawal includes drug-craving as an additional item.

# Substance Abuse: Phencycline Use Disorders

Phencyclidine (PCP) failed its development as a potential general anesthetic agent during the 1950s because of its propensity to cause psychotic episodes during emergence that were sometimes severe and violent, and lasted from hours to days. PCP psychosis closely resembles schizophrenia in terms of symptoms, signs and thought disorder. A single very small dose of PCP given to a normal subject induces a psychotic state lasting for several hours, while in a person with schizophrenia, the psychosis can be exacerbated for several weeks by the fact that it is easy to synthesize. Many users consumed PCP on a daily or near-daily basis for weeks or months at a time. There were numerous instances of severe medical toxicity, a number of deaths from overdoses, and many cases of prolonged (up to six weeks) psychoses in users without preexisting psychotic disorders. In addition to CNS effects, PCP overdose involves sympathomimetic, neuromuscular and renal effects that can result in tissue damage and death. These problems are compounded by PCP's lipophilicity, long half-life and still longer duration of action. The incidence and prevalence of PCP abuse have declined markedly since the late 1970s to early 1980s; however, PCP abuse continues and remains relatively high in certain areas of the USA. PCP exerts its characteristic effects by noncompetitive blockade of the N-methyl D-aspartate class of glutamate receptors. Ketamine is a PCP derivative that shares PCP's mechanism of action and is approved for general effects are less frequent and severe owing to the lower potency and shorter duration of ketamine action compared with PCP.

## Epidemiology

As of the year 2000, the highest rates of PCP use during the previous year were observed among 18- to 20-year-olds, followed by 12- to 17-, 21- to 25-, and 26- to 34-year-olds. In 2000, among Americans aged 12 or older, it was estimated that 54 000 had used PCP within the previous month, 264 000 within the previous year and 5 693 000 (2% of the population) within their lifetimes (Substance Abuse and Mental Health Services Administration, 2001). In the same year, PCP ranked 31st among the top 50 drugs mentioned most frequently in drug-related emergency department episodes nationwide showing a 48% increase in ER mentions compared with 1999 (Substance Abuse and Mental Health Services Administration, 2002).

In 1983, more than 66% of PCP-related deaths reported to the Drug Abuse Warning Network involved at least another one drug. Many of the PCP-related deaths were not the result of overdose or drug interaction or reaction, but the direct result of some external

event facilitated by intoxication (e.g., homicides, accidents). The various manners of death (such as drowning and being shot by police) reported are consistent with the disorientation and violent aggressive behavior that can be stimulated by PCP (Crider, 1986).

## Etiology and Pathophysiology

The effects of low-dose PCP administration have been extensively studied in volunteers. In normal subjects single intravenous doses of 0.05 to 0.1 mg/kg induced withdrawal, negativism and in some cases catatonic posturing; thinking processes became concrete, idiosyncratic and bizarre in the absence of significant physical or neurological findings; and drug effects persisted for 4 to 6 hours. In contrast to lysergic acid diethylamide (LSD) or amphetamine PCP was noted to induce disturbances in symbolic thinking perception and attention strikingly similar to those observed in schizophrenia. Administration of PCP to schizophrenic subjects caused exacerbation of illness-specific symptoms persisting up to several weeks, suggesting that schizophrenic or preschizophrenic individuals may be at significantly increased risk of behavioral effects from PCP abuse.

## Phenomenology and Variations in Presentation

Physicians must be alert to the wide spectrum of PCP effects on multiple organ systems. Because fluctuations in serum levels may occur unpredictably, a patient being treated for apparently selective psychiatric or behavioral complications of PCP abuse may suddenly undergo radical alterations in medical status; emergency medical intervention may become necessary to avoid permanent organ damage or death. Any patient manifesting significant cardiovascular, respiratory, neurological, or metabolic derangement subsequent to PCP use should be evaluated and treated in a medical service; the psychiatrist plays a secondary role in diagnosis and treatment until physiological stability has been reached and sustained.

PCP-intoxicated patients may come to medical attention on the basis of alterations in mental status; bizarre or violent behavior; injuries sustained while intoxicated; or medical complications, such as rhabdomyolysis, hyperthermia, or seizures (Baldridge and Bessen, 1990). As illicit ketamine use has increased significantly as part of the "club drug" phenomenon, it is important to remember that ketamine can induce the same spectrum of effects and complications, the chief difference from PCP being the much shorter duration of action of ketamine.

**DSM-IV-TR Criteria 292.89****Phencyclidine Intoxication**

- A. Recent use of phencyclidine (or a related substance).
- B. Clinically significant maladaptive behavioral changes (e.g., belligerence, assaultiveness, impulsiveness, unpredictability, psychomotor agitation, impaired judgment, or impaired social or occupational functioning) that developed during, or shortly after, phencyclidine use.
- C. Within an hour (less when smoked, “snorted,” or used intravenously), two (or more) of the following signs:
  - (1) Vertical or horizontal nystagmus
  - (2) Hypertension or tachycardia
  - (3) Numbness or diminished responsiveness to pain
  - (4) Ataxia
  - (5) Dysarthria
  - (6) Muscle rigidity
  - (7) Seizures or coma
  - (8) Hyperacusis
- D. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

*Specify if:*

**With perceptual disturbances**

Studies of normal volunteers suggested that the acute psychosis induced by a single low dose of PCP usually lasts for 4 to 6 hours (Javitt and Zukin, 1991). However, in some PCP users psychotic symptoms including hallucinations, delusions, paranoia, thought disorder and catatonia, with intact consciousness, have been reported to persist from days to weeks after single doses. Sudden and impulsive violent and assaultive behaviors have been reported in PCP-intoxicated patients without previous histories of such conduct.

In PCP intoxication, the central nervous, cardiovascular, respiratory and peripheral autonomic systems are affected to degrees ranging from mild to catastrophic (Table 39.1). The level of consciousness may vary from full alertness to coma. Coma of variable duration may occur spontaneously or after an episode of bizarre or violent behavior.

**Table 39.1 Nonpsychiatric Findings in Phencyclidine Intoxication**

Altered level of consciousness  
 Central nervous system changes including nystagmus, hyperreflexia, and motor abnormalities  
 Hypertension  
 Cholinergic or anticholinergic signs  
 Hypothermia or hyperthermia  
 Myoglobinuria

Nystagmus (which may be horizontal, vertical, or rotatory) has been described in 57% of a series of 1000 patients (McCarron *et al.*, 1981). Consequences of PCP-induced central nervous system hyperexcitability may range from mildly increased deep tendon reflexes to grand mal seizures (observed in 31 of a series of 1000 PCP-intoxicated patients) or status epilepticus (McCarron *et al.*, 1981; Kessler *et al.*, 1974). Seizures are usually generalized, but focal seizures or neurological deficits have been reported, probably on the basis of focal cerebral vasoconstriction (Crosley and Binet, 1979). Other motor signs have been observed, such as generalized rigidity, localized dystonias, facial grimacing and athetosis.

Hypertension, one of the most frequent physical findings, was described in 57% of 1000 patients evaluated, and it was found to be usually mild and self-limiting, but 4% had severe hypertension, and some remained hypertensive for days (McCarron *et al.*, 1981). Tachycardia occurs in 30% of patients. PCP-induced tachypnea can progress to periodic breathing and respiratory arrest (Hurlbut, 1991). Autonomic signs seen in PCP intoxication may be cholinergic (diaphoresis, bronchospasm, miosis, salivation, bronchorrhea) or anticholinergic (mydriasis, urinary retention). Hypothermia and hyperthermia have been observed (McCarron *et al.*, 1981). Hyperthermia may reach malignant proportions (Thompson, 1979). Rhabdomyolysis frequently results from a combination of PCP-induced muscle contractions and trauma occurring in relation to injuries sustained as a result of behavioral effects. Acute renal failure can result from myoglobinuria.

## Assessment

### Special Issues in Psychiatric Examination and History

The disruption of normal cognitive and memory function by PCP frequently renders patients unable to give an accurate history. Therefore, assay of urine or blood for drugs may be the only way to establish the diagnosis. PCP is frequently taken in forms in which it has been used to adulterate other drugs, such as marijuana and cocaine, often without the user's knowledge. One of the most recent and alarming manifestations of this phenomenon is a preparation known variously as “illy”, “hydro”, “wet”, or “fry”, consisting of a marijuana cigarette or blunt containing formaldehyde/formalin (which is advertised) and PCP (which often is not). By disrupting sensory pathways, PCP frequently renders users hypersensitive to environmental stimuli to the extent that physical examination or psychiatric interview may cause severe agitation. If PCP intoxication is suspected, measures should be taken from the outset to minimize sensory input. The patient should be evaluated in a quiet, darkened room with the minimal necessary number of medical staff present. Assessments may need to be interrupted periodically.

### Relevant Physical Examination and Laboratory Findings

Vital signs should be obtained immediately on presentation. Temperature, blood pressure and respiratory rate are dose-dependently increased by PCP and may be of a magnitude requiring emergency medical treatment to avoid the potentially fatal complications of malignant hyperthermia, hypertensive crisis and respiratory arrest. In all cases, monitoring of vital signs should continue at 2- to 4-hour intervals throughout treatment,

because serum PCP levels may increase spontaneously as a result of mobilization of drug from lipid stores or enterohepatic recirculation. Analgesic and behavioral changes induced by PCP not only predispose patients to physical injury but also mask these injuries, which may be found only with careful physical examination.

Because PCP is usually supplied in combination with other drugs and is often misrepresented, toxicological analysis of urine or blood is essential. However there may be circumstances in which PCP may not be detected in urine even if it is present in the body, for example, when the urine is alkaline. On the other hand, in chronic PCP users, drug may be detected in urine up to 30 days after last use (Simpson *et al.*, 1982–1983). It must be kept in mind that false-positive PCP results can be caused by the presence of venlafaxine and *O*-desmethylvenlafaxine (Sena *et al.*, 2002), or dextromethorphan (Shier, 2000). Urine should be tested for heme because of the possible complication of myoglobinuria.

### Differential Diagnosis

The presence of nystagmus and hypertension with mental status changes should raise the possibility of PCP intoxication. Because of the close resemblance of both the acute and the prolonged forms of PCP psychosis to schizophrenia, and the increased sensitivity of patients with schizophrenia to the psychotomimetic effects of the drug, an underlying schizophrenia spectrum disorder should be considered, particularly if paranoia or thought disorder persists beyond 4 to 6 weeks after last use of PCP. PCP psychosis may also resemble mania or other mood disorders. Robust response of psychotic symptoms to treatment with neuroleptics would favor a diagnosis other than simple PCP psychosis.

PCP psychosis is readily distinguishable from LSD psychosis in normal as well as in individuals with schizophrenia by the lack of typical LSD effects, such as synesthesia. In cases involving prominent PCP-induced neurological, cardiovascular, or metabolic derangement, encephalitis, head injury, postictal state and primary metabolic disorders must be ruled out. Either intoxication with or withdrawal from sedative–hypnotics may be associated with nystagmus. Neuroleptic malignant syndrome should be ruled out in the differential diagnosis of PCP-induced hyperthermia and muscle rigidity.

### Course and Natural History

As drug levels decline, the clinical picture recedes in five to 21 days through periods of moderating neurological, autonomic and metabolic impairments to a stage at which only psychiatric impairments are apparent. Once the physical symptoms and signs have cleared the period of simple PCP psychosis may last 1 day to 6 weeks, whether or not neuroleptics are administered, during which the psychiatric symptoms and signs abate gradually and progressively. Even after complete recovery flashbacks may occur if PCP sequestered in lipid stores is mobilized. Any underlying psychiatric disorders can be detected and evaluated only after complete resolution of the drug-induced psychosis.

### Overall Goals of Treatment

The hierarchy of treatment goals begins with detection and treatment of physical manifestations of PCP intoxication. Equally important are measures to anticipate PCP-induced impulsive, violent behaviors and provide appropriate protection for the patient and others. The patient must then be closely

observed during the period of PCP-induced psychosis, which may persist for weeks after resolution of physical symptoms and signs. Finally, the possibly dramatic medical and psychiatric presentation and its resolution must not divert the attention of the psychiatrist from full assessment and treatment of the patient's drug-seeking behavior.

### Physician–Patient Relationship in Psychiatric Management

In contrast to psychotic states induced by drugs such as LSD, in which “talking the patient down” (by actively distracting the patient from his LSD-induced sensory distortions and convincing the patient that his or her distress stems from nothing more than the temporary effects of a drug that soon will wear off) may be highly effective, no such effort should be made in the case of PCP psychosis, particularly during the period of acute intoxication, because of the risk of sensory overload that can lead to dramatically increased agitation. The risk of sudden and unpredictable impulsive, violent behavior can also be increased by sensory stimulation.

### Pharmacotherapy and Somatic Treatments

There is no pharmacological competitive antagonist for PCP. Oral or intramuscular benzodiazepines are recommended for agitation. Neuroleptics usually have little or no effect on acute or chronic PCP-induced psychosis or thought disorder. Because they lower the seizure threshold, neuroleptics should be used with caution. Physical restraint may be lifesaving if the patient's behavior poses an imminent threat to his or her safety or that of others; however, such restraint risks triggering or worsening rhabdomyolysis.

### Comparison of DSM-IV/ICD-10 Diagnostic Criteria

Unlike DSM-IV-TR, ICD-10 does not have a separate class for Phencyclidine-Related Disorders and instead includes PCP in the Hallucinogen class.

# Substance Abuse: Hallucinogen- and MDMA-Related Disorders

Hallucinogens alter perception, cognition and mood as their primary psychobiological action in the presence of an otherwise clear sensorium. LSD is the most common hallucinogen and is readily and cheaply available in the USA. Unlike the chronic use of stimulants amphetamine and cocaine, chronic use of hallucinogen does not lead to physiological dependence. On the other hand tolerance to LSD builds in 4 to 7 days. There is no withdrawal or documented fatalities from overdose of LSD. The 3,4-methylenedioxymethamphetamine (MDMA or Ecstasy) is a synthetic amphetamine analogue that is used to enhance affiliative emotional responses. Its use appears to be increasing, particularly among young adults. Dependence and escalation of dosage are uncommon. All these agents are neurotoxic with deleterious effects on serotonergic neurons, memory and mood. Common naturally occurring compounds include mescaline (and peyote), psilocybin and dimethyltryptamine (DMT). The dawn of modernity for synthetic hallucinogenic drugs can be placed to the moment in 1943 when Albert Hofmann, a Swiss chemist, discovered the potent psychological effects of LSD. The definition of an hallucinogenic drug has been a matter of controversy. To address the problem of classification, one may define as hallucinogenic “any agent which has alterations in perception, cognition, or mood as its primary psychobiological actions in the presence of an otherwise clear sensorium”.

## Epidemiology of Hallucinogen Abuse

Among hallucinogens, LSD remains the most popular in its class among American high school students. An annual drug survey of 45 000 students by the Monitoring the Future Program of the University of Michigan has been performed since 1975. There is a stable long-term trend of LSD lifetime use among one in 10 seniors.

## Etiology and Pathophysiology

The acute effects of “tripping” on LSD-like (i.e. with similar psychic effects, such as psilocybin or mescaline) hallucinogens are variable and profound. Table 40.1 illustrates a typical time course for the psychiatric effects of LSD.

The effective hallucinogenic doses vary widely between drugs in this class, and between individuals. The conventional explanation of this variability of response is instructional set, anticipation of drug effects due to previous experience, and

**Table 40.1** Time Course for the Psychiatric Effects of LSD-like Hallucinogens

Time	Psychiatric Effects
0–30 min	Dizziness, nausea, weakness, anxiety
30–60 min	Blurred vision, visual pseudohallucinations and hallucinations, afterimagery, geometric and imagistic imagery with eyes closed, decreased concentration, dissociation, depersonalization, out of body sensations, reduced coordination
60–240 min	Intensified afterimagery, false perceptions of movement (walls appearing to breathe or melt), loss of rectilinearity of perceptions, a rapid flood of emotions including anxiety, euphoria, and oceanic unity, loss of the sense of time
4–12 hr	Gradual return to previous mental state, but with continued arousal, headache, fatigue, contemplative frame of reference, sense of profundity

Modified from Hollister L (1984) Effects of hallucinogens in humans, in *Hallucinogens: Neurochemical, Behavioral, and Clinical Perspectives* (ed Jacobs B). Raven Press, New York. Copyright, Lippincott, Williams & Wilkins.

environmental setting affect outcome. Additionally, personality, preexisting mental illness and genetic vulnerability are also likely to be important. Unlike the chronic use of stimulants like amphetamine and cocaine, chronic use of hallucinogens does not lead to physiological dependence. On the other hand, tolerance to LSD rapidly builds in 4 to 7 days, and lasts 3 days. Titeler and colleagues (1988) have shown that hallucinogenic potency of LSD and selected phenylisopropylamines correlates with the drug’s ability to bind at the postsynaptic 5-HT<sub>2</sub> receptor.

Hallucinogens simultaneously decrease spontaneous activity in the locus coeruleus, considered a novelty detector in the midbrain, while enhancing sensory responses of the locus coeruleus by activating *N*-methyl-D-aspartate receptors. In the cerebral cortex, the drugs both inhibit and induce activity by exciting GABAergic and glutamatergic neurons respectively.

The presence of selective serotonin reuptake inhibitors blunts hallucinogenic effects, possibly through the activation of 5-HT<sub>1</sub> receptors (Aghajanian and Marek, 1999). GABA<sub>A</sub> anti-anxiety agents (e.g., benzodiazepines) promptly bring a bad trip to an end, presumably by inhibition of the locus coeruleus. Opiates are likely to have a similar outcome by reducing glutamatergic excitation of cortical systems. This may explain why hallucinogen abuse appears to be so uncommon among active opioid abusers.

### Differential Diagnosis and Treatment of Acute Intoxication

Criteria for the diagnosis of acute hallucinogen intoxication are set forth in the following *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR) (American Psychiatric Association, 2000).

Chemical identification of hallucinogens in emergency specimens with methods such as gas chromatography–mass spectrometry remain costly and time consuming. Thus, clinicians in emergency settings must rely on a careful drug history, the information from the less drug-affected friends of the patient, the mental status examination and signs Papparent from the physical examination. The high potency of this class of drugs permits their distribution in venues of single drops of solution. Thus, blotter paper (often marked with stamps of cartoon characters or New Age symbols) or a single sugar cube can easily carry more than the 50 to 100 μg

#### DSM-IV-TR Criteria 292.89

##### Hallucinogen Intoxication

- A. Recent use of a hallucinogen.
- B. Clinically significant maladaptive behavioral or psychological changes (e.g., marked anxiety or depression, ideas of reference, fear of losing one's mind, paranoid ideation, impaired judgment, or impaired social or occupational function) that developed during, or shortly after, hallucinogen use.
- C. Perceptual changes occurring in a state of full wakefulness and alertness (e.g., subjective intensification of perceptions, depersonalization, derealization, illusions, hallucinations, synesthesias) that developed during, or shortly after, hallucinogen use.
- D. Two (or more) of the following signs, developing during, or shortly after, hallucinogen use:
  - (1) pupillary dilation
  - (2) tachycardia
  - (3) sweating
  - (4) palpitations
  - (5) blurring of vision
  - (6) tremors
  - (7) incoordination
- E. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

Reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

of LSD necessary for the user to trip for 6 to 12 hours. Routes of administration other than by ingestion are rare. Autonomic arousal is the rule, with tachycardia, increased deep tendon reflexes, and dilated pupils present regardless of whether euphoria or panic is present. Hypersensitivity to visual and auditory stimuli is common, with atypical affective responses as the result. Motor function is reduced, so that such patients are not likely to act out aggressively.

The differential diagnosis of an acute hallucinogenic intoxication includes intoxication by other agents, (such as phencyclidine [PCP], cocaine, amphetamines, anticholinergics and inhalants, among others). It also includes acute schizophrenia or affective disorder, panic disorder, head injury, sedative, hypnotic, anxiolytic, or alcohol withdrawal (including gamma-hydroxybutyrate [GHB]), metabolic disorders such as hypoglycemia and hyperthyroidism, epilepsy, acute vascular events, release hallucinations of ophthalmologic disease and the complications of central nervous system (CNS) tumors. Age, along with prior clinical history, the history of the current event, physical examination and toxicology screen for suspected nonhallucinogenic agents usually reveal the diagnosis.

A patient presenting with a history of taking LSD is only correct approximately 50% of the time, judging from analysis of street samples analyzed by the Massachusetts Department of Public Health in the last decade. The street practice of adulteration or mislabeling of the drug is common. Psychosis following a smoked agent suggests phencyclidine. Differentiating between PCP and LSD is clinically important, since LSD-induced panic responds well to oral benzodiazepines, while PCP delirium requires high potency antipsychotic medications such as haloperidol. A “palm test” can be employed to differentiate PCP from LSD toxicity (Abraham and Aldridge, 1993). This is performed by the examiner holding an open palm in front of the patient, and asking “the names of all the colors you see in my palm”. The LSD patient often ticks off a series of vivid colors and occasional images. The dissociated, aggressive PCP patient attempts to attack the hand. Treatment of hallucinogen intoxication with panic is easily managed with oral benzodiazepines (diazepam 20 mg or lorazepam 2 mg) which bring the terror, as well as the trip, to an end within 30 minutes.

### LSD-Related Psychotic Disorders

Criteria for substance-induced psychotic disorders are listed below in the DSM-IV-TR Criteria.

Among the hallucinogens, LSD has been associated with the majority of, but not all, prolonged psychotic reactions following acute drug use. Psychoses are apparently rare with the abuse of botanical preparations, in all likelihood because such agents are of low potency, not widely abused, and often controlled by religious sanctions. By comparison, psychoses have been seen following the administration of LSD to patients and experimental subjects. In addition to exhibiting positive signs of schizophrenia, patients with post-LSD psychoses show affective lability and the novel addition of visual hallucinations uncommon in non-drug-related psychoses. The uniqueness of post-LSD psychosis remains controversial. One comparison of post-LSD psychosis and nondrug-related schizophrenia found no essential clinical differences between the two (Vardy and Kay, 1983).

### Differential Diagnosis and Treatment

The differential diagnosis of posthallucinogen psychosis is that for any acute psychotic disorder. This includes protracted psychoses

## DSM-IV-TR Criteria

### Substance-induced Psychotic Disorder

- A. Prominent hallucinations or delusions, **Note:** Do not include hallucinations if the person has insight that they are substance induced.
- B. There is evidence from the history, physical examination, or laboratory findings of either (1) or (2):  
 (1) the symptoms in Criterion A developed during, or within a month of, substance intoxication or withdrawal  
 (2) medication use is etiologically related to the disturbance
- C. The disturbance is not better accounted for by a psychotic disorder that is not substance induced. Evidence that the symptoms are better accounted for by a psychotic disorder that is not substance induced might include the following: the symptoms precede the onset of the substance use (or medication use); the symptoms persist for a substantial period of time (e.g., about a month) after the cessation of acute withdrawal or severe intoxication or are substantially in excess of what would be expected given the type or amount of the substance used or the duration of use; or there is other evidence that suggests the existence of an independent nonsubstance-induced psychotic disorder (e.g., a history of recurrent nonsubstance-related episodes).
- D. The disturbance does not occur exclusively during the course of a delirium.

**Note:** This diagnosis should be made instead of a diagnosis of substance intoxication or substance withdrawal only when the symptoms are in excess of those usually associated with the intoxication or withdrawal syndrome and when the symptoms are sufficiently severe to warrant independent clinical attention.

Code specific substance-induced psychotic disorder:  
 292.11 amphetamine (or amphetamine-like substance), with delusions; 292.12 amphetamine (or amphetamine-like substance), with hallucinations; 292.11 hallucinogen, with delusions; 292.12 hallucinogen, with hallucinations.

#### *Specify:*

With onset during intoxication: if criteria are met for intoxication with the substance and the symptoms develop during the intoxication syndrome.

With onset during withdrawal: if criteria are met for withdrawal from the substance and the symptoms develop during, or shortly after, a withdrawal syndrome.

Reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

following the use of the dissociative anesthetics phencyclidine and ketamine, amphetamines, and cocaine; schizophrenia and affective disorders, migraine, deliria from CNS infections, closed head injuries, tumors, vascular events, and the toxic effects of

### Clinical Vignette

A 19-year-old man used LSD for the fourth time. In the past, his trip on LSD ran an 8-hour course. Now, however, auditory and visual hallucinations persisted over the next week. At the same time his behavior became increasingly agitated and bizarre. His speech became rapid and incoherent. He was unable to sleep. His energy was increased though he talked of committing suicide. He expressed the delusion that he had sexual relations with a pet, and that he was androgynous. He was admitted to a psychiatric hospital where he showered with his clothes on and pulled a towel rack off the wall. Four-point restraints were required. His past history was negative for prior psychosis. There was no history of drug dependency. His family history was positive for depression. The patient was treated at the outset with neuroleptics which were supplemented with lithium carbonate in the fourth week. He remained disoriented, delusional and hallucinatory until the illness remitted 2 months after his last use of LSD.

#### Comment

This case illustrates the continuum between LSD use and an acute psychotic reaction. Salient are signs consistent with the positive symptoms of schizophrenia, including multimodal hallucinations, bizarre delusions and behavior, and thought disorder. Like other patients in this class, without predisposing factors, this man had a relatively healthy premorbid adjustment and good outcome. The patient has avoided mind-altering drugs since discharge. There has been no relapse in a 16-year follow-up.

bromine, heavy metals and anticholinergic drugs. Central to diagnosis is a careful premorbid history, complemented by data from friends and family on the patient's recent medical history and behavior. Neurological examination, an acute urine for toxicological screening, and computed tomography or magnetic resonance imaging of the brain are helpful in ruling out treatable nonLSD-related psychotic disorders.

Treatment for post-LSD psychoses includes neuroleptics, electroconvulsive therapy (ECT), and lithium.

### Hallucinogen Persisting Perception Disorder (HPPD)

The definition of hallucinogen persisting perception disorder is shown in the following DSM-IV-TR Criteria.

#### Differential Diagnosis and Treatment

It is not uncommon for a patient suffering from HPPD to consult multiple clinicians before a diagnosis is made. Because the symptoms are primarily perceptual, an HPPD subject may consult an ophthalmologist, neurologist, or psychologist before seeing a psychiatrist. Often patients come for help having made their own diagnoses using the DSM-IV or internet chat groups devoted to HPPD. Despite a patient's certainty about their diagnosis, the clinician is obligated to rule out other sources of chronic organic hallucinosis, including other drug toxicities, strokes, CNS tumors, infections and head trauma. Magnetic resonance images of the brain are usually negative. Quantitative electroencephalography shows accelerated alpha and visual evoked potentials, especially in the posterior cerebrum.

**DSM-IV-TR Criteria** 292.89**Hallucinogen Persisting Perception Disorder (Flashbacks)**

- A. The reexperiencing, following cessation of use of a hallucinogen, of one or more of the perceptual symptoms that were experienced while intoxicated with the hallucinogen (e.g., geometric hallucinations, false perception of movement in the peripheral visual fields, flashes of color, intensified colors, trails of images of moving objects, positive afterimages, halos around objects, macropsia, and micropsia).
- B. The symptoms in Criterion A cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- C. The symptoms are not due to a general medical condition (e.g., anatomical lesions and infections of the brain, visual epilepsies) and are not better accounted for by another mental disorder (e.g., delirium, dementia, schizophrenia) or hypnopompic hallucinations.

Reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

Treatment at the present time is palliative. Benzodiazepines, olanzepine, sertraline, naltrexone and clonidine have anecdotally been reported to help in selected cases. Risperidone has been reported to exacerbate HPPD symptoms. Marijuana can chronically induce an exacerbation of HPPD. Because HPPD is also exacerbated by CNS arousal, affect, stress and stimulants, these are to be reduced or avoided. HPPD is worse with one's eyes closed, or when entering a dark environment. Thus, sunglasses, which serve to reduce the difference between outdoor and indoor luminance, may reduce HPPD symptoms when the patient enters an interior space.

**MDMA ("Ecstasy")**

3,4-methylenedioxymethamphetamine (MDMA, commonly known as "ecstasy," and chemically *N*-methyl-1-[3,4-methylenedioxyphenyl]-2-aminopropane) is a synthetic amphetamine analogue that is also similar to mescaline. During the 'psychedelic' 1970s, recreational use of MDMA took root due to its psychological effects and the fact that it was available legally. Recreational use was partially fueled by reports of the use of MDMA as a psychotherapeutic adjunct.

The publicity that followed the scheduling of MDMA only served to increase its popularity, particularly on college campuses. Recently, the use of MDMA has increased and its pattern of use has changed. These factors have heightened public awareness of the drug and paradoxically led to an increase in use and adverse consequences. Emerging evidence supports the hypothesis that MDMA is a neurotoxin in humans with long-lived sequelae on cognition, memory and emotions.

**Epidemiology**

Despite its existence for nearly 90 years, the recreational use of MDMA appears to have had its origins in the 1960s (Pope *et al.*,

2001). Initial drug use centered around college campuses (Pope *et al.*, 2001; Peroutka *et al.*, 1988). At that time, use of MDMA was generally in small groups in private places (Peroutka *et al.*, 1988). Accurate epidemiologic data are not available for the 1960s. However, by 1977 about 2.8% of US college students used MDMA (Strote *et al.*, 2002). College is the first time that people are likely to begin use of MDMA (Cuomo *et al.*, 1994; Randell, 1992). Nonetheless, use in high school students has also increased, so that in 1998, 4.4% of 10th graders and 5.6% of high school seniors had tried MDMA (Johnston *et al.*, 1999). In a survey of 14,000 college students at 119 American colleges by the Harvard School of Public Health College Alcohol Study, there was a 69% increase in use between 1997 and 1999 (from 2.8 to 4.7%) (Strote *et al.*, 2002). At 10 high use schools with a 1997 rate of 4.7%, the rate increased to 10.6% by the year 2000 (Strote *et al.*, 2002). Over the same time the use of marijuana did not significantly change (38.5% in 1997 and 37.6% in 2000) (Strote *et al.*, 2002). MDMA is the only illicit drug to see continued increase in use. In surveys of a large New England college performed in 1969, 1978, 1989 and 1999, all drug use peaked in 1978 and dropped thereafter but MDMA use has continued to increase. The increasing popularity of MDMA is not just an American phenomenon, but is seen in both Europe (Cregg and Traquey, 1993; Christophersen, 2000) and Australia (Topp *et al.*, 1999).

In addition to increased popularity of MDMA, the pattern of use appears to have changed. Initial use was in small groups at doses ranging from 75 to 150 mg with an occasional booster of 50 to 100 mg (Peroutka *et al.*, 1988; Downing, 1986; Siegel, 1986; Liester, 1992). The 1990s saw the onset of the rave phenomenon. These are generally large gatherings in warehouses or dance clubs. Dosage utilized in raves are much more variable ranging from 100 to 750 mg and as high as 1,250 mg/night (Brown *et al.*, 1995; Forsyth, 1996). Concomitant drug use is also more common in raves (Strote *et al.*, 2002; Gervin *et al.*, 2001; Gerhard, 2001). These include alcohol, marijuana and opiates. Furthermore, the term "ecstasy," which was originally used to refer specifically to MDMA, has grown to refer to other related compounds such as 3,4-methylenedioxyamphetamine (MDA) and 3,4-methylenedioxyethylamphetamine (MDE or Eve) (Gerhard, 2001). The combination of these variables increases the risks of adverse consequences associated with MDMA use (see later).

MDMA users generally limit the frequency of use of the drug. Most report limiting use of MDMA to twice per month or less. Fridays and Saturdays are the most common days of use because users say they need 1 day to recover after use (Peroutka *et al.*, 1988; Liester *et al.*, 1992). More frequent use is associated with a loss of the desired effect of the drug (Gerhard *et al.*, 2001).

Prior to its placement on Schedule 1 by the DEA, MDMA was considered as an adjunct to psychotherapy (Shulgin and Nichols, 1978; Greer and Tolbert, 1986, 1998). In this setting, a dosage of 50 to 200 mg (with modal doses ranging from 100 to 150 mg), with a booster of 50 to 75 mg several hours later, was used. There are no controlled studies of the use of MDMA in psychotherapy. However, there is one open study of 29 subjects in which the dosage used was 75 to 150 mg after a 6-hour fast with an offered second dose of 50 to 75 mg. All subjects reported positive attitudinal and emotional changes. Twenty-two felt that their insight into their own psychopathology was enhanced. Twenty-one subjects in couples treatment reported increased closeness and communication with their partner (Greer and Tolbert, 1986). All subjects reported adverse consequences similar to those reported by recreational drug users. While the use of MDMA as a psychotherapeutic adjunct appears to have advocates (Greer and

Tolbert, 1998), the documentation of neurotoxicity in humans (Reneman *et al.*, 2002; McCann *et al.*, 1998; Semple *et al.*, 1999) makes such use dubious.

## Pharmacology

MDMA is toxic to serotonergic neurons. Serotonergic loss is evident through several markers which include reduced brain serotonin, 5-hydroxyindoleacetic acid (5-HIAA), and the serotonin transporter. Immunocytochemical studies suggest that serotonergic neurons are damaged, but the cell bodies are preserved. Recovery from MDMA-induced serotonergic damage can occur. In monkeys the damage persists at least 7 years. In humans, serotonergic damage after repeated MDMA use is evident through several different types of studies. CSF 5-HIAA levels are reduced in MDMA users, an effect that is more pronounced in women than in men.

## Diagnosis

A typical MDMA user is a college student. In a survey of 14000 college students in 119 American colleges, MDMA users were more likely to use marijuana, smoke cigarettes and engage in binge alcohol consumption (Strote *et al.*, 2002). They were also more likely to have multiple sex partners (Strote *et al.*, 2002). They considered art and parties important, but they were not academic underachievers.

## Acute Positive Psychological Effects

Unlike many drugs of abuse which are frequently used alone, MDMA is almost always used in the company of others. Most MDMA users report positive mood and emotional effects as they relate to others. Experienced MDMA users report a greater capacity for empathy, communication and understanding. Users also report increased self-esteem, high energy, relaxation, sensual awareness, euphoria and dissociation.

## Physical Consequences of MDMA Use

Humans exhibit complications that are related to both the sympathomimetic and serotonergic properties of MDMA. These include nausea, vomiting, anorexia, hypertension, palpitations, diaphoresis, headaches, difficulty walking, muscle aches and tension, hot and cold flashes, urinary urgency, nystagmus, blurred vision, insomnia and dry mouth. The common complaints of trismus and bruxism may reflect MDMA enhancement of serotonin activation of the 5HT<sub>1B</sub> receptors of the trigeminal motor nuclei (Tancer and Johanson, 2001).

At least two MDMA-related deaths have been associated with automobiles (Hooft *et al.*, 1994; Cifasi and Long, 1996).

## Clinical Manifestations of Long-term of MDMA Neurotoxicity

Former chronic ecstasy users (an average of 527 tablets) have higher self-reported depression. The predictors of developing this depressive syndrome are maximum quantity of pills consumed over a 12-hour period and mild, frequent life stress. Heavy MDMA use has also been associated with higher rates of psychopathology including obsessive and compulsive behaviors, anxiety, somatization and loss of libido. The relationship between MDMA use and these syndromes is unclear, but since these syndromes involve serotonergic mechanisms,

additional investigation into these potential long-term sequelae is warranted. MDMA users have been noted to have problems with memory, attention, reasoning, impulse control and sleep abnormalities.

## MDMA Somatic Toxicity

MDMA has been associated with a wide range of somatic toxic events. These include thrombotic or hemorrhagic strokes, leukoencephalopathy, myocardial infarction, arrhythmias and pneumothorax. The wide range of manifestations suggests that most of these cases are either idiosyncratic or related to impurities remaining from the synthetic process. Since much of the MDMA supply is synthesized in small “basement” laboratories, the quality control of the manufacturing process may not be adequate. Cases of severe medical illness or death due to electrolyte and fluid are more likely due to MDMA use. These complications may be related to the specific environment in raves. In raves people are exposed to hot, crowded environments. In association with the increased body temperature caused by MDMA dehydration and its consequences are likely. MDMA may also cause serotonergic hyperstimulation and produce a fatal serotonin syndrome-like (illness).

## Treatment

There have been no studies examining the treatment of MDMA use. The issue of how a practitioner may help his/her patient discontinue MDMA use is never addressed in the literature. This may be due to the rarity of presentation of subjects seeking treatment for MDMA addiction. Serotonin reuptake inhibiting antidepressants may offer a possible treatment for subjects who present with an MDMA addiction.

## Comparison of DSM-IV/ICD-10

The ICD-10 and DSM-IV-TR criteria sets for Hallucinogen Intoxication are almost the same.

# Substance Abuse: Inhalant-related Disorders

This chapter reviews the disorders of deliberately inhaling large quantities of volatile solvents and gases for minutes to hours, most often repeatedly over days, months and frequently for many years. This is referred to as inhalant disorders in DSM-IV. The most frequently chemicals now present in the products that are abused include toluene, butane, nitrous oxide, gasoline mixtures (including hexane and benzene), different chlorocarbons such as trichloroethylene, fluorocarbons and organic nitrites. Acute symptoms include: dizziness, headache, disorientation, ataxia, foul breath, with conditions proceeding to nausea, slurred speech, belligerence, irritability and delirium. Chronic conditions are characterized by a strong psychological, but weaker physical dependence, without any known dually diagnosed mental disorder. Known associated physical disorders include cognitive dysfunction, limb dysmetria, hearing loss, arrhythmia, metabolic acidosis, peripheral neuropathies, hematologic abnormalities, significant embryopathic changes, and some liver and lung changes.

Several subcategories of inhalants can be established based on chemical classes of products and primary abuse groups as follows: 1) industrial or household cleaning and paint-type solvents including paint thinners or solvents, degreasers or dry cleaning solvents, solvents in glues, art or office supply solvents such as correction fluids, and solvents in magic markers (gasoline is similar to these products); 2) propellant gases used in household or commercial products, such as butane in lighters, or fluorocarbons in electronic (personal computer, office equipment) cleaners or refrigerant gases; 3) household aerosol sprays such as paint, hair and fabric protector sprays; 4) medical anesthetic gases such as ether, chloroform, halothane and nitrous oxide; and 5) aliphatic nitrites. Nitrous oxide is also available in whipped cream dispensers (e.g., whippets) and for octane boosters in car racing, and is used outside the medical theater by nonprofessionals. Most of the foregoing compounds affect the central nervous system (CNS) directly, whereas nitrites act on cardiovascular smooth muscle rather than as an anesthetic in the CNS. The nitrites are also used primarily as sexual enhancers rather than as mood alterants. Therefore, when discussing “inhalant abuse,” we will be referring primarily to substances other than nitrites. One item worthy of note: the exclusion of anesthetics from the inhalant-related disorders section in the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (DSM-IV-TR) is not medically correct, as almost all of the inhalants act physiologically as would any anesthetic and some, particularly the anesthetics nitrous oxide and trichloroethylene (TCE), are abused by the primary inhalant abuser discussed herein.

Many anesthetics have a potential for abuse, mostly by medical personnel. That these substances are abused by middle-class professionals not only demonstrates the diversity of the groups that abuse inhalants but also focuses on the basic nature of the physical properties of most of these volatile agents. That is, many anesthetics produce a light-headedness that relates to euphoria. Almost all solvents would produce anesthesia if sufficient amounts are inhaled with the proper amounts of oxygen present. As with any anesthetic, death is possible and too often occurs with these substances.

## Inhalant Use Disorders

### Inhalant Dependence

Dependence on inhalants is primarily psychological, with a less dramatic associated physical dependence occurring in some heavy users. There is at least a psychological dependence and often a weak physical dependence on these substances. A mild withdrawal syndrome occurs in 10 to 24 hours after cessation of use (only in those who have excessively abused inhalants) and lasts for several days. Symptoms include general disorientation, sleep disturbances, headaches, muscle spasms, irritability, nausea and fleeting illusions. However, this is not an easily identified or a characteristic withdrawal syndrome that is useful for many practitioners in a clinical setting. The need to continue use is undeniably strong in many individuals; specific treatments for inhalant dependence, other than the drug therapy and/or psychotherapy used for other drug dependence, need to be developed.

### Inhalant Abuse

Abuse of inhalants may lead to harm to individuals (e.g., accidents involving automobiles, falling from buildings when in an impaired or intoxicated state [illusionary feelings], or self-inflicted harm such as attempted or successful suicide). Frozen lips caused by rapidly expanding gases or serious burns may also occur. Chronic inhalant use is often associated with familial conflict and school problems.

### Inhalant-induced Disorders

The primary disorder is inhalant intoxication, which is characterized by the presence of clinically significant maladaptive behavioral or psychological changes (e.g., belligerence, assaultiveness, apathy, impaired judgment, impaired social or occupational functioning) that develop during the intentional

short-term, high-dose exposure to volatile inhalants (diagnostic criteria A and B in DSM-IV-TR). The maladaptive changes occurring after intentional and nonintentional exposure include disinhibition, excitedness, light-headedness, visual disturbances (blurred vision, nystagmus), incoordination, dysarthria, an unsteady gait and euphoria. Higher doses of inhalants may lead to depressed reflexes, stupor, coma and death, sometimes caused by cardiac arrhythmia. Lethargy, generalized muscle weakness, and headaches may occur some hours later depending on the dose.

## Epidemiology

### Prevalence

Inhalant abuse is a worldwide problem. Countries are increasingly evaluating the abuse of solvents.

Current estimates of sniffing volatile substances to “get high” rank inhalants high in the “ever use” category of substance abuse, especially for the younger population. Some surveys of teenage use showed that one in six had tried an inhalant and that over 220 000 persons of the US population had done so in the past month during the year 2000 (Substance Abuse and Mental Health Services Administration, 2001). As many as 20 000 to 40 000 youth got high on inhalants several times a month. Some

of the highest rates were noted for 8th graders. The practice of “sniffing”, “snorting”, “huffing”, “bagging”, or inhaling to get high describes various methods of inhalation. These terms refer to the inhalation of volatile substances from 1) filled balloons, 2) bags and 3) soaked rags and/or sprayed directly into oral orifices. Abusers can be identified by various telltale clues such as organic odors in the breath or clothes, stains on the clothes or around the mouth, empty spray paint or solvent containers, and other unusual paraphernalia. These clues may enable one to identify a serious problem of solvent abuse before it causes serious health problems or death.

### Toxicology of Inhalant Abuse

The majority of inhalant abusers are never seen in a hospital or outpatient facility. Although many do not need medical attention for their inhalant habit, of those who do, many often die before reaching the hospital as a result of asphyxia, cardiac arrhythmia, or related overdose effects after inhaling fluorocarbons, low-molecular-weight hydrocarbon gases (butane, propane), nitrous oxide, or other solvents including toluene during either the first or a subsequent episode. Death may also occur after inhalation of toluene-containing substances as a result of metabolic acidosis or related kidney failure if left untreated.

### Clinical Manifestations After Chronic Inhalant Abuse

Chronic high-level exposure to organic solvents occurs in the inhalant abuse setting at levels several thousand times higher than in the occupational setting and results in numerous irreversible disease states. Table 41.1 describes several well-characterized disorders and identifies the solvent when corroborated by animal studies. Some substances have been strongly correlated with the development of a disorder through numerous case studies.

### Treatment

Individuals need different treatments based on the severity of the dependence and any medical complications. Primary care physicians should address the medical issues identified earlier as well as other medical concerns before dealing with the dependence on solvents and other drugs. During this period, sedatives, neuroleptics and other forms of pharmacotherapy are not useful in the treatment of inhalant abusers and should be avoided in most cases as they are likely to exacerbate the depressed state. Once it is determined that the individual is detoxified, that is, has low levels of solvent or other depressant drug, then therapy with other drugs, such as antianxiety drugs, may be useful. The determination of detoxification, even in the absence of drug (solvent) administration, is not well defined or systematic. It may take several days for the major “reversible” intoxication state to be reduced to a level at which coherent cognition can occur. The use of various psychological assessment tools can assist not only in evaluating the intoxication but also in following the progress of the treatment. Little can be done during this period other than to facilitate improvement of the basic health of these individuals, provide supportive care and build the individual’s self-esteem.

There is no accepted treatment approach for inhalant abuse. Many drug treatment facilities refuse treatment of the inhalant abuser because many feel that inhalant abusers are resistant to treatment) or that there is no standard or accepted treatment. One

#### DSM-IV-TR Criteria 292.89

##### Inhalant Intoxication

- A. Recent intentional use or short-term, high-dose exposure to volatile inhalants (excluding anesthetic gases and short-acting vasodilators).
- B. Clinically significant maladaptive behavioral or psychological changes (e.g., belligerence, assaultiveness, apathy, impaired judgment, impaired social or occupational functioning) that developed during, or shortly after, use of or exposure to volatile inhalants.
- C. Two (or more) of the following signs developing during, or shortly after, inhalant use or exposure:
  - (1) dizziness
  - (2) nystagmus
  - (3) incoordination
  - (4) slurred speech
  - (5) unsteady gait
  - (6) lethargy
  - (7) depressed reflexes
  - (8) psychomotor retardation
  - (9) tremor
  - (10) generalized muscle weakness
  - (11) blurred vision or diplopia
  - (12) stupor or coma
  - (13) euphoria
- D. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

**Table 41.1** Diseases Observed in Humans After Chronic Inhalant Abuse

Condition†	Syndrome	Substance	Animal Studies*
<b>Slowly Reversible and/or Irreversible Syndromes</b>			
Encephalopathy	Cognitive dysfunction	“Toluene,”† other solvents	—
Cerebellar syndrome	Limb dysmetria	“Toluene”	Rat
	Dysarthria		—
Sensorineural otic	High-frequency hearing loss	TCE, toluene	Rat, mouse
Sensorineural			
Optic nerve	Visual loss	“Toluene”	—
Oculomotor	Oculomotor disturbances (nystagmus)	Xylene, TCE	Rabbits
Myeloneuropathy	Sensory loss	Nitrous oxide	Rat, mouse
	Spasticity		
Axonal neuropathy	Distal sensory loss, limb weakness	Hexane, methyl butyl ketone	Rat, monkey
Cardiotoxicity	Arrhythmia	Chlorofluorocarbons, butanes, propanes	Mouse, rat, dog
Leukemia	Myelocytic	Benzene	Rat, mouse
<b>Mostly Reversible Syndromes</b>			
Trigeminal neuropathy	Numbness, paresthesia	TCE and/or dichloroacetylene	Rat
Renal acidosis	Metabolic acidosis	“Toluene”	Rat
	Hypokalemia		—
Carboxyhemoglobin	Hypoxia	Methylene chloride, tobacco	Human, rat
Methemoglobinemia	Syncope, blue	Nitrites, organic	Rat
Neonatal syndrome	Retarded growth, development	“Toluene”	Rat
Hepatotoxicity	Fatty vacuoles, plasma liver enzymes	Chlorohydrocarbons	Rat
Immunomodulatory	Loss of immune cell function	Nitrites, organic	Rat

\*Symptoms observed in animal studies with these solvents.

†Quotation marks around substance indicates uncertainty about this solvent (alone) producing these symptoms.

facility that focuses solely on the comprehensive treatment of inhalant abusers, the International Institute on Inhalant Abuse based in Colorado ([www.allaboutinhalants.com](http://www.allaboutinhalants.com)), uses a three-phase model that allows longer periods of treatment.

The inhalant abuser typically does not respond to usual drug rehabilitation treatment modalities. Several factors may be involved, particularly for the chronic abuser who may have significant psychosocial problems as well as irreversible brain injury. Treatment becomes slower and progressively more difficult when the severity of brain injury worsens as abuse progresses through transient social use (experimenting in groups) to chronic use in isolation. For these and other reasons, longer therapies are necessary than are utilized in most drug treatment facilities. Also, neurological impairment, the breadth of which still needs to be established, may be a major complication slowing the progress of rehabilitation. This is not as significant a problem with other forms of drug abuse.

Drug screening would be useful in monitoring inhalant abusers. Routine urine screening for hippuric acid (the major metabolite of toluene metabolism) performed two or three times

weekly can detect the high level of exposure to toluene commonly seen in inhalant abusers. More frequently performed expired breath analysis for toluene or other abused compounds is also available. As alcohol is a common secondary drug of abuse among inhalant abusers, alcohol abuse should be monitored and considered in the approach to treatment.

### Comparison of DSM-IV/ICD-10 Diagnostic Criteria

The ICD-10 and DSM-IV-TR criteria sets for Inhalant Intoxication are nearly equivalent (except that DSM-IV-TR lists additional symptoms).

# Substance Abuse: Nicotine Dependence

Nicotine dependence is the most common substance use disorder in the USA and increases morbidity and mortality more than any other substance use disorders. In the USA about 25% of the population is addicted to tobacco. Tobacco use has serious health consequences for the user, family members and others who inhale secondhand environmental tobacco smoke or are exposed during pregnancy. Treatment can be effective. There are six FDA-approved medications for use in tobacco addiction treatment, including bupropion and five nicotine replacement medications (patch, gum, spray, inhaler and lozenge). Behavioral psychosocial therapies are also as effective as medications, however, treatment providers do not often use this approach. Integrated medication and behavioral therapy is effective in helping smokers quit in about 45% of cases. About 44% of all cigarettes consumed in the USA are by individuals with mental illness or addiction, and specialized treatments can help this heavy smoker population. The diagnosis of Nicotine Dependence follows the DSM-IV TR criteria for substance dependence found on p. 476.

## Definition

The DSM-IV nicotine withdrawal syndrome describes a characteristic set of symptoms that develops after abrupt cessation or a reduction in the use of nicotine products after at least several weeks of daily use and is accompanied by four of the following signs and symptoms: 1) dysphoria or depressed mood; 2) insomnia; 3) irritability, frustration, or anger; 4) anxiety; 5) difficulty concentrating; 6) restlessness or impatience; 7) decreased heart rate; and 8) increased appetite or weight gain (American Psychiatric Association, 1994). The withdrawal symptoms must also cause clinically significant distress or impairment in social, occupational, or other important areas of functioning and must not be secondary to a general medical condition or be accounted for by another mental disorder.

Other symptoms that may be associated with nicotine withdrawal include craving for nicotine, a factor thought to be significant in relapse; a desire for sweets; and impaired performance on tasks requiring vigilance. To some extent, the degree of physiological dependence predicts severity of the withdrawal syndrome and difficulty stopping smoking.

The prevalence of cigarette smoking is higher at lower socioeconomic levels. Slightly more males than females smoke, although more males than females are successful in stopping smoking. There is evidence that the number of cigarettes per smoker is increasing, leaving a more hard-core and potentially more dependent group of smokers. There has also been a recent increase

in the rate of smoking among adolescents, particularly in the number of teenage girls smoking. This increased smoking rate amongst adolescents is particularly alarming, as smokers typically start smoking at an early age, with more than 60% of smokers beginning by age 14 years and nearly all by age 18 years.

## Cooccurring Psychiatric or Substance Use Disorders

Nicotine dependence and smoking are two to three times more common in individuals with psychiatric and other substance use disorders than in the general population. Smoking-related illnesses are the primary cause of death among those in recovery from other substances. It is estimated that 55 to 90% of individuals with psychiatric disorders smoke versus the 23% of the general population. The prevalence of smoking is especially high in patients with schizophrenia (70–90%), affective disorders (42–70%) and alcohol dependence (60–90%) or other substance use disorders (70–95%).

There is no simple reason why so many psychiatric patients smoke.

## Etiology and Pathophysiology

Nicotine dependence has been called a “pediatric disease” since most smokers started during adolescence. By the age of 18, 90% of those who will ever try a cigarette have done so, and age 18 years is the average age at which individuals become daily smokers. As with other substance use disorders, the etiology of nicotine dependence is multifactorial and includes biological, psychological and social factors, including genetic factors.

Nicotine is the primary psychoactive agent in tobacco smoke and smokeless tobacco and has powerful addictive properties. As an indication of the addictive potential of this substance, one-third to one half of all children and adolescents who smoke one cigarette progress to become habitual users. Nicotine is considered to be the “gateway drug” to the use of other substances.

Nicotine has a multitude of effects. Some are acute, while others appear only after chronic usage. It acts in two primary areas of the brain: the mesolimbic dopaminergic system (the brain reward pathway), which is related to the euphoriant effects of the drug, and the locus coeruleus, which mediates stress reactions and vigilance and relates to the higher mental and cognitive functions. There are specific nicotine receptor sites (the nicotinic cholinergic receptors) throughout the central nervous system in

the hypothalamus, hippocampus, thalamus, midbrain, brain stem and cerebral cortex. In addition, nicotine affects nearly all aspects of the endocrine–neuroendocrine system, including the catecholamine, serotonin, corticosteroid and pituitary hormones. Its endocrine effects are mediated via the hypothalamic–pituitary axis and the adrenal medullary cortex. Centrally it causes release of acetylcholine, norepinephrine, serotonin, dopamine, vasopressin, growth hormone, corticotropin, cortisol, prolactin and endorphins.

Nicotine has stimulant and depressive effects on both the central and the peripheral nervous systems. It also affects the cardiovascular system, the gastrointestinal system and the skeletal motor system. Nicotine stimulates the cholinergic nervous system (sympathetic and parasympathetic). Through this variety of central and peripheral actions, nicotine improves mood and decreases anxiety; decreases distress in response to stressful stimuli and decreases aggression; improves overall cognitive function and performance (improves reaction time, concentration, vigilance and stimulus-processing capacity, increases attention, memory and learning, improves the ability to disregard irrelevant stimuli); and decreases the appetite for simple carbohydrates, decreases stress-induced eating and increases resting metabolic rate. Many individuals soon become tolerant to these effects so that they smoke not to achieve them, but rather to avoid withdrawal symptoms.

### Course and Natural History

The National Health Interview Survey found that 70% of smokers interviewed reported they wanted to quit smoking at some point in their lifetime, and about 33% of smokers try to quit each year. Only about 3% of quit attempts without formal treatment are successful, and in recent years about 30% of smokers who want to quit are seeking treatment. Outcomes for nicotine dependence treatment vary by the type of treatment and the intensity of treatment with specific reports ranging from about 15 to 45% 1-year abstinence rates following treatment. Cessation attempts result in high relapse rates, with the relapse curve for smoking cessation paralleling that for opiates. Most individuals relapse during the first 3 days of withdrawal and most others will relapse within the first 3 months. Withdrawal symptoms are most severe within the first 1 to 3 days of abstinence, often continue for 3 to 4 weeks, and in some persons last for up to 6 months or longer. Current depressive symptoms and a history of depression are predictors of relapse. Weight gain may also contribute to relapse, particularly in women. In contrast, several factors have been found to predict worse outcomes at smoking cessation. Predictors include individual factors, manifestations of the addiction such as severity of withdrawal, and social and environmental circumstances.

Nicotine dependence, like other substance use disorders, can be thought of as a chronic relapsing illness with a course of intermittent episodes alternating with periods of remission for most smokers. About 65% of those who stop smoking relapse in 3 months and another 10% relapse in 3 to 6 months, and with treatment the overall relapse rate is still about 75 to 80% by 1 year. However, these reported lower outcome rates do not consider the additive effects over time related to multiple quit attempts, since about 40 to 50% of smokers in the USA have been able to quit smoking in their lifetime. Less than 25% of the individuals who have quit smoking are successful on their first attempt. Repeated failures are common before successful abstinence, with the average smoker attempting to quit five or six times before success.

**Table 42.1** Assessing Nicotine Use and Nicotine Dependence

<p>Current and past patterns of tobacco use (include multiple sources of nicotine)</p> <p>Current motivation to quit</p> <p>Objective measures: breath co level or cotinine level (saliva, blood, urine)</p> <p>Assess prior quit attempts (number and what happened in each attempt)</p> <p>Why quit? How long abstinent? Why relapsed?</p> <p>What treatment was used (how used and for how long)</p> <p>Assess withdrawal symptoms and dependence criteria</p> <p>Psychiatric and other substance use history</p> <p>Medical conditions</p> <p>Their common triggers (car, people, moods, home, phone calls, meals, etc.)</p> <p>Perceived barriers against and supports for treatment success</p> <p>Preference for treatment strategy</p>
--

Recent prior attempts at quitting do increase the odds that individuals will be able to quit smoking on a future attempt. Relapse can occur even after a long time of abstinence, with about 33% of former smokers who are abstinent for 1 year eventually relapsing 5 to 10 years after cessation.

### Evaluation and Assessment

Before formal intervention is undertaken, it is beneficial and important to perform a comprehensive evaluation to determine the biological, psychological and social factors that are most significant in the initiation and maintenance of nicotine use and dependence. Comprehensive evaluation of the patient is outlined in Table 42.1.

Assessment of the psychiatric history is also important. Numerous studies have shown the significance of current and past depression in relation to smoking, as well as the increased prevalence rates of cigarette smoking in patients with a variety of psychiatric disorders, such as MDD, schizophrenia, and alcohol and substance abuse (see section on comorbidity). The presence of these comorbid disorders may also make successful smoking cessation less likely (see section on special features influencing treatment), especially if undiagnosed and untreated.

Assessing the patient for a history of current alcohol or other substance abuse is also important, as the prevalence of smoking in persons with alcohol dependence as well as in other substance abusers is much higher than in the general population. A careful medical history should also be obtained. The presence of significant tobacco-related medical illness can sometimes serve as crucial leverage to help motivate the individual to attempt cessation. Current medications and medical conditions may also be important considerations in determining the approach to cessation, especially with regard to pharmacotherapy. For example, a history of seizures or an eating disorder is usually a contraindication to the use of bupropion/Zyban (nonnicotine pill medication). The individual should be assessed for pulmonary symptoms and signs (cough), and if there is a long history of significant nicotine use, pulmonary function tests should be considered. The presence of significant cardiovascular disease, especially a history of recent myocardial infarction, is especially relevant to planning psychopharmacological interventions. If the individual is already

taking a psychiatric medication, consider it important to realize that quitting smoking may result in an increase in medication blood levels and side effects.

### Overall Approach to Treatment

Nicotine dependence treatment targets severity of the problem, co-occurring disorders and the different motivational levels to change. Treatment is provided in a range of levels of intensity of care (self-help, brief treatment and once or twice per week outpatient treatment) and may include different modalities (self-help guides, internet resources, medications and individual or group therapy). Formal treatment options have expanded rapidly in the past 25 years to include six FDA-approved medications, a range of effective psychosocial interventions including internet and phone-line services. Unfortunately, most insurance plans do not cover nicotine dependence treatment, and only some prescription plans will cover the medications. Few individuals receive combined medications and therapy treatment. Most receiving treatment get medication treatments, and only about 3% of the individuals receiving medication treatments will also receive psychosocial treatment despite the fact that this combination improves outcomes by 50%. Primary care treatment providers tend to offer brief counseling treatment services with follow-up visits. In addition, many individuals receive minimal formal treatment and either purchase over-the-counter nicotine replacement patch or gum, or go to Nicotine Anonymous or other self-help groups in attempting to quit on their own.

### Phases of Treatment

The general approach to the treatment of nicotine dependence considers three phases of treatment (engagement, quitting, and relapse prevention) (Table 42.2).

The importance of each of the biopsychosocial factors in initiating and maintaining smoking can vary considerably in different individuals. As a result, smoking cessation interventions should be tailored to the individual and his or her particular circumstances. This may be one reason why “one size fits all” generic treatment interventions have had such a low success rate. It must also be kept in mind that nicotine dependence is as complex in its components and determinants as other addictions and that more comprehensive multicomponent treatments may be required. When a smoker is ready for a cessation attempt, a “quit date” should be selected. After cessation, close monitoring should occur during the early period of abstinence. Before the quit date, the person should be encouraged to explore and organize social support for the self-attempt. Plans to minimize cues associated with smoking (e.g., avoiding circumstances likely to contribute to relapse) are important, as is considering alternative coping behaviors for situations with a higher potential for relapse. A telephone or face-to-face follow-up during the first few days after cessation is critical because this is the time that withdrawal symptoms are most severe, with 65% of patients relapsing by 1 week. A follow-up face-to-face meeting within 1 to 2 weeks allows a discussion of problems that have occurred (e.g., difficulties managing craving) and serves as an opportunity to provide reinforcement for ongoing abstinence. Even after the early period of abstinence, periodic telephone or face-to-face contacts can provide continued encouragement to maintain abstinence, allow problems with maintaining abstinence to be addressed, and provide feedback regarding the health benefits of abstinence.

If an initial attempt at cessation using only information and brief advice from the physician has been unsuccessful, pharmacotherapy may be used unless contraindications are present or unless the person has had few or no significant withdrawal symptoms. The most common pharmacotherapy approaches are nicotine replacement therapies (NRTs: patch, gum, spray, or inhaler) or bupropion for nicotine dependence. Combining different types of NRT and bupropion is becoming more common in clinical practice, including using these medications for at least several months and in some cases 1 year or longer. Maintenance medications are being considered in an effort of harm reduction in a more select group of patients. If a detoxification/quit attempt with pharmacotherapy alone fails, psychosocial treatments and the use of higher NRT dosages/multiple medications are possible clinical next steps. Psychosocial treatments are often available through organizations such as the American Cancer Society, American Lung Association, the American Heart Association, or through local hospitals that provide health prevention and public education programs (American Cancer Society/National Cancer Institute, 1989). If pharmacotherapy is unacceptable or contraindicated, behavioral therapy (BT) alone should be provided. Failure with pharmacotherapy or BT alone suggests the need for more detailed in-depth assessment and more intensive and multimodal interventions.

### Self-help

Many smokers have successfully quit smoking without participating in formal treatment and the success rate improves with multiple attempts and probable self-learning through trial and error and learning from others. Eventually about 50% of smokers are able to quit and more than 90% of successful quitters have been able to do so without the assistance of professionals or formal programs. These numbers reflect multiple factors including the limitations on access to treatment (nonexistent health insurance coverage and limited number of providers with expertise to help), the cumulative process of multiple attempts and learning from others and from self-help materials, and the severity of the nicotine dependence. The advantage of quitting without professional intervention is the decreased expense and time commitment; however, professional treatment may be necessary for higher severity cases that are often complicated by other behavioral health problems. The primary unassisted method of detoxification from nicotine dependence is precipitous cessation (cold turkey), which is used by more than 80% of smokers. This is followed by spontaneous strategies to handle cravings and triggers. Some smokers attempt to limit intake, taper the number of cigarettes smoked, or switch to a reduced tar or nicotine brand. Special filters and holders are also available to decrease the amount of smoke that is available from a cigarette. These methods are usually less successful because smokers have been shown to alter smoking behavior by increasing the frequency, volume, or duration of the inhalation to ensure maintenance of blood levels of nicotine adequate to prevent withdrawal symptoms. Some smokers use non-prescription pills that are analogues of nicotine, such as lobeline, to help manage or prevent withdrawal symptoms. These agents have not been shown to be effective in controlled studies.

Some geographical areas have Nicotine Anonymous groups that are structured similarly to Alcoholics Anonymous or Narcotics Anonymous groups. These groups are based on the 12-Step approach to recovery from addictions. Nicotine Anonymous is a relatively new organization (founded in 1985)

**Table 42.2 Three Phases of Nicotine Dependence Treatment****Engagement Phase**

- Do a comprehensive evaluation of nicotine use and dependence
- Provide MET personalized feedback from the assessment
- Assess motivational level to quit and attempt to set a target quit date
- Explore previous quit attempts – what worked? What did not work? What triggered the return to tobacco use?
- Assess patient preference for treatment (medications, psychosocial treatments, group vs. individual, self-help, etc.) and provide education on treatment
- Create a treatment plan
- Strengthen and renew patient’s motivation to quit smoking (MET orientation)
- Identify cues and triggers for usage
- Self-monitoring of smoking behavior (write down when use)
- Help patients gain understanding of their own tobacco use patterns
- Help increase knowledge about triggers and cues
- Help patients understand environmental influences on their smoking
- Begin education about nicotine, tobacco addiction, withdrawal symptoms, etc.
- Begin disconnecting smoking behavior and linked behaviors (no smoking while driving car, talking on phone, during meal time, etc.)
- Help them get medication evaluation and medications for the quitting phase

**Quitting Phase**

- Start medications on quit date (NRT) or before quit date (bupropion), sometimes begin NRT (gum, spray, inhaler, not patch) in small amounts and reduce tobacco usage in an equivalent or greater amount
- Teach specific coping techniques for handling withdrawal symptoms, cues/triggers and how to enhance social support
- Help patient prepare emotionally, behaviorally and physically for the quit date and the early abstinence period
- Help identify support systems, anticipate challenges and address ways to handle people, places, things, and mood challenges
- Address nutrition and exercise components
- Address role of family/friends in supporting or sabotaging treatment
- Continue to strengthen client’s resolve to quit
- Continue relapse prevention therapy approaches
- Assess triggers to craving and use and high-risk situations
- Coping with cravings, thoughts and urges
- Problem solving
- Smoke refusal skills
- Planning for emergencies
- Seemingly irrelevant decisions
- Relapse analysis for slips

**Relapse Prevention Phase**

- Continue relapse prevention strategies for long-term abstinence
- Reinforce specific coping skills, including mood management and patient specific triggers
- Teach positive coping skills for dealing with frustration and anxiety
- Compliment success and provide encouragement
- Continue focus on maintaining motivation and commitment for abstinence
- Monitor progress
- Provide treatment within your discipline and make referrals when appropriate
- Encourage the use of peer support such as Nicotine Anonymous help the client gain personal insight and keep growing in their recovery
- Manage any relapses/slips to continue the course
- Continue medications as needed

and does not have the extensive network that other 12-Step programs like Alcoholics Anonymous or Narcotics Anonymous have developed. No formal controlled studies of the benefits of this intervention have been carried out. In addition, self-help written materials can play an important role in educating patients about the negative health effects of nicotine, the benefits of quitting and the nature of the addiction. Self-help literature, internet resources and Nicotine Anonymous can be effectively integrated into formal treatments of brief interventions, individual and

group treatments. Even smokers with major health conditions, such as chronic obstructive pulmonary disease or cardiovascular disease, often have a difficult time attaining and maintaining abstinence. Numerous psychological and pharmacological treatments have been developed to assist with smoking cessation.

Even a brief face-to-face intervention by a physician or other medical staff can increase the likelihood of cessation two- to tenfold (Klesges *et al.*, 1990). The impact of physician’s brief advice to quit has received the most study relative to other

disciplines such as nursing; however, clearly all disciplines have an opportunity to make an impact. Physicians can inquire about a patient's smoking status, urge the patient to stop smoking, and spend a brief time counseling the patient about cessation strategies. Multiple follow-up interventions, even telephone contacts by other medical staff, can further improve the cessation rate. Resources are available to assist physicians in providing effective antismoking interventions, which can even be used by those not highly skilled in counseling. Physicians' advice appears to be most successful with patients with a serious medical problem or specific medical reason for quitting (e.g., pregnancy or congestive heart disease). In addition, because an estimated 70% of smokers in the USA visit their physicians at least once a year, an important opportunity exists for providing this type of smoking cessation intervention.

### Specific Medication and Psychosocial Treatment Interventions

It should be noted that even brief face-to-face intervention by a physician or other medical staff increase the likelihood of cessation two- to tenfold. There are now numerous effective psychosocial and pharmacological approaches that can be used in nicotine dependence treatment. Psychosocial intervention alone, pharmacotherapy alone, or combined approaches may be used. Given patients' preferences and current concerns with cost-effectiveness, less costly single-modality interventions are often used initially, whereas more costly multimodal interventions are often reserved for persons for whom cessation attempts have failed. This may not be the wisest strategy, but it is the most common.

Pharmacological interventions have become an important component of treating nicotine dependence. Approaches used parallel other addictions in treating acute withdrawal (detoxification), protracted withdrawal and even maintenance for harm reduction. The primary medications are NRT and bupropion. All six of these modalities are FDA approved and have demonstrated efficacy.

**Nicotine replacement therapy (NRT)** is the most widely used medication option and is available over-the-counter (patch and gum) or by prescription (patch, gum, spray and inhaler). The principle behind nicotine replacement is that nicotine is the dependence producing constituent of cigarette smoking, and that smoking cessation and abstinence can be achieved by replacing nicotine without the harmful impurities in cigarette smoke. The abuse liability of nicotine replacement appears to be minimal. The substituted nicotine initially prevents significant withdrawal symptoms that may lead to relapse during the early period of smoking cessation. The substituted nicotine is then gradually tapered and discontinued.

**Nicotine gum** was the first NRT approved and it slowly releases nicotine from an ion exchange resin when chewed. The nicotine released is absorbed through the buccal mucous membranes. The NRT gum is available in doses of 2 and 4 mg, and the recommended dosing is in the range of nine to 16 pieces per day. Nicotine gum is more effective when used in conjunction with some type of psychosocial intervention, particularly BT. Outcome is more positive when a definite schedule for gum use is prescribed – for example, one piece of gum per hour while awake – than when used on an as-needed basis. (Tapering may be necessary after 4 to 6 months of use, especially for individuals using higher total daily doses of gum. Nicotine gum is often not effectively utilized in patients with temporomandibular joint problems, dental problems and dentures. Nicotine gum requires

a highly motivated patient and a good deal of time in instructing the patient in proper use of the gum. Many individuals find the gum difficult to learn to use properly. Patients must be instructed that nicotine gum is not like bubble gum and that the gum is crunched a few times and “parked” between the gum and cheek. It should not be used soon after drinking acidic substances such as coffee, soda, or orange juice because the acidic environment in the mouth interferes with its release and absorption.

The *nicotine patch* transdermal delivery system provides continual sustained release of nicotine, which is absorbed through the skin. This form of nicotine replacement more than doubles the 1-year cessation rate (Hughes, 1994). There is a dose–response relationship, with patients receiving higher doses attaining higher cessation rates. The nicotine patch eliminates the conditioning of repeated nicotine use, which remains present with the use of other NRT products. Compliance rates are higher because it involves once-daily dosing and its administration is simple and discreet. The typical starting dose of NRT patch is 21 or 15 mg patch, however, in some cases multiple patches are used. Lower dose patches available at 7 and 14 mg are used to taper after smoking cessation. The patch delivers approximately 0.9 mg of nicotine/hour. Steady-state nicotine levels are 13 to 25 ng/mL and the highest levels are seen soon after patch application. The nicotine patch is often used for a total of 6 to 12 weeks but can be used for much longer (American Psychiatric Association, 1996). The transdermal patch does not allow for self-titrated dosing, craving and nicotine withdrawal symptoms like the other NRT routes (gum, spray, inhaler); however, the nicotine blood levels are significantly less than with smoking. The patch can be used more discreetly and can be used despite dental or temporomandibular joint problems.

Although the nicotine patch is well tolerated, about 25% of patients have significant local skin irritation or erythema and 10% discontinue the patch because of intolerable side effects. Other side effects include sleep problems with the 24-hour patches.

Some experts suggest using nicotine gum concurrently with transdermal nicotine on an as-needed basis to cover emergent withdrawal symptoms or craving not controlled by replacement from the transdermal patch, whereas others suggest simply increasing the dose of the transdermal patch or using gum initially and then switching to the patch (Gourley, 1994; Fagerstrom *et al.*, 1993). Combining transdermal nicotine and nicotine gum increases the potential for significant side effects.

The **nicotine nasal spray** is rapidly absorbed and produces a higher nicotine blood level than does transdermal nicotine or gum. A single dose of the spray delivers 0.5 mg to each nostril and it can be used one to three times/hour. It has been suggested that the effective daily dose in nicotine dependent smokers is 15 to 20 sprays (8–10 mg).

The **nicotine inhaler** provides nicotine through a cartridge that must be “puffed”. It mimics the upper airway stimulation experienced with smoking; however, absorption is primarily through the oropharyngeal mucosa. Although the blood level of nicotine is lower than with other forms of nicotine replacement (8–10 ng/mL), the inhaler has been shown to be effective. Side effects of the inhaler and spray include local irritation, cough, headache, nausea, dyspepsia, the need for multiple dosing and the impossibility of discreet use.

**Bupropion**, the non-nicotine pill FDA-approved medication option, is a heterocyclic, atypical antidepressant that blocks the re-uptake of both dopamine and norepinephrine. Its efficacy as an aid to smoking cessation was first demonstrated in three

double-blind placebo-controlled trials. Smoking cessation rates appear to improve further when bupropion is combined with the nicotine patch (Nides, 1997).

Combined NRTs/bupropion or serial pharmacotherapeutic approaches may also be beneficial, especially in more difficult to treat cases of nicotine dependence. For example, combining the patch with other nicotine replacement medications like nicotine gum or the spray allows for both more rapid onset of action and reduction of withdrawal symptoms through steady levels of nicotine released by the patch. Combining nicotine replacement with non-nicotine replacement strategies (e.g., bupropion and nicotine patch) has been beneficial in further improving outcomes in some

### Clinical Vignette 1

A 50-year-old divorced woman, Ms D, had been smoking about 30 cigarettes per day for more than 30 years. She reported only one prior attempt to quit, which resulted in significant depressive symptoms that resolved after she returned to smoking. However, the symptoms had been so disabling that she never again seriously considered another quit attempt. She reported a period of significant depressive symptoms of several months' duration after her divorce 2 years previously, with some lingering symptoms that met the criteria for dysthymic disorder. She had not previously received treatment for her depressive symptoms. She lived alone and had limited social support. With regard to her dysthymia, she complained of low energy, excessive sleeping and poor concentration. Treatment for both the depression and nicotine dependence were reviewed. Ms D was interested to try the bupropion since it may help her with both her mood and the nicotine dependence. The plan was to first stabilize her depression and then select a quit date. She started bupropion SR 150 mg in the morning and after 7 days increased the dosage to 300 mg (second dose at about 5 PM). After approximately 1 month there was substantial improvement in her depressive symptoms. During this time she had been provided with educational materials about nicotine dependence, tobacco and nicotine dependence treatment. She was willing to begin an 8-week behaviorally-oriented group for smoking cessation at the local community hospital clinic. She selected a quit date that would coincide with the projected quit date within the group treatment, and she desired to have an NRT option available in case she continued to have intensive cravings even while on the bupropion and participating in the group treatment. She was prescribed nicotine gum 4 mg and instructed in its use. She reported having persistent cravings on the quit day and began taking about 6 to 10 pieces of the 4 mg dose per day. She successfully completed the Nicotine Dependence Treatment Group and continued both nicotine gum and the bupropion for the next 4 months with monthly monitoring. At that time, she gradually tapered and discontinued the nicotine gum during a period of 2 months. She continued her antidepressant medication, bupropion SR, with monthly monitoring for the next 3 months. At that time, she was free of depressive symptoms, had become more socially active and had remained abstinent from cigarettes. The antidepressant was discontinued after 9 months, and she remained free of depression and abstinent from nicotine 2 years later.

studies and is common in clinical practice. The combination approach offers the advantage of multiple neurobiological mechanisms of action.

## Psychosocial Treatments

In contrast with the treatment of other substance use disorders, psychosocial treatment is underutilized and has not evolved to be the cornerstone of treatment. This limited utilization of psychosocial treatments does not match the very positive outcomes from either psychosocial treatments alone (25% 1-year abstinence with BT) or when combined with NRT or bupropion (50% improvement compared with NRT or bupropion alone), however, it does match the lack of health care coverage for this service.

As in treating other substance use disorders, the core psychotherapy approaches are motivational enhancement therapy (MET), cognitive-behavioral therapy (CBT) (relapse prevention), and 12-Step facilitation. Psychosocial interventions, particularly BT, have been shown to increase abstinence rates significantly. However, only 7% of smokers attempting to quit smoking are willing to participate in BT (Ferry *et al.*, 1992). In addition, it is more expensive than pharmacotherapy and more labor-intensive.

## Combined Psychosocial and Psychopharmacological Therapies

All nicotine dependence treatment practice guidelines recommend the integration of nicotine dependence treatment medications (NRT and bupropion) with behavioral and supportive psychosocial treatment approaches. Empirical evidence supports the finding that medications double the quit rate compared with placebo, and face-to-face BT can double the quit rate compared with minimal psychosocial intervention. BT also can increase medication compliance. Integrated treatment further increases the quit rate by another 50% and triples the outcome rate compared with a control group (Fiore *et al.*, 1990).

## Comparison of DSM-IV/ICD-10 Diagnostic Criteria

The DSM-IV-TR and ICD-10 symptom lists for nicotine withdrawal include some different items: the ICD-10 list has craving, malaise, increased cough and mouth ulceration and does not include the DSM-IV-TR decreased heart rate item.

# Substance Abuse: Opioid Use Disorders

## Introduction

The term **opioids** describes a class of substances that act on opioid receptors. Numerous opioid receptors have been identified, but the physiologic and pharmacologic responses in man are best understood for the mu ( $\mu$ ) and kappa ( $\kappa$ ) receptors. The  $\mu$  receptor, for which morphine is a prototypical agonist, appears to be the one most closely related to opioid analgesic and euphoric effects. Opioids can be naturally-occurring substances such as morphine, semi-synthetics such as heroin, and synthetics with morphine-like effects such as meperidine. These drugs are prescribed as analgesics, anesthetics, antidiarrheal agents, or cough suppressants. In addition to morphine and heroin, the opioids include codeine, hydromorphone, methadone, oxycodone and fentanyl among others. Drugs such as buprenorphine, a partial agonist at the  $\mu$  receptor, and pentazocine, an agonist-antagonist, are also included in this class because their physiologic and behavioral effects are mediated through opioid receptors (Table 43.1).

Opioids are the most effective medications for relief of severe pain and are widely used for that purpose. Their euphoric properties can also result in inappropriate use, abuse and dependence (i.e., “addiction”), which is why they have been placed under the Controlled Substances Act. The more potent opioids approved for medical use are under schedule II: examples are fentanyl, hydromorphone, methadone, morphine; others are under schedules III and IV.

## Epidemiology of Opioid Abuse and Dependence

Heroin is the most commonly abused drug of this class. The 2000 National Household Survey obtained information on nonmedical use of analgesics and heroin separately. For heroin, the survey showed that 1.3% of the population had used in their lifetime; in the adolescent groups, 0.6% of 16- to 17-year-olds had used in their lifetime, but by age 18 to 20 the percentage was the same as in the adult population, 1.3%. When the data for nonmedical use of opioid pain relievers are examined, particularly in adolescent populations, the numbers are more alarming, with 12.4% of 16- to 17-year-olds having used these agents and 15.8% of 18- to 20-year-olds. It is unclear what proportion of the users met criteria for dependence or abuse since diagnoses were not part of the Household Survey (National Household Survey, 2000).

Heroin addiction has traditionally been associated with large urban areas, especially those in the northeast and mid-Atlantic states.

In spite of significant increases in resources that are committed to stop the supply, the purity, and availability of heroin for sale to addicts “on the street” have increased markedly during the last several years. This increase in purity and availability is probably a significant contributor to the increase that has recently occurred in opioid-related emergency room visits and applications for methadone treatment. There also appears to have been an increase in the abuse of prescription opioids, mainly in nonurban areas. Oxycodone and hydrocodone containing products have traditionally been the main prescription opioids of abuse. Attention has recently focused on oxycontin, a long-acting formulation of oxycodone that contains doses up to 80 mg/tablet. Though the slow absorption of this medication is unlikely to result in abuse when taken as prescribed, addicts have discovered that the tablets can be crushed, freeing much of the oxycodone which can then be inhaled or injected to produce a potent euphoria.

## Etiology and Pathophysiology of Opioid-related Disorders

Opioid-related disorders are felt to arise from a variety of social, psychological and biological factors that interact to produce a “case”. Among those identified as especially important are opioid use within the individual’s immediate social environment and peer group; availability of opioids; a history of childhood conduct disorder or adult antisocial personality disorder; and a family history of one or more substance use disorders. The families of persons with opioid dependence are likely to have higher levels of psychopathology, especially an increased incidence of alcohol and drug use disorders, and antisocial personality. The exact mechanism or mix of factors that produce opioid dependence or abuse are unknown, as are the factors that contribute to the chronic relapsing pattern that is typically seen in many of these patients.

## Clinical Picture of Opioid-related Disorders

Heroin is usually taken by injection, though it can be smoked, inhaled (“snorted”), or taken orally. Smoking and inhalation are commonly seen only when very pure heroin is available and is currently on the rise in the northeastern US; tar heroin is also commonly smoked in the Pacific Northwest. Hydromorphone (Dilaudid®), morphine and meperidine (Demerol®) are also usually injected though they can be taken orally; fentanyl is always injected. Codeine and other analgesics made for oral ingestion (such as Percodan® or Percocet®) are usually taken orally. All of these drugs can cause intoxication, withdrawal, dependence and abuse.

**Table 43.1 Opioids\***

Drug	Active Metabolite	Route of Administration	Relative Potency	Medical Use	Plasma Half-Life (Hours)	Duration of Action (Hours)
Morphine		IM	1	Analgesia	2	4–6
Heroin	Morphine	IM	1–2	None	0.5	3–5
Codeine		PO	0.05	Analgesia, antitussive	2–4	4–6
Fentanyl		IM	40–100	Analgesia	3–4	1–2
Hydromorphone		IM	13	Analgesia	2–3	4–6
Oxycodone		PO	0.5–1	Analgesia		4–6
Methadone		PO	0.50	Analgesia, opioid substitution	15–40	18–30
<i>l</i> - $\alpha$ -acetylmethadol (LAAM)		PO	0.40	Opioid substitution	14–104†	48–80
	Nor-LAAM				13–130†	
	Dinor-LAAM				97–430†	
Buprenorphine		SL	N/A (partial agonist)	Analgesia (opioid substitution, investigational)	6–12	4–6 (for analgesia) 12–48‡

\*IM, intramuscular; PO, by mouth; SL, sublingual; N/A, not applicable.

†At steady state.

‡Appears to be dose dependent.

## Intoxication

Opioid intoxication is characterized by maladaptive and clinically significant behavioral changes developing within minutes to a few hours after opioid use (see DSM-IV-TR for substance intoxication on p. 410 on general approaches to substance abuse disorder). Symptoms include an initial euphoria sometimes followed by dysphoria or apathy. Psychomotor retardation or agitation, impaired judgment, and impaired social or occupational functioning are commonly seen. Intoxication is accompanied by pupillary constriction unless there has been a severe overdose with consequent anoxia and pupillary dilatation. Persons with intoxication are often drowsy (described as being “on the nod”) or even obtunded, have slurred speech, impaired memory and demonstrate inattention to the environment to the point of ignoring potentially harmful events. Dryness of secretions in the mouth and nose, slowing of gastrointestinal activity and constipation are associated with both acute and chronic opioid use. Visual acuity may be impaired as a result of pupillary constriction. The magnitude of the behavioral and physiologic changes depends on the dose as well as individual characteristics of the user such as rate of absorption, chronicity of use and tolerance. Symptoms of opioid intoxication usually last for several hours, but are dependent on the half-life of the particular opioid that has been used. Severe intoxication following an opioid overdose can lead to coma, respiratory depression, pupillary dilatation, unconsciousness and death.

## Withdrawal

Opioid withdrawal is a clinically significant, maladaptive behavioral and physiological syndrome associated with cessation or reduction of opioid use that has been heavy and prolonged (see DSM-IV-TR criteria for substance withdrawal from general approaches to substance abuse disorders p. 410). It can also be precipitated by

administration of an opioid antagonist such as naloxone or naltrexone. Patients in opioid withdrawal typically demonstrate a pattern of signs and symptoms that are opposite the acute agonist effects. The first of these are subjective and consist of complaints of anxiety, restlessness and an “achy feeling” that is often located in the back and legs. These symptoms are accompanied by a wish to obtain opioids (sometimes called “craving”) and drug-seeking behavior, along with irritability and increased sensitivity to pain. Additionally, patients typically demonstrate three or more of the following: dysphoric or depressed mood; nausea or vomiting; diarrhea; muscle aches; lacrimation or rhinorrhea; increased sweating; yawning; fever; insomnia; pupillary dilatation; fever; and piloerection. Piloerection and withdrawal-related fever are rarely seen in clinical settings (other than prison) as they are signs of advanced withdrawal in persons with a very significant degree of physiologic dependence; opioid-dependent persons with “habits” of that magnitude usually manage to obtain drugs before withdrawal becomes so far advanced. For short acting drugs such as heroin, withdrawal symptoms occur within 6 to 24 hours after the last dose in most dependent persons, peak within 1 to 3 days and gradually subside over a period of 5 to 7 days. Symptoms may take 2 to 4 days to emerge in the case of longer acting drugs such as methadone or levo-alpha-acetylmethadol (LAAM). Less acute withdrawal symptoms are sometimes present and can last for weeks to months. These more persistent symptoms can include anxiety, dysphoria, anhedonia, insomnia and drug craving.

## Dependence

Opioid dependence is diagnosed by the signs and symptoms associated with compulsive, prolonged self-administration of opioids which are used for no legitimate medical purpose, or if a medical condition exists that requires opioid treatment, are used

in doses that greatly exceed the amount needed for pain relief. Persons with opioid dependence typically demonstrate continued use in spite of adverse physical, behavioral and psychological consequences. Almost all persons meeting criteria for opioid dependence have significant levels of tolerance and will experience withdrawal upon abrupt discontinuation of opioid drugs. Persons with opioid dependence tend to develop such regular patterns of compulsive use that daily activities are typically planned around obtaining and administering drugs.

Opioids are usually purchased on the illicit market, but they can also be obtained by forging prescriptions, faking or exaggerating medical problems, or by receiving simultaneous prescriptions from several physicians. Physicians and other health care professionals who are dependent will often obtain opioids by writing prescriptions or by diverting opioids that have been prescribed for their own patients.

### Abuse

Opioid abuse is a maladaptive pattern of intermittent use in hazardous situations (driving under the influence, being intoxicated while using heavy machinery, working in dangerous places, etc.), or periodic use resulting in adverse social, legal, or interpersonal problems (see DSM-IV-TR criteria on p. 409). All of these signs and symptoms can also be seen in persons who are dependent; abuse is characterized by less regular use than dependence (i.e., compulsive use not present) and by the absence of significant tolerance or withdrawal. As with other substance use disorders, opioid abuse and dependence are hierarchical and thus persons diagnosed as having opioid abuse must never have met criteria for opioid dependence.

### Assessment and Clinical Picture

Opioid use disorders can occur at any age, including adolescence and the geriatric years, but most affected persons are between 20 and 45 years. Neonates whose mothers are addicted can experience opioid withdrawal. Rarely, young children are affected with some cases of dependence having been reported in persons who are 8 to 10 years of age. Males are more commonly affected, with the male:female ratio typically being 3 or 4 to 1.

A nonjudgmental and supportive yet firm approach to these patients is especially important. They typically have engaged in antisocial or other forms of problematic behavior. They are often embarrassed or afraid to describe the extent of their behavior, and have extremely low self-esteem. At the same time, they are prone to be impulsive, manipulative and to act-out when frustrated. Communicating a feeling of nonjudgmental support in the context of setting limits, along with a clear and informed effort to provide appropriate help will encourage optimum therapeutic opportunities.

### Physical Examination

Sclerosed veins (“tracks”) and puncture marks on the lower portions of the upper extremities are common in intravenous users. When these veins become unusable or otherwise unavailable, persons will usually switch to veins in the legs, neck or groin. Veins sometimes become so badly sclerosed that peripheral edema develops. When intravenous access is no longer possible, persons will often inject directly into their subcutaneous tissue (“skin-popping”) resulting in cellulitis abscesses, and circular-appearing scars from healed skin lesions. Tetanus is a relatively rare but

extremely serious consequence of injecting into the subcutaneous tissues. Infections also occur in other organ systems, including bacterial endocarditis, hepatitis B and C, and HIV infection.

Persons who “snort” heroin or other opioids often develop irritation of the nasal mucosa. Difficulties in sexual function are common, as are a variety of sexually transmitted diseases. Males often experience premature ejaculation associated with opioid withdrawal, and impotence during intoxication or chronic use. Females commonly have disturbances of reproductive function and irregular menses.

### Laboratory Findings

During dependence, routine urine toxicology tests are often positive for opioid drugs and remain positive for most opioids for 12 to 36 hours. Methadone and LAAM, because they are longer acting, can be identified for several days. Fentanyl is not detected by standard urine tests but can be identified by more specialized procedures. Oxycodone, hydrocodone and hydromorphone are often not routinely included on urine toxicology tests though they can be identified by gas chromatography/mass spectrometry. Testing for fentanyl is not necessary in most programs, but needs to be performed in assessing and treating health care professionals such as anesthesiologists who have access to this drug. Concomitant laboratory evidence of other abuseable substances such as cocaine, marijuana, alcohol, amphetamines and benzodiazepines is common.

Hepatitis screening tests are often positive, either for hepatitis B antigen (signifying active infection) or hepatitis B and/or C antibody (signifying past infection). Mild to moderate elevations of liver function tests are common, usually as a result of chronic infection with hepatitis C but also from toxic injury to the liver due to contaminants that have been mixed with injected opioids, or from heavy use of other hepatotoxic drugs such as alcohol. Low platelet count, anemia, or neutropenia, as well as positive HIV tests or low CD-4 cell counts are often signs of HIV infection. HIV is commonly acquired via the practice of sharing injection equipment, or by unprotected sexual activity that may be related to the substance use disorder, for example, exchanging sex for drugs or money to buy drugs.

### Differential Diagnosis

Individuals who are dependent on “street” opioids are usually easy to diagnose due to the physical signs of intravenous use, drug-seeking behavior, reports from independent observers, the lack of medical justification for opioid use, urine test results, and the signs and symptoms of intoxication or withdrawal.

The signs and symptoms of opioid withdrawal are fairly specific, especially lacrimation and rhinorrhea, which are not associated with withdrawal from any other abuseable substances. Other psychoactive substances with sedative properties such as alcohol, hypnotics, or anxiolytics can cause a clinical picture that resembles opioid intoxication. A diagnosis can usually be made by the absence of pupillary constriction, or by the lack of response to a naloxone challenge. In some cases, intoxication is due to opioids along with alcohol or other sedatives. In these cases the naloxone challenge will not reverse all of the sedative drug effects.

Difficult diagnostic situations are seen among persons who fabricate or exaggerate the signs and symptoms of a painful illness (such as kidney stones, migraine headache, back pain, etc.). Because pain is subjective and difficult to measure, and because some of these individuals can be very skillful and deceptive, diagnosis can be difficult and time-consuming. Drugs that are

obtained in such deceptions may be used by the individual in the service of his/her dependence or abuse, or may be sold on the illicit drug market for profit. These individuals cause problems not only for physicians, but also for patients with disorders that need opioids for pain relief.

Persons with opioid dependence will often present with psychiatric signs and symptoms such as depression or anxiety. Such subjective distress often serves to motivate the patient to seek treatment, and thus can be therapeutically useful. These symptoms can be the result of opioid intoxication or withdrawal, or they might result from the pharmacological effects of other substances that are also being abused such as cocaine, alcohol, or benzodiazepines. They may also represent independent, non-substance-induced psychiatric disorders that require long-term treatment. The correct attribution of psychiatric symptoms that are seen in the context of opioid dependence and abuse follows the principles that are outlined in the substance-related section and other relevant parts of DSM-IV-TR.

### Course and Natural History of Opioid Dependence

Opioid dependence can begin at any age, but problems associated with opioid use are most commonly first observed in the late teens or early twenties. Once dependence occurs it is usually continuous over a period of many years even though periods of abstinence are frequent. Reoccurrence is common even after many years of forced abstinence, such as occurs during incarceration. Increasing age appears to be associated with a decrease in prevalence. This tendency for dependence to remit generally begins after age 40 and has been called “maturing out”. However, many persons have remained opioid dependent for 50 years or longer. Thus, though spontaneous remission can and does occur, most cases of untreated opioid dependence follow a chronic, relapsing course for many years.

### Treatment

There are currently a number of effective pharmacological and behavioral therapies for the treatment of opioid dependence, with these two approaches often combined to optimize outcome. There are also some newer treatment options, which may take various forms. For example, methadone maintenance is an established treatment, while the use of buprenorphine/naloxone in an office-based setting represents a new variation on that theme. Clonidine has been used extensively to treat opioid withdrawal while lofexidine is a structural analog that appears to have less hypotensive and sedating effects. The depot dosage form of naltrexone, currently under development, may increase compliance with a medication that has been an effective opioid antagonist but which has been underutilized due to poor acceptance by patients. In almost every treatment episode using pharmacotherapy, it is combined with some type of psychosocial or behavioral treatment. Recent research has documented the value of these additional treatments and provided insight into the ones that are the most effective.

### Detoxification: Long-term, Short-term, Rapid and Ultra-rapid

Detoxification from opioids, for most patients, is only the first phase of a longer treatment process. Most patients seeking treatment have been addicted to heroin or other opioids for 2 to

3 years, and some for 30 years or more. Thus, treatment usually involves changes in individuals' lifestyles. Though generally ineffective in achieving sustained remission unless combined with long-term pharmacological, psychosocial, or behavioral therapies, detoxification alone continues to be widely used. It is sometimes the only option available for individuals who do not meet the Food and Drug Administration (FDA) criteria for, do not desire, or do not have access to agonist medications such as methadone or methadyl acetate (LAAM).

Pharmacologic detoxification is generally ineffective in achieving sustained remission unless combined with long-term pharmacologic, psychosocial, or behavioral therapies.

The detoxification process may include use of opioid agonists (e.g., methadone); partial agonists (e.g., buprenorphine); antagonists (e.g., naloxone, naltrexone); or nonopioid alternatives such as clonidine, benzodiazepines, or nonsteroidal anti-inflammatory agents. In many cases, one or more medications are combined, such as naloxone with clonidine and a benzodiazepine. The choice of detoxification medication and the duration of the process depend on numerous factors including patient preference, clinician expertise and experience, type of treatment facility, licensing and available resources. Ultimately, however, the goal of detoxification is the achievement (and maintenance) of a drug-free state while minimizing withdrawal. Unfortunately detoxification for some individuals appears to be used in a punitive manner or as an expedient means to achieve a drug-free state rapidly with no follow-up pharmacological or behavioral therapy.

Opioid detoxification paradigms are frequently categorized according to their duration: long-term (typically 180 days), short-term (up to 30 days), rapid (typically 3–10 days) and ultra-rapid (1–2 days). These temporal modifiers provide only a coarse description of the paradigm; they do not provide other important information such as the medications used or whether postdetoxification pharmacological, psychosocial, or behavioral therapy is provided. However, some general guidelines typically apply.

The most common detoxification protocols, and those for which the most data are available, are the long-term (typically 180 days) and short-term (up to 30 days) paradigms involving the use of methadone. Unfortunately, these strategies have not generally been associated with acceptable treatment response using relapse to opioid use as an outcome criterion. Results from more rapid detoxification evaluations using short- or even intermediate term (up to 70 days) medication-tapering protocols are even less encouraging and have an unfortunately low success rate. It should be noted, however, that provision of additional services such as counseling, behavioral therapy, treatment of underlying psychopathologies, job skills training and family therapy to address concomitant treatment needs can improve outcome though success rates remain low, even with these services.

Rapid detoxification involves the use of an opioid antagonist, typically naltrexone or naloxone, in combination with other medications (such as clonidine and benzodiazepines) to mitigate the precipitated withdrawal syndrome. The procedure is intended to expedite and compress withdrawal in order to minimize discomfort and decrease treatment time. Ultra-rapid detoxification also utilizes other medications, along with an opioid antagonist, to moderate withdrawal effects. However, rather than individuals being awake as they are during the rapid detoxification process, they are placed under general anesthesia or, alternatively, deeply sedated. A recently published study (Hensel and Kox, 2000) in which ultra-rapid detoxification was followed by naltrexone maintenance and supportive psychotherapy, indicated that 49 of

72 patients were opioid abstinent 12 months following detoxification. However this study and other studies involved self-selected individuals thus making it impossible to know the overall effectiveness of this type of intervention.

A major concern regarding ultra-rapid detoxification is the occurrence of potentially serious adverse effects, such as respiratory distress or other pulmonary and renal complications during or immediately following the procedure. A high frequency of vomiting has also been reported. The degree to which serious adverse events occur has not yet been determined. In spite of the emerging evidence about serious adverse events, ultra-rapid detoxification may be appropriate for highly selected individuals based on considerations of previous treatment history, economic factors and patient choice. However, patients seeking this treatment must be thoroughly informed that serious adverse events, including sudden unexpected deaths, have occurred in association with this procedure and its use should probably be limited to inpatient settings where monitoring by anesthesiologists and other highly trained staff is available.

Buprenorphine, a  $\mu$ -opioid partial agonist, has also been used as a detoxification agent. Results from inpatient studies have shown that it is safe, well tolerated and mitigates opioid withdrawal signs and symptoms over a range of doses and detoxification schedules. Clonidine, an alpha-2-adrenergic agonist, has been shown to suppress many of the autonomic signs and symptoms of opioid withdrawal. It can cause sedation and hypotension but has been used with few problems when appropriate monitoring is available. It does not suppress the subjective discomfort of withdrawal and, probably for that reason, is not well accepted by most patients.

Other alpha-2-adrenergic agonists have also been evaluated in order to find agents that are as or more effective, but less sedating and hypotensive than clonidine. Lofexidine, a medication that was originally promoted as an antihypertensive but was shown to lack clinically significant hypotensive effects, has been the most studied. When compared with clonidine, it has been found equally to suppress autonomic signs and symptoms of opioid withdrawal but with less sedation and hypotension. When compared with methadone dose tapering, lofexidine detoxification was associated with opioid withdrawal effects that peaked sooner, but resolved to negligible levels more rapidly. Data regarding the potential effectiveness of guanabenz and guanfacine have also been reported, but further studies are required to assess the potential utility of these medications. In summary, recent studies have shown that lofexidine is likely to be a useful opioid detoxification agent whose efficacy approximates that of clonidine but with fewer side effects.

### Opioid Agonist Pharmacotherapy

Methadone maintenance has become the most commonly used pharmacotherapy for opioid dependence. Methadone acts at the  $\mu$ -opioid receptor and its ability to suppress opioid withdrawal for 24 to 36 hours following a single oral dose makes it an ideal medication for this purpose. Another  $\mu$ -opioid agonist, LAAM, received FDA approval for maintenance treatment in 1993. LAAM is a long-acting congener of methadone that suppresses withdrawal for 48 to 72 hours and thus has the advantage of requiring less frequent clinic visits than methadone, which must be taken daily. A third medication, buprenorphine, has received FDA approval. It has been mentioned above as a detoxification agent and will be discussed later and in more

detail as it has unique properties that are likely to result in it being used with fewer regulatory controls than methadone and LAAM.

Both methadone and LAAM are Schedule II controlled substances and can only be used for maintenance and detoxification in programs that are licensed and regulated by the FDA and the Drug Enforcement Administration (DEA). The regulations specify who is eligible for treatment, procedures that are required for its administration, the number of take-home doses permitted, and the type of medication storage security needed. Treatment programs have been inspected approximately every 3 years for the past 30 years and violations have resulted in sanctions ranging from administrative citations to criminal prosecution.

A combination of regulations has resulted in a treatment system that is separated from the mainstream of other medical care and that consists almost entirely of specially licensed and inspected clinics. Clinics are often located in old buildings that have been converted to comply with regulations but that were never intended for medical use. At the present time, it is estimated that approximately 179 000 patients are being maintained on methadone or LAAM at 940 or more sites, and that this number represents only about 20% of all persons with opioid dependence in the USA (Addiction Treatment Forum, 2000). This situation is very unlike that of some other western countries such as Spain and Switzerland where 50% or more of persons with opioid dependence are reported to be on agonist therapy, with substantial numbers of others in residential treatment.

The appropriate dose of agonist medication has been a subject of both federal and state regulations, although there has been a gradual shift toward allowing more clinical judgment in its determination. A number of studies have been done during the last 25 years to determine the optimal dose and, although it is clear that some patients do well on low doses of methadone or LAAM (about 20–50 mg), studies have consistently shown that most individuals need higher doses if they are to achieve maximum benefit from agonist treatment. The results of these comparison studies are generally supportive of the guidelines originally proposed by Dole and Nyswander, who recommended doses in the 80 to 120 mg/day range (Dole and Nyswander, 1968)

Physicians who choose to treat persons with opioid dependence under new regulations will need to notify the Secretary of Health and Human Services in writing of their intent and show that they are qualified to provide addiction treatment by virtue of certification or experience. No physician will be allowed to treat more than 30 patients at one time without special approval according to the proposed legislation. This change in the regulations will be especially important for buprenorphine and the buprenorphine/naloxone combination as it will provide better access to treatment for persons who are unwilling or unable to be treated in the current methadone or LAAM system. The overall intent of the proposed regulatory reform is better to integrate maintenance treatment into the mainstream of medical care, and to make it more available and improve its quality. These changes are likely to influence the ways that buprenorphine is used in opioid addiction treatment.

The greatest advantage of buprenorphine compared with full agonists such as methadone and LAAM is the plateau effect of  $\mu$ -agonist activity. A number of large trials have confirmed the utility of buprenorphine for agonist maintenance therapy. Buprenorphine has the potential to be abused and can produce addiction; however, most persons who abuse buprenorphine initiated opioid use with other drugs.

Buprenorphine, in combination with naloxone, has less potential for abuse than buprenorphine alone. The therapeutic utility of combining naloxone with buprenorphine derives from the low sublingual bioavailability of naloxone as compared with buprenorphine. Parenteral misuse of the combination by persons addicted to opioids would be expected to produce antagonist like effects; thus, most persons with opioid dependence would be unlikely to inject the combination more than once. The use of the buprenorphine/naloxone combination in an office-based setting represents an innovative alternative to the restrictive methadone or LAAM maintenance paradigm and should expand the availability of agonist maintenance treatment with a relatively low risk for abuse or diversion. In addition, the partial agonist activity of buprenorphine results in a much lower risk for overdose death than is the case with methadone or LAAM.

### Antagonist Maintenance

Naltrexone is the prototypical opioid antagonist used in abstinence therapy, blocking the effects of heroin and other opioids through competitive receptor inhibition. Naltrexone has no opioid agonist effects and is a competitive opioid antagonist. It is orally effective and can block opioid effects for 24 hours when administered as a single daily dose of 50 mg; doses of 100 to 150 mg can block opioid effects for 48 to 72 hours. Despite a favorable adverse event profile (nausea is typically the most common side effect), naltrexone is generally not favored by opioid addicts because, unlike opioid agonists and partial agonists, it produces no positive, reinforcing effects. Furthermore, it may be associated with the precipitation of an opioid withdrawal syndrome if used too soon after opioid use stops, an effect that can be minimized by administering a naloxone challenge prior to giving the first dose of naltrexone.

### Psychosocial/Behavioral Treatments

In addition to challenges related to ambivalence about stopping opioid use, patients often have serious problems with nonopioid substance abuse and/or with medical, psychiatric, legal, employment and family/social issues that preexist or result from the addiction. Research has found that addressing these additional problems can be helpful, but is complex and requires coordination between agonist pharmacotherapy staff, and other medical and psychosocial services.

### Individual Drug Counseling

The most common type of psychosocial treatment in opioid agonist maintenance is individual drug counseling. Counselors are typically persons at the masters level or below who deliver a behaviorally focused treatment aimed to identify specific problems, help the patient access services that may not be provided in the clinic (e.g., medical, psychiatric, legal, family/social), stop substance use and improve overall adjustment. Functions that counselors perform include monitoring methadone and LAAM doses and requesting changes when needed, reviewing urine test results, responding to requests for take-home doses, assisting with family problems, responding to crises, writing letters for court or social welfare agencies, recommending inpatient treatment when necessary, and providing support and encouragement for a drug-free lifestyle.

Counseling usually addresses both opioid and nonopioid use. Although nicotine (tobacco) use is not always included, the increased emphasis on adverse health effects of smoking has resulted in more attention to stop smoking at all levels, including drug counseling. Counselors and patients typically have weekly, 30- to 60-minute sessions during the first weeks or months of treatment with reductions in frequency to biweekly or monthly depending on progress. The frequency of counseling can vary widely depending on the severity of the patient's problems, clinic requirements and counselor workload.

The importance of regular counseling was clearly demonstrated in a study by McLellan and coworkers (1993) in which patients were randomly assigned to minimal counseling (one 5- to 10-minute session per month), standard counseling (one 45-minute session per week), or enhanced counseling (standard plus on-site referral to psychiatric, medical and family/social services). Results showed a dose-response relationship with the minimal condition doing significantly worse than standard, and enhanced counseling doing the best overall; however, about 30% of patients did well in the minimal counseling condition. This study clearly demonstrated the positive benefits achieved by drug counseling and showed that, for most patients, counseling is necessary to bring out the maximum benefits from agonist maintenance.

Though most counseling is individual, some programs use group therapy exclusively and others do not use it at all. Most agonist programs that use groups have them only for patients with focal problems such as HIV disease, PTSD, homelessness, or loss of close personal relationships. Many programs encourage patients to participate in self-help groups, but ask them to select a group that accepts persons who are on agonist maintenance treatment. Some programs have self-help groups that meet on site. Counselors, like psychotherapists, can vary widely in the results they achieve. This variability seems more related to the ability to form a positive, helping relationship than to specific techniques.

Contingency management techniques are always included in drug counseling, if only to fulfill regulations about requiring progress in treatment as a condition of providing take-home doses; studies have shown that such contingencies can be helpful. For example, an opportunity to receive take-home medications in return for drug-free urine tests is a powerful and practical motivator for many patients. More flexibility in dispensing take-home doses as contingencies for positive behaviors could be an additionally useful result of the regulatory reforms that were described earlier. Another contingency that is easily applicable and which some programs have used with positive results is requiring a negative alcohol breath test prior to dispensing the daily dose of methadone or LAAM.

Though counseling and other services are effective enhancements of agonist treatment, compliance is often an issue and clinics vary in the way they respond to this problem. Some remind patients of appointments, others do not permit patients to be medicated unless they keep appointments, and others suspend patients who miss appointments. For noncompliant patients, a powerful contingency is requiring certain behaviors for patients to remain on the program, a procedure that is often formalized in a "treatment contract". Here, the patient is given the option of stopping heroin and other drug use, keeping regular counseling appointments, looking for work, or correcting other behaviors that need improvement as a condition for remaining in treatment. Patients who fail are administratively detoxified, suspended for months to years, and referred to another program, although the referrals are not always successful. The long-term effects of this form of contingency management have not been well studied.

## Therapeutic Communities (TCs)

These programs are another approach that has been shown to be useful for treating opioid dependence, especially patients with a long history of addiction and a strong motivation to become drug-free, either as a result of internal processes or from external pressures such as being given the choice of entering prison for a drug-related crime, or getting treatment in a TC. These programs are very selective, self-governing and long-term (6–18 months). They occur in residential settings where patients share responsibilities for maintaining the treatment milieu (cleaning, cooking and leading group therapy). Confrontation of denial and behaviors such as lying and “conning”, combined with group support for healthy, positive change are used to restructure character and the addictive lifestyle. Medications such as methadone, LAAM, or naltrexone are rarely used; however, medications for specific psychiatric or medical conditions are usually available after careful screening and evaluation. Many TCs have large numbers of individuals who have been referred by the criminal justice system including some who have tried but not responded to agonist maintenance on repeated occasions. Though dropout rates are high, studies have shown that over 80% of individuals who complete TCs have a sustained remission and demonstrate significant improvement in psychiatric symptoms, employment and criminal behavior (Inciardi *et al.*, 1997; DeLeon, 1999).

## Addressing Comorbidity

Patients seeking treatment for opioid dependence are typically using one or more other substances (cocaine, alcohol, benzodiazepines, amphetamines, marijuana, nicotine), and have additional problems in the psychiatric, medical, family/social, employment, or legal areas. In fact, it is rare to find a person with only opioid dependence and no other substance use, or without a psychiatric, medical, or family/social problem. The presence of these problems, perhaps with the exception of nicotine dependence, tends to magnify the severity of the opioid dependence and makes the patient even more difficult to treat. An example of a successful treatment of a difficult patient is given in the following clinical vignette.

### Clinical Vignette

A 42-year-old male presented for treatment of opioid dependence; this was his sixth episode of methadone maintenance. The patient had a long history of alcoholism that interfered with treatment in the past and had begun using cocaine regularly. Historically, the patient had done fairly well on methadone as far as illicit opioid use was concerned, but clinic attendance and his ability to comply with clinic rules, especially regarding take-home doses, had been severely compromised by alcohol use. In the past, the patient would remain in treatment for about a year, then become angry over his inability to obtain take-home doses (due to ongoing positive Breathalyzer readings) and drop out of treatment; relapse to opioid use always immediately followed. During previous treatment episodes, the patient had frequently been offered inpatient detoxification for alcoholism but always refused because 1) “alcohol was not his problem, heroin was the problem” and 2) he could not take time off work (as a stockperson in a liquor store).

When the patient presented for treatment this time, he had severe social stressors; was unemployed (secondary to his alcohol problems) and living with his parents, who were threatening to put him out because of drug use.

The patient was told that, this time, methadone would not be offered unless he first entered the hospital. After some discussion, he agreed that as part of his treatment plan he would first enter the hospital for 21 to 28 days of treatment including alcohol detoxification and stabilization on methadone; he would then be discharged to maintenance therapy. This approach worked. After inpatient discharge, the patient kept regular counseling appointments, continued to attend self-help meetings to which he had been introduced while on the inpatient unit, “requested” daily Breathalyzer testing, and turned down an offer to return to his job in the liquor store. Over the past 3 years, his liver function tests returned to normal levels, he was stable on 65 mg of methadone/day with urine tests negative for opioids, although occasionally his urine was positive for cocaine. He was able to comply fully with a treatment regimen for a back injury sustained 2 years ago and currently enrolled in school.

## Psychiatric

Among the psychiatric disorders seen in persons with opioid dependence, antisocial personality disorder is one of the most common. Diagnostic studies of persons with opioid dependence have typically found rates of antisocial personality disorder ranging from 20 to 50%, as compared with less than 5% in the general population. PTSD is also seen with increased frequency.

Opioid dependent persons are especially at risk for the development of brief depressive symptoms, and for episodes of mild to moderate depression that meet symptomatic and duration criteria for major depressive disorder or dysthymia. These syndromes represent both substance-induced mood disorders as well as independent depressive illnesses. Brief periods of depression are especially common during chronic intoxication or withdrawal, or in association with psychosocial stressors that are related to the dependence. Insomnia is common, especially during withdrawal; sexual dysfunction, especially impotence, is common during intoxication. Delirium or brief, psychotic-like symptoms are occasionally seen during opioid intoxication.

The data on psychiatric comorbidity among opioid addicts and its negative effect on outcome have stimulated research on the effect of combining psychiatric and substance abuse treatment. Studies have shown that tricyclic antidepressants can be useful for chronically depressed opioid dependent persons who are treated with methadone maintenance and that professional psychotherapy can be useful for psychiatrically impaired, methadone-maintained opioid addicts. The main result in most pharmacotherapy and psychotherapy studies with methadone-maintained addicts has usually been a reduction in psychiatric symptoms such as depression, although some have shown reductions in substance use as well.

Less than 5% of persons with opioid dependence have psychotic disorders such as bipolar illness or schizophrenia; however, these patients can present special problems since programs typically have few psychiatric staff. As a result, these patients are sometimes excluded from methadone treatment because they

cannot be effectively managed within the constraints of the available resources. Others are treated with methadone, counseling and the same medications used for nonaddicted patients with similar disorders. Women with opioid dependence can present special challenges because many have been sexually abused as children, have other psychiatric disorders, and are involved in difficult family/social situations. Abusive relationships with addicted males are common, sometimes characterized by situations in which the male exerts control by providing drugs. These complex psychiatric and relationship issues have emphasized the need for comprehensive psychosocial services that include psychiatric assessment and treatment, and access to other medical, family and social services.

## Medical

Medical comorbidity is a major problem among persons with opioid dependence; HIV infection, AIDS, and hepatitis B and C have become some of the most common problems. Sharing injection equipment including “cookers” and rinse water, or engaging in high-risk sexual behaviors are the main routes of infection. Sexual transmission appears to be a more common route of HIV transmission among females than males because the HIV virus is spread more readily from males to females than from females to males. Females who are intravenous drug users and also engage in prostitution or other forms of high-risk sex are at extremely high risk for HIV infection. Cocaine use has been found to be a significant risk factor as a single drug of abuse or when used in combination with heroin or other opioids (Booth *et al.*, 2000).

Recent studies have identified several important interactions between methadone and drugs to treat HIV. One important interaction is that methadone increases plasma levels of zidovudine; the associated symptoms resemble methadone withdrawal. There have been instances in which methadone doses have been increased in response to complaints of withdrawal with increasing doses compounding the problem. Another important interaction involves decreased methadone blood levels secondary to nevirapine that may result in mild to moderate withdrawal. This interaction can be important if the patient is taken off either of these two drugs while on methadone, since the result may be a sudden rise in methadone blood levels with signs and symptoms of over medication.

As mentioned earlier, mortality is high and studies have found annual death rates of approximately 10 per 1000 or greater, which is substantially higher than demographically matched samples in the general population (Gronbladh *et al.*, 1990). Common causes of death are overdose, accidents, injuries, and medical complications such as cellulitis, hepatitis, AIDS, tuberculosis and endocarditis. The cocaine and alcohol dependence that is often seen among opioid-dependent persons contributes to cirrhosis, cardiomyopathy, myocardial infarction and cardiac arrhythmias. Tuberculosis has become a particularly serious problem among intravenous drug users, especially heroin addicts. In most cases, infection is asymptomatic and evident only by the presence of a positive tuberculin skin test. However, many cases of active tuberculosis have been found, especially among those who are infected with HIV.

Other medical complications of heroin dependence are seen in children born to opioid-dependent women. Perhaps the most serious is premature delivery and low birthweight, a problem that can be reduced if the mother is on methadone maintenance and receiving prenatal care. Another is physiological dependence on opioids, seen in about half the infants born to women maintained

on methadone or dependent on heroin or other opioids. Effective treatments for neonatal withdrawal are available and long-term adverse effects of opioid withdrawal have not been demonstrated. A recent study found that methadone is present in the breast milk of women maintained on doses as high as 180 mg but that the concentration is very low and no adverse effects were observed in the infants (McCarthy and Posey, 2000). HIV infection is seen in about one-third of infants born to HIV-positive mothers, but can be reduced to about 10% if HIV-positive pregnant women are given zidovudine prior to delivery. HIV can also be transmitted by breast-feeding, and thus formula is recommended for HIV-positive mothers with the exception of countries where it is unavailable or unaffordable. Thorough washing of infants born to HIV-infected mothers immediately after delivery also appears to reduce the incidence of HIV infection.

## Integrated Treatment

The comorbidity data have led to research that has demonstrated the positive effects of integrating psychiatric and medical care within agonist and other substance abuse treatment programs. Clinical experience and National Institute on Drug Abuse demonstration projects have shown that integration of these services can be done, and with very positive results since patients are seen frequently and treatment retention is high (Umbricht-Schneiter *et al.*, 1994). Related to this line of research are studies that have shown improved compliance with directly observed antituberculosis pharmacotherapy. These findings have important implications for tuberculosis control policies in methadone programs since intravenous drug users are at very high risk for tuberculosis infection and because maintenance programs provide settings in which directly observed therapy can be easily applied. Similar principles apply to administration of psychotropic medication in noncompliant patients with schizophrenia or other major Axis I disorders.

## Harm Reduction

Harm reduction is concerned with minimizing various negative consequences of addiction. As such, the focus is shifted away from drug use to the consequences of use and its attendant behaviors. Examples of harm reduction include needle exchange programs, efforts directed at reducing drug-use-associated behaviors that may result in the transmission of HIV, and making changes in policies (including increasing treatment availability) that reduce heroin use and the criminal behavior associated with drug procurement. Harm reduction refers not only to reducing harm to the individual addict, but also to family, friends and to society generally. A number of authors have identified the limitations of harm reduction when it is used as a sole strategy to combat the adverse effects of addiction.

With regard to opioids, much of the health-related harm from their improper or illicit use is secondary to elements other than the substances themselves. Sequelae from unhygienic methods of administration and poor injection technique are typically more serious than the constipation or other side effects of the drugs themselves, acute overdoses notwithstanding. At current levels of use, greater harm is expected to result from the use of alcohol and tobacco than from opioids. With regard to opioid addiction treatment, medications such as methadone, LAAM and buprenorphine, among others (including supervised heroin substitution) used for maintenance agonist treatment, may be considered harm-reduction measures.

## Comparison of DSM-IV/ICD-10 Diagnostic Criteria

The DSM-IV-TR and ICD-10 criteria sets for opioid intoxication are almost the same. The DSM-IV-TR and ICD-10 symptom lists for opioid withdrawal include some different items: the ICD-10 list has craving, abdominal cramps and tachycardia and does not include the fever and dysphoric mood items from the DSM-IV-TR criteria set.

# Substance Abuse: Sedative, Hypnotic, or Anxiolytic Use Disorders

Sedative–hypnotics and anxiolytics include prescription sleeping medications and most medications used for the treatment of anxiety. Pharmacologically alcohol is appropriately included among sedative–hypnotics; however, it is generally considered separately as it is in DSM-IV-TR (American Psychiatric Association, 2000). The medications usually included in the category of sedative–hypnotics are listed in Table 44.1.

Sedative–hypnotics are among the most commonly prescribed medications. They are also often misused and abused and can produce severe, life-threatening dependence. With the exception of the benzodiazepines and newer hypnotics (e.g., eszopiclone, zaleplon, zopiclone and zolpidem), overdose with sedative–hypnotics can be lethal. Benzodiazepines and the newer hypnotics are rarely lethal if taken alone; in combination with alcohol or other drugs, however, they can be lethal.

When the benzodiazepines were introduced into clinical medicine in the early 1960s, their lack of lethality in overdose led physicians to believe that they were without harmful effects. Over time, it was recognized that the benzodiazepines could produce severe physiological dependence and could be drugs of abuse. Nonetheless, their medical utility in treatment of disabling anxiety, episodic sleep disturbances and seizures has made them indispensable to medical practice.

Considerations of sedative–hypnotic use disorders should reflect a sensible balance between their medical utility, side effects, and abuse and dependence. Some abuse and dependence that inevitably occur must be accepted to keep them available in clinical practice.

## Substance-related Disorders of Sedative–Hypnotics

The term “misuse” is commonly applied to prescription sedative–hypnotics, but the DSM-IV-TR does not provide explicit criteria for misuse as it does for abuse and dependence. When medications are taken in higher doses or more frequently than prescribed, or by someone other than the person for whom the medication was prescribed, or for reasons other than what would normally be considered medical use, the behavior is generally considered misuse of the medication.

DSM-IV-TR defines abuse and dependence in terms of behavioral and physiological consequences to the person taking the

medication. The criteria for abuse and dependence are intended to apply as uniformly as possible across classes of drugs, and the criteria do not distinguish the source of the medication or the intended purpose for which it was taken. Further, when most people, including physicians speak of drug dependence, they are referring to physical dependence. DSM-IV-TR uses the term dependence to denote a more severe form of substance use disorder than abuse, and it uses the specifier “with or without physiological dependence” to indicate whether the patient has significant physical dependence. Physiological dependence is not necessarily required for a diagnosis of drug dependence. A diagnosis of substance dependence is made only when a patient has dysfunctional behaviors that are a result of the drug use.

The qualification that the dysfunctional behavior is the “result” of drug use is extremely important, and observation of the patient over time in a medication-free state may be necessary to determine which is driving which. The patient, the patient’s family members and the treating psychiatrist may disagree about what is causing symptoms or behavioral dysfunction. Likewise, the underlying motivation for “drug-seeking” behavior may vary. For example, a patient whose panic attacks are ameliorated by a medication may exhibit what may be interpreted as drug-seeking behavior if access to the medication is threatened. The terms **anxiolytic** and **minor tranquilizer** are also frequently sources of confusion. In classic pharmacology sedative–hypnotics are drugs or medications that produce a dose-related depression of consciousness. Drug classes are formed by combining drugs or medications that have similar pharmacological profiles.

## Etiology and Pathophysiology

### Sedative–Hypnotics and GABA Receptors

Many neurons in the central nervous system (CNS) have receptors for the neurotransmitter gamma-aminobutyric acid (GABA). Benzodiazepines attach to receptors that are allosteric to the GABA<sub>A</sub> receptor, that is, occupancy of the benzodiazepine receptor potentiates GABA at the GABA<sub>A</sub> receptor. The molecular pharmacology of the receptor is exceedingly complex. Chronic exposure to benzodiazepines may uncouple the benzodiazepine receptor from the GABA<sub>A</sub> receptor. The uncoupling may explain in part why over time benzodiazepines appear to become less

**Table 44.1 Medications Usually Included in the Category of Sedative–Hypnotics**

Generic Name	Trade Names	Common Therapeutic Use	Therapeutic Dose Range (mg/d)
<i>Barbiturates</i>			
Amobarbital	Amytal	Sedative	50–150
Butobarbital	Butisol	Sedative	45–120
Butalbital	Fiorinal, Sedapap	Sedative/analgesic	100–300
Pentobarbital	Nembutal	Hypnotic	50–100
Secobarbital	Seconal	Hypnotic	50–100
<i>Benzodiazepines</i>			
Alprazolam	Xanax	Antianxiety	0.75–6
Chlordiazepoxide	Librium	Antianxiety	15–100
Clonazepam	Klonopin	Anticonvulsant	0.5–4
Clorazepate	Tranxene	Antianxiety	15–60
Diazepam	Valium	Antianxiety	5–40
Estazolam	ProSom	Hypnotic	1–2
Flunitrazepam	Rohypnol*	Hypnotic	1–2
Flurazepam	Dalmane	Hypnotic	15–30
Halazepam	Paxipam	Antianxiety	60–160
Lorazepam	Ativan	Antianxiety	1–16
Midazolam	Versed	Anesthesia	–
Oxazepam	Serax	Antianxiety	10–120
Prazepam	Centrax	Antianxiety	20–60
Quazepam	Doral	Hypnotic	15
Temazepam	Restoril	Hypnotic	7.5–30
Triazolam	Halcion	Hypnotic	0.125–0.5
<i>Others</i>			
Chloral hydrate	Noctec, Somnos	Hypnotic	250–1000
Eszopiclone	Lunesta	Hypnotic	1–3
Ethchlorvynol	Placidyl	Hypnotic	200–1000
Glutethimide	Doriden	Hypnotic	250–500
Meprobamate	Miltown, Equanil, Equagesic	Antianxiety	1200–1600
Methyprylon	Noludar	Hypnotic	200–400
Zaleplon	Sonata, (Stilnox, other countries)	Hypnotic	5–20
Zolpidem	Ambien	Hypnotic	5–10

\*Rohypnol is not marketed in the USA.

effective in controlling symptoms in some patients, which give them an impetus to increase dosage.

## Epidemiology

The prevalence of sedative–hypnotic disorders is not known with precision. Unlike most drugs of abuse (e.g., cocaine or heroin) that are manufactured in clandestine laboratories and distributed through the street-drug black markets, sedative–hypnotics are exclusively manufactured by pharmaceutical companies. Sedative–hypnotics that are used and abused by addicts are obtained either from the black market, where they have been diverted from medical channels, or from physicians and pharmacies under treatment subterfuge. Drug dependence may arise as an inadvertent consequence of medical treatment or through patient’s self-administration of sedative–hypnotics obtained from illicit sources or sequential visits to different physicians. By some indicators, tranquilizer and sedative–hypnotic use is increasing.

Insomnia and anxiety disorders are common and sedative–hypnotics are among the most commonly prescribed medications worldwide. Sedative–hypnotic abuse and dependence disorders are common, but involve only a small percentage of the people

who use these medications. Most people do not find the subjective effects of sedative–hypnotics pleasant or appealing beyond their therapeutic effects (e.g., relief of anxiety or facilitation of sleep). Many addicts, on the other hand, have a subjectively different response to sedative–hypnotics and like the subjective effects of sedative–hypnotics. The qualitative difference in subjective response to medications by addicts is one extremely important factor in understanding why medications that are safe and efficacious for nonaddicts cannot be safely prescribed for addicts. In addition, addicts may take doses of medications far in excess of recommended dosage, take them by injection or means other than prescribed (e.g., dissolving tablets and injecting them, crushing tablets and snorting them), or take them in combination with other prescription medications or street drugs such as heroin or cocaine that are extremely likely to produce adverse consequences.

## Patterns of Abuse

Some sedative–hypnotics, such as the short-acting barbiturates, are primary drugs of abuse, that is, they are injected for the “rush” or are taken orally to produce a state of disinhibition similar to that achieved with alcohol. Sedative hypnotics may also be taken

in combination with other primary intoxicants, such as alcohol or heroin, to intensify the desired subjective effects.

Drug addicts may also use sedative–hypnotics to self-medicate withdrawal of drugs such as heroin. When the avowed intent is to stop the use of drugs such as heroin, physicians may be lured into thinking that addicts' self-administration of sedative–hypnotics is not “abuse” but rather a reasonable approximation of medical use. While on occasion this may be the case, often it is not. Addicts' episodic attempts to stop using heroin by self-medicating opiate withdrawal symptoms with sedative–hypnotics without entering drug abuse treatment is rarely successful, and may result in the secondary development of sedative–hypnotic dependence.

Addicts may also use sedative–hypnotics to reduce unpleasant side effects of stimulants, particularly cocaine or methamphetamine. Impairment of judgment and memory produced by the sedative–hypnotic in combination with wakefulness of a stimulant may result in unpredictable behavior.

### Barbiturates

Injection of a barbiturate is associated with the usual infectious risk of injecting street drugs, but the barbiturates are particularly pernicious if inadvertently injected into an artery or if the solution is injected or leaked from a vein or artery into tissue surrounding the vessel. Barbiturates are irritating to tissue, and the affected tissue becomes indurated and may abscess. In addition, barbiturate solution injected into an artery produces intense vasoconstriction and blockage of the arterioles, resulting in gangrene of areas supplied by the artery.

### Methaqualone

Methaqualone (Quaalude) was removed from the US market in 1984 because of its abuse. Subsequently, it has continued to be sold on the street-drug black market. Some tablets sold on the black market as Quaalude contain methaqualone, apparently diverted from countries where methaqualone is still available; others contain diazepam, phenobarbital, or another sedative–hypnotic.

### Benzodiazepines

Benzodiazepines are often used or misused by addicts to self-medicate opiate withdrawal, to intensify the CNS effects of methadone, or to ameliorate the adverse effects of cocaine or methamphetamine.

The benzodiazepine, flunitrazepam (Rohypnol, Narcozep), is singled out for additional discussion in this chapter on benzodiazepine abuse because of the media and legislative attention it received during the 1990s, and because it is still widely abused in Europe and other areas of the world. Flunitrazepam, a potent benzodiazepine hypnotic, was never marketed in the USA but is widely available by prescription in many other countries in 1- or 2-mg oral dosage forms and for injection.

Flunitrazepam has many street names, including rophies, ropies, roopies, roofies, ruffes, rofinol, loops and wheels. Tablets of Rohypnol have the name of the manufacturer Roche engraved on them and a number indicating the milligram strength (either 1 or 2). Drug abusers usually prefer the 2-mg tablets, which are often called “Roche dos” or just “Roche” (usually pronounced “row-shay”). Although flunitrazepam is similar in many respects to other benzodiazepines in abuse potential flunitrazepam is among the benzodiazepines with highest abuse potential and has considerable appeal among heroin addicts.

In the mid-1990s Rohypnol achieved notoriety as the “date-rape drug”. Because of the media attention, considerable public debate ensued and the US Congress was prompted to pass

legislation increasing penalties for rape when Rohypnol or other drugs were used to facilitate it. Subsequently, GHB (gamma-hydroxybutyric acid), which has some properties of a sedative–hypnotic, was also called a “date-rape drug.”

Flunitrazepam and other benzodiazepines have also been associated with deaths among opiate addicts taking buprenorphine. Although buprenorphine alone or benzodiazepines alone are rarely fatal, the combination appears to increase the risk of overdose. Benzodiazepines and buprenorphine may have synergistic action in suppressing respiration.

### Zolpidem

Zolpidem (Ambien) is an imidazopyridine hypnotic, chemically unrelated to the benzodiazepines. However, it binds to a subunit of the same GABA–benzodiazepine complex as the benzodiazepines and its sedative effects are reversed by the benzodiazepine antagonist flumazenil.

A few case reports of abuse suggest that some patients increase the dosage many times above what is prescribed and that zolpidem produces a withdrawal syndrome similar to that of other sedative–hypnotics (Aragona, 2000). The case histories also describe significant tolerance to the sedative effects of zolpidem.

Zolpidem is rapidly absorbed and has a short half-life (2.2 hours). Its sedative effects are additive with alcohol. Like triazolam, zolpidem decreases brain metabolism of glucose. In addition to dependence, zolpidem has produced idiosyncratic psychotic reactions.

### Zaleplon

Like zolpidem, this drug is chemically unrelated to the benzodiazepines and binds to the omega-1 receptor, which is a subunit of the GABA-benzodiazepine receptor. Studies in volunteers with a history of drug abuse suggest abuse potential similar to triazolam. Peak plasma concentration occurs about 1 hour following oral ingestion. It is rapidly metabolized with a half-life of about 1 hour. Impairment of short-term memory may occur at dosages of 10 to 20 mg.

### Acute Intoxication with Sedative–Hypnotics

The acute toxicity of sedative–hypnotics consists of slurred speech, incoordination, ataxia, sustained nystagmus, impaired judgment and mood lability. When taken in large amounts sedative–hypnotics produce progressive respiratory depression and coma. The amount of respiratory depression produced by the benzodiazepines is much less than that produced by the barbiturates and other sedative–hypnotics. Consistent with its general approach, the DSM-IV-TR diagnosis of intoxication requires “clinically significant maladaptive behavioral or psychological changes” developing after drug use in addition to the signs and symptoms of acute toxicity.

### Dependence

Sedative–hypnotics can produce tolerance and physiological dependence. Physiological dependence can be induced within several days with continuous infusion of anesthetic doses. Patients who are taking barbiturates daily, for example, for a month or more above the upper therapeutic range listed in Table 44.1 should be presumed to be physically dependent and in need of medically managed detoxification.

### Withdrawal Syndrome

The withdrawal syndrome arising from the discontinuation of short-acting sedative–hypnotics is similar to that from stopping

or cutting down on the use of alcohol. Signs and symptoms of sedative–hypnotic withdrawal include anxiety, tremors, nightmares, insomnia, anorexia, nausea, vomiting, postural hypotension, seizures, delirium and hyperpyrexia. The syndrome is qualitatively similar for all sedative–hypnotics; however, the time course of symptoms depends on the particular drug. With short-acting sedative–hypnotics (e.g., pentobarbital, secobarbital, meprobamate, oxazepam, alprazolam and triazolam), withdrawal symptoms typically begin 12 to 24 hours after the last dose and peak in intensity between 24 and 72 hours (symptoms may develop more slowly in patients with liver disease or in the elderly because of decreased drug metabolism). With long-acting drugs (e.g., phenobarbital, diazepam and chlorthalidone), withdrawal symptoms peak on the fifth to eighth day. The withdrawal delirium may include confusion, visual and auditory hallucinations. The delirium generally follows a period of insomnia. Some patients may have only delirium; others only seizures; and some may have both delirium and convulsions.

### **Iatrogenic Dependence**

Patients treated for months to years with benzodiazepines and other sedative–hypnotics may become physically dependent on sedative–hypnotics. The possibility of physical dependence should be discussed with the patient and, in some cases, the patient's family. The distinction between physical dependence as a process of neuroadaptation and physical dependence as a component of a substance-use disorder should be explained in detail. Patients need to be advised against abruptly stopping the medication because of the possibility of developing severe withdrawal symptoms, including seizures.

### **Diagnosis and Differential Diagnosis**

The diagnosis of sedative–hypnotic abuse and dependence is based primarily on drug-use history and the DSM-IV-TR criteria of continuing behavior dysfunction caused by the drug. With dependence developing from prescribed use, the practical difficulty is determining when the dysfunction is a result of the drug use rather than the disorder for which the medication was prescribed.

### **Phenomenology and Variations in Presentations**

Long-term use of benzodiazepines can result in physical dependence in nondrug-dependent medical patients. Withdrawal symptoms “or” return of symptoms suppressed by the benzodiazepines may make discontinuation difficult.

Some patients who are physically dependent on or unable to discontinue a medication do not necessarily have a substance-use disorder. Physical dependence results from neuroadaptive changes resulting from long-term exposure to a medication. Inability to discontinue the medication may simply mean that patients are unwilling to tolerate the severity of postwithdrawal symptoms that develop. In the absence of medication-produced dysfunction, the continuation of the medication may be an appropriate choice. Patients who do not have a substance-use disorder take medications in the quantity prescribed. They follow their physicians' recommendations, and they do not mix them with drugs of abuse.

Abusers of alcohol and other drugs rarely present for primary treatment of sedative–hypnotic dependency. From the

drug-abusing patient's point of view, sedative–hypnotic use is an effort to self-medicate anxiety or insomnia, which is often the result of alcohol or stimulant abuse.

## **Assessment**

### **Drug Use History**

The patient's drug use history is usually the first source of information that is used in assessing sedative–hypnotic abuse or dependence. If the sedative–hypnotics were being used for treatment of insomnia or anxiety, the history is often best obtained as part of the history of the primary disorder and its response to treatment. A detailed history of use of all sedative–hypnotics, including alcohol, should be elicited from the patient. When framed in terms of the presenting disorder, patients are generally more candid about their drug use and their relationship with past treating physicians.

For many reasons, patients may minimize or exaggerate their drug use and not accurately report the behavioral consequences of their use. High doses of benzodiazepines or therapeutic doses of benzodiazepines in combination with alcohol may disrupt memory. Patients are likely to attribute impairment of function to the underlying disorder rather than to the medication use. Observations of patients' behavior by family members can be a source of valuable information. Whenever possible, the patient's history should be supplemented by medical and pharmacy records to help piece together as accurate a picture of drug use as possible. Pharmacy records may be helpful in establishing and verifying patient's drug use history, and urine testing can be useful in verifying recent drug use history.

Patients who are obtaining some or all of their medication from street sources may not know what they have been taking, as deception in the street-drug marketplace is common. For example, tablets sold as methaqualone have been found to contain phenobarbital or diazepam.

### **Physical Findings**

Sustained horizontal nystagmus is a reliable indicator of sedative–hypnotic intoxication. Onset of tremor, abnormal sweating and blood pressure or pulse increase may be produced by sedative–hypnotic withdrawal.

### **Laboratory Tests**

Urine toxicology can be useful in monitoring patients' use of drugs and in confirming a history of drug or medication use. The detection time varies widely for benzodiazepines. Diazepam or chlorthalidone may be detected for weeks following chronic or high-dose use, whereas others, such as alprazolam or clonazepam, may not be detectable in routine toxicology urinalysis. Because of the variability in laboratory cutoffs and detection time and different drugs included in the screening panel, the analytical laboratory should be asked about what they routinely screen for and the detection limits.

### **Course and Natural History**

Once a diagnosis of sedative–hypnotic dependence is manifested it is unlikely that a patient will be able to return to controlled, therapeutic use of sedative–hypnotics. All sedative–hypnotics, including alcohol, are cross-tolerant, and physical dependence

and tolerance are quickly re-established if a patient resumes use of sedative-hypnotics.

If after sedative-hypnotic withdrawal the patient has another primarily psychiatric disorder, such as generalized anxiety disorder (GAD), panic attacks, or insomnia, alternate treatment strategies other than sedative-hypnotics should be used if possible. Definitive diagnosis of a psychiatric disorder during early abstinence is often not possible because protracted withdrawal symptoms may mimic anxiety disorders, and disruption of sleep architecture for days to months after drug withdrawal is extremely common.

If the sedative-hypnotic dependence has developed secondary to stimulant or alcohol use, primary treatment of the chemical dependence should be a priority. Often the symptom that was driving the sedative-hypnotic use disappears after the patient is drug abstinent.

### Detoxification

Three general strategies are used for withdrawing patients from sedative-hypnotics, including benzodiazepines. The first is to use decreasing doses of the agent of dependence. The second is to substitute phenobarbital or some other long-acting barbiturate for the addicting agent, and gradually withdraw the substitute medication. The third, used for patients with a dependence on both alcohol and a benzodiazepine, is to substitute a long-acting benzodiazepine, such as chlordiazepoxide, and taper it during 1 to 2 weeks.

The pharmacological rationale for phenobarbital substitution is that phenobarbital is long-acting and little change in blood levels of phenobarbital occurs between doses. This allows the safe use of a progressively smaller daily dose. Phenobarbital is safer than the shorter-acting barbiturates; lethal doses of phenobarbital are many times higher than toxic doses, and the signs of toxicity (e.g., sustained nystagmus, slurred speech and ataxia) are easy to observe. Finally, phenobarbital intoxication usually does not produce euphoria or behavioral disinhibition, so most patients view it as a medication, not as a drug of abuse.

The withdrawal strategy selected depends on the particular benzodiazepine, the involvement of other drugs of dependence, and the clinical setting in which the detoxification program takes place. The gradual reduction of the benzodiazepine of dependence is used primarily in medical settings for dependence arising from treatment of an underlying condition. The patient must be cooperative, must be able to adhere to dosing regimens, and must not be abusing alcohol or other drugs.

Substitution of phenobarbital can also be used to withdraw patients who have lost control of their benzodiazepine use or who are polydrug-dependent. Phenobarbital substitution has the broadest use for all sedative-hypnotic drug dependencies and is widely used in drug treatment programs.

### Stabilization Phase

The patient's history of drug use during the month before treatment is used to compute the stabilization dose of phenobarbital. Although many addicts exaggerate the number of pills they are taking, the patient's history is the best guide to initiating pharmacotherapy for withdrawal. Patients who have overstated the amount of drug that they have taken will become intoxicated during the first day or two of treatment. Intoxication is easily managed by omitting one or more doses of phenobarbital and reducing the daily dose.

To compute the initial daily starting dose of phenobarbital, the patient's average daily use of each sedative-hypnotic is estimated. Next, the patient's average daily sedative-hypnotic dose for each drug is converted to its phenobarbital withdrawal equivalent by multiplying the average daily dose by the drug's phenobarbital conversion constant shown in either Table 44.2 or 44.3. Finally, the phenobarbital withdrawal equivalences for each drug are added together. In any case, the maximum daily phenobarbital dose is limited to 500 mg/day. The total daily amount of phenobarbital is divided into three doses per day.

Before receiving each dose of phenobarbital, the patient is checked for signs of phenobarbital toxicity: sustained nystagmus, slurred speech, or ataxia. Of these, sustained nystagmus is

**Table 44.2 Phenobarbital Withdrawal Equivalents of Nonbenzodiazepines**

Generic Name	Trade Name	Dose Equal to 30 mg of Phenobarbital for Withdrawal* (mg)	Phenobarbital Conversion Constant
<i>Barbiturates</i>			
Amobarbital	Amytal	100	0.33
Butobarbital	Butisol	100	0.33

Pentobarbital	Nembutal	100	0.33
Secobarbital	Seconal	100	0.33
<i>Others</i>			
Chloral hydrate	Noctec, Somnos	500	0.06
Ethchlorvynol	Placidyl	500	0.06
Glutethimide	Doriden	250	0.12
Meprobamate	Miltown	1200	0.025
Methyprylon	Noludar	200	0.15
Zaleplon	Sonata	10	3
Zolpidem	Ambien	5	6

\*Phenobarbital withdrawal conversion equivalence is not the same as therapeutic dose equivalence.

†Butalbital is in combination with opiate or nonopiate analgesics.

**Table 44.3 Phenobarbital Withdrawal Equivalents of Benzodiazepines**

Generic Name	Trade Name	Dose Equal to 30 mg of Phenobarbital for Withdrawal* (mg)	Phenobarbital Conversion Constant
Alprazolam	Xanax	1	30
Chlordiazepoxide	Librium	25	1.2
Clonazepam	Klonopin	2	15
Clorazepate	Tranxene	7.5	4
Diazepam	Valium	10	3
Estazolam	ProSom	1	30
Flurazepam	Dalmane	15	2
Halazepam	Paxipam	40	0.75
Lorazepam	Ativan	2	15
Oxazepam	Serax	10	3
Prazepam	Centrax	10	3
Quazepam	Doral	15	2
Temazepam	Restoril	15	2
Triazolam	Halcion	0.25	120

\*Phenobarbital withdrawal conversion equivalence is not the same as therapeutic dose equivalence.

the most reliable. If nystagmus is present, the scheduled dose of phenobarbital is withheld. If all three signs are present the next two doses of phenobarbital are withheld, and the daily dosage of phenobarbital for the next day is halved.

If the patient is in acute withdrawal and has had, or is in danger of having withdrawal seizures, the initial dose of phenobarbital is administered by intramuscular injection. If nystagmus and other signs of intoxication develop after 1 to 2 hours after the intramuscular dose, the patient is in no immediate danger from barbiturate withdrawal. Patients are maintained with the initial dosing schedule of phenobarbital for 2 days. If the patient has neither signs of withdrawal nor phenobarbital toxicity (slurred speech, nystagmus, unsteady gait) phenobarbital withdrawal is begun.

### Withdrawal Phase

Unless the patient develops signs and symptoms of phenobarbital toxicity or sedative–hypnotic withdrawal, phenobarbital is decreased by 30 mg/day. Should signs of phenobarbital toxicity develop during withdrawal, the daily phenobarbital dose is decreased by 50% and the 30 mg/day withdrawal is continued from the reduced phenobarbital dose. Should the patient have objective signs of sedative–hypnotic withdrawal, the daily dose is increased by 50% and the patient is restabilized before continuing the withdrawal.

### Psychotherapy

The self-medication model, even if accurate in a particular case, is not a good one because once drug abuse or dependence becomes established the drug use takes on a life of its own regardless of the underlying reason for initiation. Rarely is treatment with insight-oriented psychotherapy successful in stopping the drug use. During early recovery, most patients are coping with subtle withdrawal symptoms, repairing relationships and learning to function without reliance on psychoactive drugs. Patients with underlying psychiatric disorders may have the additional burden of emergence of symptoms that had been ameliorated by their drug use. Psychotherapy during early recovery should be supportive and focused on coping with current life difficulties. Psychotherapists should remain vigilant for symptoms of panic

attacks, generalized anxiety, depression, or sleep disturbances that interfere with current function and should initiate appropriate psychopharmacological or somatic treatments when appropriate.

Psychotherapy can, however, have an important role in motivating a patient for primary treatment of drug dependency. Therapists can help break down patients' denial of their drug dependence by helping them see how drug use is interfering with relationships and undermining their ability to function. In some instances, it is desirable to continue the psychotherapeutic relationship while the patient is undergoing treatment for chemical dependence. With drug abusers, it is often desirable to separate the medication management from psychotherapy to prevent the psychotherapy from becoming bogged down in discussions of medications and medication side effects.

### Twelve-step Recovery

Alcoholics Anonymous, Narcotics Anonymous and Cocaine Anonymous groups are important treatment adjuncts for many people recovering from alcohol and other forms of drug dependence. Although many groups are becoming more tolerant of appropriate use of pharmacotherapies, many individuals who attend 12-step recovery meetings are adamantly opposed to any form of psychotropic medication use and counsel fellow members to stop their use. Strong opposition to medications is usually based on their own or friends' bad experience with medications. Some individuals recover without medications and believe that recovery is of better quality if not supported by a pharmacological crutch.

Patients with underlying psychiatric disorders and the need for treatment with psychopharmacotherapeutic medications often require ongoing support from their psychotherapist if they must have medication.

### Additional Treatment Considerations

#### Psychiatric Comorbidity

Most patients who are being prescribed long-term benzodiazepine therapy have underlying major depressive disorder, panic disorder,

### Clinical Vignette

A 33-year-old woman was referred by her internist for treatment of alcohol dependence after an overdose of alprazolam (Xanax) and alcohol. The patient had ingested about 30 tablets of alprazolam (2 mg) and a bottle of wine after an argument with her husband. The patient and her husband were in the process of an acrimonious separation, and during the 3 months before her hospitalization, the patient had increased her alcohol consumption to 1.5 bottles of wine each night. The patient stated that she had wanted to die and that she had heard that the combination of alprazolam and alcohol was lethal. She had not previously made a suicide attempt; however, she was under the ongoing care of a psychiatrist because of panic attacks. A previous psychiatrist had started the patient with alprazolam about 6 years before the overdose. Before she had started alprazolam, the panic attacks had become disabling. While she was taking 4 mg/day of alprazolam, the panic attacks became infrequent, and when they occurred were much attenuated. She had resumed employment as a travel agent. Her usual alcohol consumption consisted of one or, at the most, two glasses of wine with the evening meal. Until the overdose, she took alprazolam exactly as prescribed, 2 mg twice a day at the same time each day. Her psychiatrist verified that her refills were consistent with her history. The patient was frightened by having overdosed and acknowledged that her alcohol use was excessive and that she needed treatment; however, she did not want to discontinue alprazolam because she feared return of the panic attacks.

### Discussion

This patient presents a challenging clinical situation, often referred to in the chemical dependence treatment field as dual diagnosis: a major psychiatric disorder and chemical dependence. Alcohol and drug treatment programs generally want patients to discontinue all psychoactive medications when they enter treatment. Chemical dependence treatment staffs often observe that alcohol-abusing patients increase their use of prescription medication when they stop drinking.

Because the patient's panic attacks had been disabling, and because the alcohol abuse seemed a response to an acute situational stress, the patient began outpatient (4 nights/week) chemical dependence treatment, she and her husband began couples therapy, and the patient increased the frequency of visits with her psychiatrist. With the increased support, the patient completed the separation from her husband, remained abstinent from alcohol, and remained on a carefully monitored dose of alprazolam.

or GAD. The clinical dilemma is deciding which patients are receiving appropriate maintenance therapy for a chronic psychiatric condition. Physical dependence on benzodiazepines may be acceptable if the patient's disabling anxiety symptoms are ameliorated. The reason for the patient's request for benzodiazepine withdrawal from long-term, stable dosing should be carefully explored. Valid reasons to discontinue benzodiazepine treatment include: 1) breakthrough of symptoms that were previously well controlled; 2) impairment of memory or other

neurocognitive functions; and 3) abuse of alcohol, cocaine, or other medications.

Patients with severe underlying psychiatric disorders may have unrealistic hopes of becoming medication-free. Often the origin of request for benzodiazepine withdrawal comes from concerned friends or relatives.

### Abuse Potential of Benzodiazepines

Most people do not like the subjective effects of benzodiazepines, especially in high doses. Even among drug addicts, the benzodiazepines alone are not common intoxicants. They are, however, widely used by drug addicts to self-medicate opiate withdrawal and to alleviate the side effects of cocaine and amphetamines. Patients receiving methadone maintenance use benzodiazepines to boost (enhance) the effects of methadone. Some alcoholic patients use benzodiazepines either in combination with alcohol or as a second-choice intoxicant, if alcohol is unavailable. Fat-soluble benzodiazepines that enter the CNS quickly are usually the benzodiazepines preferred by addicts.

Addicts whose urine is being monitored for benzodiazepines prefer benzodiazepines with high milligram potency, such as alprazolam or clonazepam. These benzodiazepines are excreted in urine in such small amounts that they are often not detected in drug screens, particularly with thin-layer chromatography.

### Treatment of High-dose Benzodiazepine Dependence

For high-dose benzodiazepine dependence, the pharmacological treatment strategy is the same as that for barbiturates. The phenobarbital conversion equivalents are shown in Table 44.3. The dose conversions computed using Table 44.3 prevent the emergence of severe withdrawal of the classic sedative-hypnotic types. Some patients who take high doses of benzodiazepines, or even therapeutic doses for months to years, may have prolonged withdrawal symptoms.

### Low-dose Benzodiazepine Withdrawal Syndromes

Many people who have taken benzodiazepines in therapeutic doses for months to years can abruptly discontinue the drug without developing withdrawal symptoms. But other patients, taking similar amounts of a benzodiazepine develop symptoms ranging from mild to severe when the benzodiazepine is stopped or when the dosage is substantially reduced. Characteristically, patients tolerate a gradual tapering of the benzodiazepine until they are at 10 to 20% of their peak dose. Further reductions in benzodiazepine dose then cause patients to become increasingly symptomatic. In addition medicine literature, the low-dose withdrawal may be called therapeutic-dose withdrawal, normal-dose withdrawal, or benzodiazepine discontinuation syndrome. The symptoms can ultimately be categorized as symptom reemergence, symptom rebound, or a prolonged withdrawal syndrome.

Many patients experience a transient increase in symptoms for 1 to 2 weeks after benzodiazepine withdrawal. The symptoms are an intensified return of the symptoms for which the benzodiazepine was prescribed. This transient form of symptoms intensification is called **symptom rebound**. The term comes from sleep research in which rebound insomnia is commonly observed after sedative-hypnotic use. Symptom rebound lasts a few days to weeks after discontinuation. Symptom rebound is the most common withdrawal consequence of prolonged benzodiazepine use.

The symptoms for which the benzodiazepine has been taken may return to the same level as before benzodiazepine therapy. This is called symptom reemergence (or recrudescence). In other words, the patient's symptoms, such as anxiety, insomnia, or muscle tension, that had abated during benzodiazepine treatment return.

The reason for making a distinction between symptom rebound and symptom reemergence is that symptom reemergence suggests that the original symptoms are still present and must be treated. Symptom rebound is a transient withdrawal syndrome that will disappear over time.

A few patients experience a severe, protracted withdrawal syndrome that includes symptoms (e.g., paresthesia and psychosis) that were not present before. This withdrawal syndrome has generated much of the concern about the long-term safety of the benzodiazepines.

### Risk Factors for Low-dose Benzodiazepine Withdrawal

Some drugs or medications may facilitate neuroadaptation by increasing the affinity of benzodiazepines for their receptors. Phenobarbital, for example, increases the affinity of diazepam to benzodiazepine receptors and prior treatment with phenobarbital has been found to increase the intensity of chlordiazepoxide (45 mg/day) withdrawal symptoms. Patients at increased risk for development of the low-dose withdrawal syndrome are those with a family or personal history of alcoholism, those who use alcohol daily and those who concomitantly use other sedatives. Case-control studies suggest that patients with a history of addiction, particularly to other sedative-hypnotics, are at high risk for low-dose benzodiazepine dependence. The short-acting, high-milligram-potency benzodiazepines appear to produce a more intense low-dose withdrawal syndrome.

### Treatment of Protracted Benzodiazepine Withdraw

Phenobarbital conversions based on Table 44.3 are not adequate to suppress symptoms. For example, someone discontinuing 20 mg of diazepam would have a computed phenobarbital conversion of 60 mg. In managing low-dose withdrawal, an approach is to begin with about 200 mg/day of phenobarbital and then taper the phenobarbital slowly as tolerated. If palpitations or other symptoms of autonomic hyperactivity are bothersome, beta-adrenergic blockers, such as propranolol or 2-adrenergic agonists, such as clonidine, may be useful adjuncts. Reports on the use of clonidine to reduce benzodiazepine withdrawal severity have yielded mixed results.

### Comparison of DSM-IV/ICD-10 Diagnostic Criteria

The DSM-IV-TR and ICD-10 Criteria sets for Sedative, Hypnotic, or Anxiolytic Intoxication are almost equivalent (except that ICD-10 also includes "erythematous skin lesions or blisters"). The DSM-IV-TR and ICD-10 symptom lists for Sedative, Hypnotic, or Anxiolytic Withdrawal include some different items: the ICD-10 list has craving, postural hypotension, headache, malaise or weakness and paranoid ideation and do not include the DSM-IV-TR anxiety item.

# Schizophrenia and Other Psychoses

## Diagnosis

In DSM-IV, criterion A of schizophrenia includes delusions, hallucinations, disorganized speech, disorganized or catatonic behavior and negative symptoms. Two or more of these symptoms are required during the active phase of the illness. However, if the patient describes bizarre delusions or auditory hallucinations consisting of a voice commenting on the patient's behavior or voices conversing, only one of these symptoms is required to reach the diagnosis. It is important to distinguish negative symptoms, which are often difficult to appreciate, from the myriad factors that may contribute to the severity and serious morbidity associated with schizophrenia. Patients who are not motivated to attend to their personal hygiene or suffer from alogia and a flattened affect are sadly at a disadvantage in society. The addition of negative symptoms as a separate criterion in DSM-IV recognizes the prominence of these symptoms in patients with schizophrenia.

### DSM-IV-TR Criteria 295.xx

#### Schizophrenia

A. Characteristic symptoms: Two (or more) of the following, each present for a significant portion of time during a 1-month period (or less if successfully treated):

- (1) delusions
- (2) hallucinations
- (3) disorganized speech (e.g., frequent derailment or incoherence)
- (4) grossly disorganized or catatonic behavior
- (5) negative symptoms, i.e., affective flattening, alogia, or avolition

**Note:** Only one criterion A symptom is required if delusions are bizarre or hallucinations consist of a voice keeping up a running commentary on the person's behavior or thoughts, or two or more voices conversing with each other.

B. Social/occupational dysfunction: For a significant portion of the time since the onset of the disturbance, one or more major areas of functioning such as work, interpersonal relations, or self-care are markedly below the level achieved prior to the onset (or when the onset is in childhood or adolescence, failure to achieve expected level of interpersonal, academic, or occupational achievement).

- C. Duration: Continuous signs of the disturbance persist for at least 6 months. This 6-month period must include at least 1 month of symptoms (or less if successfully treated) that meet criterion A (i.e., active-phase symptoms) and may include periods of prodromal or residual symptoms. During these prodromal or residual periods, the signs of the disturbance may be manifested by only negative symptoms or two or more symptoms listed in criterion A present in an attenuated form (e.g., odd beliefs, unusual perceptual experiences).
- D. Schizoaffective and mood disorder exclusion: Schizoaffective disorder and mood disorder with psychotic features have been ruled out because either (1) no major depressive, manic, or mixed episodes have occurred concurrently with the active-phase symptoms; or (2) if mood episodes have occurred during active-phase symptoms, their total duration has been brief relative to the duration of the active and residual periods.
- E. Substance/general medical condition exclusion: The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.
- F. Relationship to a pervasive developmental disorder: If there is a history of autistic disorder or another pervasive developmental disorder, the additional diagnosis of schizophrenia is made only if prominent delusions or hallucinations are also present for at least a month (or less if successfully treated).

### DSM-IV Subtypes of Schizophrenia

In DSM-IV, schizophrenia has been divided into clinical subtypes, based on field trials of the reliability of symptom clusters. The subtypes are divided by the most prominent symptoms, although it is acknowledged that the specific subtype may exist simultaneously with or change over the course of the illness. DSM-IV also initiates an optional dimensional descriptor, which allows the condition to be characterized by the presence or absence of a psychotic, disorganized, or negative symptom dimension over the entire course of the illness.

## Paranoid Type

In DSM-IV, paranoid-type schizophrenia is marked by hallucinations or delusions in the presence of a clear sensorium and unchanged cognition. Disorganized speech, disorganized behavior and flat or inappropriate affect are not present to any significant degree. The delusions (usually of a persecutory or grandiose nature) and the hallucinations most often revolve around a particular theme or themes. Because of their delusions, these patients may attempt to keep the interviewer at bay, and thus they may appear hostile or angry during an interview. This type of schizophrenia may have a later age of onset and a better prognosis than the other subtypes.

### DSM-IV-TR Criteria 295.30

#### Paranoid Type

A type of schizophrenia in which the following criteria are met:

- A. Preoccupation with one or more delusions or frequent auditory hallucinations.
- B. None of the following is prominent: disorganized speech, disorganized or catatonic behavior, or flat or inappropriate affect.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

## Disorganized Type

Disorganized schizophrenia, historically referred to as hebephrenic schizophrenia, presents with the hallmark symptoms of disorganized speech and/or behavior, along with flat or inappropriate (incongruent) affect. Any delusions or hallucinations, if present, also tend to be disorganized and are not related to a single theme. Furthermore, these patients would not be classified as having catatonic schizophrenia. These patients in general have more severe deficits on neuropsychological tests. According to DSM-IV, these patients tend to have an earlier age at onset, an unremitting course, and a poor prognosis.

### DSM-IV-TR Criteria 295.10

#### Disorganized Type

A type of schizophrenia in which the following criteria are met:

- A. All of the following are prominent:
  - (1) disorganized speech
  - (2) disorganized behavior
  - (3) flat or inappropriate affect
- B. The criteria are not met for catatonic type.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

### DSM-IV-TR Criteria 295.20

#### Catatonic Type

A type of schizophrenia in which the clinical picture is dominated by at least two of the following:

- (1) motoric immobility as evidenced by catalepsy (including waxy flexibility) or stupor
- (2) excessive motor activity (that is apparently purposeless and not influenced by external stimuli)
- (3) extreme negativism (an apparently motiveless resistance to all instructions or maintenance of a rigid posture against attempts to be moved) or mutism
- (4) peculiarities of voluntary movement as evidenced by posturing (voluntary assumption of inappropriate or bizarre postures), stereotyped movements, prominent mannerisms, or prominent grimacing
- (5) echolalia or echopraxia

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

## Catatonic Type

Catatonic schizophrenia has unique features that distinguish it from other subtypes of schizophrenia in DSM-IV for Catatonic Schizophrenia. During the acute phase of this illness, patients may demonstrate marked negativism or mutism, profound psychomotor retardation or severe psychomotor agitation, echolalia (repetition of words or phrases in a nonsensical manner), echopraxia (mimicking the behaviors of others), or bizarreness of voluntary movements and mannerisms. Some patients demonstrate a waxy flexibility, which is seen when a limb is repositioned on examination and remains in that position as if the patient were made of wax. Patients with catatonic stupor must be protected against bodily harm resulting from the profound psychomotor retardation. They may remain in the same position for weeks at a time. Because of extreme mutism or agitation, patients may not be able to report any difficulties. Some patients may experience extreme psychomotor agitation, with grimacing and bizarre postures. These patients may require careful monitoring to safeguard them from injury or deterioration in nutritional status or fluid balance.

## Undifferentiated Type

There is no hallmark symptom of undifferentiated schizophrenia; thus, it is the subtype that meets the criterion A for schizophrenia

### DSM-IV-TR Criteria 295.90

#### Undifferentiated Type

A type of schizophrenia in which symptoms that meet criterion A are present, but the criteria are not met for the paranoid, disorganized, or catatonic type.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

but does not fit the profile for paranoid, disorganized, or catatonic schizophrenia.

### Residual Type

The diagnosis of residual schizophrenia, according to DSM-IV, is appropriately used when there is a past history of an acute episode of schizophrenia but at the time of presentation the patient does not manifest any of the associated psychotic or positive symptoms. However, there is continued evidence of schizophrenia manifested in either negative symptoms or low-grade symptoms of criterion A. These may include odd behavior, some abnormalities of thought processes, or delusions or hallucinations that exist in a minimal form. This type of schizophrenia has an unpredictable, variable course.

#### DSM-IV-TR Criteria 295.60

##### Residual Type

A type of schizophrenia in which the following criteria are met:

- A. Absence of prominent delusions, hallucinations, disorganized speech, and grossly disorganized or catatonic behavior.
- B. There is continuing evidence of the disturbance, as indicated by the presence of negative symptoms or two or more symptoms listed in criterion A for schizophrenia, present in an attenuated form (e.g., odd beliefs, unusual perceptual experiences).

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

One must avoid imposing Western definitions of psychosis on nonWestern societies. Psychosis and delusions, by definition, must be beliefs or experiences that are incongruent with those of the patient's social or cultural background. To determine where culture-bound beliefs end and delusions or inappropriate behaviors begin in a multicultural world is clearly not possible using only a written algorithm such as DSM-IV. A critical step toward sound cross-cultural clinical care is developing an awareness of and a respect for diversity. Utilizing the expertise of persons familiar with a specific culture allows appropriate diagnosis and treatment of schizophrenia worldwide.

### Epidemiological Findings: Incidence and Prevalence

The incidence of schizophrenia is defined as the number of new cases in a given population, usually per 1000 persons, during a specific period of time (1 year by convention). In an illness with an insidious onset, such as schizophrenia, accurate incidence rates can be difficult to determine. The incidence varies depending on the methods and the diagnostic criteria used. For example, the US–UK study is often cited as an example of epidemiological variation based on different diagnostic criteria (Kramer, 1969). This study, conducted in the 1960s, found a lower incidence of schizophrenia in the UK than in the USA. It is now widely accepted that this difference was found because a broader definition

of schizophrenia was being used in the USA, and it did not reflect true differences in the incidence of schizophrenia in each country.

The data obtained from World Health Organization (WHO) studies are important in part because the same diagnostic criteria were used in all countries studied. According to the results of the International Pilot Study of Schizophrenia, schizophrenia is found in all cultures and the incidence rates per 1000 people annually ranged from 0.15 in Denmark to 0.42 in India (WHO, 1973).

Because schizophrenia is a chronic illness, the incidence rates must, by definition, be much lower than the prevalence rates. Prevalence is defined as the number of cases present in a specified population at a given time or time interval (e.g., at a specific point in time, during a time period, or over a lifetime). Lifetime prevalence represents the proportion of persons who have ever had the illness at a given time. Lifetime prevalence rates of schizophrenia, based on the Epidemiology Catchment Area (ECA) data, were approximately 1% (range across three sites, 1–1.9%) (Robins *et al.*, 1984). Point prevalence rates based on International Pilot Study of Schizophrenia data showed no significant differences across study centers: schizophrenia was found universally with relatively equal frequencies in a wide variety of cultures.

### Sociodemographical Characteristics

#### Age

An investigation of late-onset schizophrenia found that 28% of patients had the onset of illness after age 44 years and 12% after age 63 years, based on 470 chart reviews of patients who had sought psychiatric help during a period of 20 years (Castle and Murray, 1993). Although the majority of patients have an early age at onset, a certain subgroup of patients may have a disturbance that meets all the criteria of schizophrenia with onset in their forties or later.

The phenomenology of late-onset compared with early-onset schizophrenia may be distinct, with later-onset cases having a higher level of premorbid social functioning and exhibiting paranoid delusions and hallucinations more often than formal thought disorder, disorganization and negative symptoms. Studies have also shown a high comorbid risk of sensory deficits, such as loss of hearing or vision, in patients with late-onset schizophrenia. Specifically, late-onset patients are more likely to report visual, tactile and olfactory hallucinations and are less likely to display affective flattening or blunting. One of the most robust findings among the late-onset cases is the higher prevalence seen in women. This does not appear to be due to sex differences in seeking care, societal role expectations or delay between emergence of symptoms and service contact.

#### Gender

A large body of data suggests that although men and women have an equivalent lifetime risk; the age at onset varies with sex. Strong evidence that onset of schizophrenia is on average 3.5 to 6 years earlier in men than in women.

There is undoubtedly a subgroup of patients who have a later onset of illness (after age 45 years), and this subgroup is made up predominantly of women. Among these female schizophrenia patients, there is a higher incidence of comorbid affective symptoms. When the effects of gender, premorbid personality,

marital status and family history of psychosis on the age at onset were removed in a reanalysis of the WHO 10-country study data, there was a significant attenuation of the gender differences (Jablensky and Cole, 1997).

### Race

The ECA data have shown that there is no significant difference in the prevalence of schizophrenia between black and white persons when corrected for age, sex, socioeconomic status and marital status (Robins and Regier, 1991). This finding is significant because it refutes prior studies that have shown the prevalence of schizophrenia to be much greater in the black population than in the white population.

### Marital Status and Fertility

A study of marriage and fertility rates of individuals with schizophrenia compared with the general population showed that, on average, by the age of 45 years, three times as many of those with schizophrenia as of the general population are still unmarried (40% of men and 30% of women with schizophrenia are still single by age 45). Studies have also shown that fertility rates are lower in patients with schizophrenia compared with the general population. These observations may be related, and further investigation of the role of premorbid function, negative symptoms and fertility rates, including rates among unmarried patients, is warranted. With the advent of the newer and more effective antipsychotic medications, and their increased use in first episode patients, it is possible that we may witness improved fertility and marriage rates in patients with schizophrenia.

### Socioeconomic Status

For many years, epidemiological studies revealed a higher incidence and prevalence of schizophrenia in groups with lower socioeconomic status. In the past half century, studies have found that the actual incidence of schizophrenia does not vary with social class, based on first admission rates, adoption studies and a series of studies examining the social class of the fathers of people with schizophrenia. When these findings did not validate the original theory, it became clear that lower socioeconomic status was more a result than a cause of schizophrenia. This led to the acceptance of the downward drift hypothesis, which stated that because of the nature of schizophrenic symptoms, people who develop schizophrenia are unable to attain employment and positions in society that would allow them to achieve a higher social status. Thus, these patients drift down the socioeconomic ladder, and because of the illness itself they may become dependent on society for their well-being.

### Season of Birth and Onset

That season of birth differs between individuals with schizophrenia and the general population has by now gained wide acceptance. This factor has been studied in the 20th century, with the predominant view that the birth rate of people with schizophrenia is highest in late winter. Torrey and colleagues (1997) confirmed this, reviewing approximately 250 studies and concluding that there is an excess of schizophrenia births during winter. In fact, there is approximately a 5 to 8% greater likelihood for individuals with schizophrenia to be born during winter months compared with the general population. This higher incidence of winter births has been found in both hemispheres, offering further evidence that this phenomenon is related to the colder months rather than specific calendar months.

### Morbidity and Mortality

The economic costs of schizophrenia have been estimated to be six times the costs of myocardial infarction. The WHO has estimated that mental illness accounts for as much as two-fifths of all disability funding in the USA. In the USA, the cost of schizophrenia in 1994 was \$44.9 billion and rising. Much of the cost of schizophrenia is due to the high morbidity of this chronic illness. Premorbid deficits, cognitive deficits and negative symptoms account for much of the disability. Also, schizophrenia patients with more severe courses may require repeated hospitalizations and may not be capable of maintaining independent living or stable employment.

The mortality rate of schizophrenia is estimated to be twice that of the general population. Approximately 10% of the mortality is secondary to suicide. Young male patients with schizophrenia are most likely to complete suicide attempts, especially early in their illness. Degree of social isolation, agitation, depression, a sense of hopelessness, a history of prior suicide attempts and recent loss may be associated with increased risk of suicide among schizophrenia patients. There is also some evidence that an increased number of relapses, rehospitalizations and discharges lead to an increased risk of suicide. There have been observations that suicide rates of schizophrenia patients may be increasing in the era of shorter hospital stays and community treatment. However, with the advent of the novel antipsychotic medications and especially with clozapine use, it is possible that this risk of suicide may even out or decrease due to their possible protective effects against suicide. Other factors leading to increased mortality rates in schizophrenia patients include an increased incidence of accidents as well as a more frequent association with other medical illnesses (including cardiovascular disease), comorbid substance abuse, a general neglect of health, an increased rate of damaging behaviors such as smoking and poor diet, decreased access to health services and depression.

### Comorbidity with Other Illnesses

Schizophrenia is associated with an increased frequency of tuberculosis (not accounted for by institutionalization), celiac disease, myxedema and arteriosclerotic heart disease. Patients who present with atypical psychoses have been noted to have an increased risk of ankylosing spondylitis and uroarthritis, which may indicate a relationship between the histocompatibility complex and schizophrenia. Along these lines, there is a strikingly decreased risk for rheumatoid arthritis among patients with schizophrenia.

### Etiology

The cause of schizophrenia is currently not known. A leading view is that schizophrenia may be heterogeneous with respect to etiology. Thus, multiple causative mechanisms may give rise to distinct disease subtypes. If this is true, it is important for psychiatric researchers to differentiate the homogeneous subtypes of this illness. Moreover, it has been proposed that more than one causative mechanism might interact (the so-called double-hit hypothesis) to cause the illness in some individuals. In this section, the main etiological theories of schizophrenia are examined.

### Genetics

Schizophrenia represents a daunting challenge for genetic researchers for several reasons: the paucity of extended

multigenerational family histories containing large numbers of affected individuals; the possibility of genetic heterogeneity, such as more than one phenotype or more than one genetic variant; and a lack of agreement on the mode of transmission. The focus of research has shifted to multiple genes of small to moderate effects which may compound their effects through interactions with each other and with other nongenetic risk factors.

### Family Prevalence Studies

Wide agreement now exists that the rate of schizophrenia among first-degree family members of persons with schizophrenia is higher than in control families. The chance of occurrence is approximately 10 times greater among these individuals than in individuals with no first-degree relatives with schizophrenia. There is approximately six times and two times greater chance of developing schizophrenia in second- and third-degree relatives of individuals with schizophrenia respectively. In addition, the higher prevalence of schizophrenia spectrum disorders among family members of individuals with schizophrenia, such as schizoaffective disorder and schizoid and schizotypal personality disorders, provides support for a common genetic basis for this family of schizophrenia-like illnesses.

### Adoption Studies

Adoption studies constitute a powerful experimental strategy for examining the role of genetic versus environmental factors. In these studies, the rates of schizophrenia are compared in relatives of adoptees with and without schizophrenia. Danish adoption studies conducted in the 1960s and 1970s provided compelling evidence that adoptees with schizophrenia had higher rates of schizophrenia in their first-degree relatives than control adoptees. A reanalysis of these data in the late 1980s confirmed the original finding that biological relatives of schizophrenia adoptees had significantly higher rates of schizophrenia (4.1%) than biological relatives of nonschizophrenia (control) adoptees (0.5%). Several methodological issues are important in interpreting the data from adoption studies, including the diagnostic status of biological fathers and levels of psychopathology in adoptive families. Additional factors to consider are the intrauterine environment, birth complications and length of time from birth to adoptive placement.

### Twin Studies

Another approach to examining genetic contributions to schizophrenia involves concordance studies of dizygotic (nonidentical) and monozygotic (identical) twin pairs. Available data indicate that the concordance of schizophrenia among dizygotic twins is approximately 8 to 12%. This is much greater than the 1% rate found in the general population and comparable to the rate of concordance of schizophrenia among first-degree siblings. The concordance of schizophrenia among monozygotic twins is approximately 50%. Even though the high rate of concordance among monozygotic twin pairs is compelling evidence for genetic contributions, the fact that it is not higher than 50% suggests a role for additional, perhaps nongenetic, factors in the etiology of schizophrenia. The number of sets of adopted-away, monozygotic twin pairs affected with schizophrenia is relatively small. However, data available on the limited number of pairs meeting these criteria support the strong concordance of schizophrenia in monozygotic twins.

### Linkage and Association Studies

The Human Genome Project with its 3 billion base pairs and approximately 35 000 genes has ushered us into the “Genomic Era”. However, systematic genome scans done recently have not resulted in strong evidence for linkage to any chromosomal region. At the time of this writing, no genetic linkage or association related to schizophrenia has been discovered. There have been reports of suggestive linkages but there has been a failure to replicate these findings. It has become painfully clear that the replication studies are, in many ways, more important to establishing linkage than the initial report. Genes that have been found not to be associated with schizophrenia include the dopamine  $D_2$  and  $D_4$  genes.

The initial enthusiasm for these strategies has waned as no gene has yet been isolated for schizophrenia or bipolar disorder. Impediments that have limited the success of linkage and association studies are etiologic and phenotypic heterogeneity of schizophrenia, lack of power and high false positive rates. Thus, newer approaches such as multi-investigator collaborative studies to increase the power have already been implemented.

Meanwhile, modern functional genomic approaches such as DNA microarrays, based on the principles of nucleic acid hybridization, can check a tissue sample for presence of thousands of genes simultaneously. For example, Mirnics and colleagues (2000) employed cDNA microarrays and compared transcriptomes in schizophrenia and matched control subjects and found that only a few gene groups consistently differed between subjects and controls. In all subjects with schizophrenia, the most changed gene group was related to **presynaptic group secretory function** (PSYN) gene group and in particular the “mechanics” of neurotransmitter release.

Weinberger and colleagues (2001) suggest that the gene that encodes the postsynaptic enzyme catechol-*o*-methyl transferase (COMT) is preferentially involved in the metabolism of dopamine in frontal lobe. Dopamine is hypothesized to underlie aspects of cognition in frontal lobe such as information processing. Based on animal studies, family-based association studies and fMRI studies in schizophrenia patients and general population, Weinberger and colleagues propose an interesting hypothesis that the COMT genotype with valenine allele (val/val type) may increase the risk of developing schizophrenia due to its effect on dopamine-mediated prefrontal information processing.

Researchers are urgently searching for schizophrenia phenotypes for subgroups or dimensions that may define etiologically or genetically distinct subtypes. Similarly, the field is yearning for **endophenotypes** with simpler architecture than schizophrenia possibly to guide to newer leads in research. Latent genetically influenced traits, which may be related only indirectly to the classic disease symptoms defined in major classification systems, are known as “endophenotypes”. They reflect an underlying susceptibility to the disease phenotype (or some form of it). In schizophrenia we are interested in endophenotypes that are measurable by neurophysiological or neuropsychological means. Crucial characteristics of any endophenotype include the fact that it can be measured before the explicit onset of the illness, and that it represents the genetic liability of nonaffected relatives of probands with the disorder.

### Viral Hypotheses

Two lines of evidence that have provoked the most interest in the possibility that viral infections are causative of schizophrenia

are an increase in birth during influenza epidemics of individuals who subsequently develop schizophrenia and an increase in winter births among patients with schizophrenia because of the higher rate of viral infections in winter months. However, negative results from multiple studies have raised serious questions about this theory. Several studies have demonstrated an excess of winter births among patients with schizophrenia. Although statistically significant, the association between winter births and schizophrenia appears relatively small, occurring in less than 10% of cases. Thus, season of birth remains an interesting (and unresolved) research issue but has little use as a risk factor for the illness from a clinical perspective. Exposure to influenza *in utero* and excess winter births are interesting although indirect lines of evidence for a viral cause of schizophrenia. To date, there has been no direct confirmation for any viral agent causing this illness, such as viral isolates or consistent findings of specific viral antibodies. Advances in neurovirology, however, are providing new insights into the role of viruses in brain diseases, leading to new hypotheses about schizophrenia. One area involves the search for neurotropic retroviruses.

### Immune Dysfunction

Several research groups are exploring the possibility that schizophrenia may be associated with impaired immune function including alterations in autoimmunity. Anticardiolipin antibody and antinuclear antibody, two autoantibodies that are used as markers of autoimmune vulnerability, have been shown to be increased in patients with schizophrenia in some but not all studies of this illness. Two other markers relevant to autoimmune function, impaired T lymphocyte proliferative response to the mitogen phytohemagglutinin and impaired interleukin-2 production, have shown more consistent alterations in patients with schizophrenia than in control populations. Some of the most intriguing work in this area is focused on finding autoantibodies to brain tissue.

### Birth Complications

Numerous studies have reported a higher rate of pregnancy and birth complications in patients with schizophrenia than in control populations. The complication rates vary widely among studies, probably because of the inherent difficulties in obtaining reliable and valid retrospective data in this area. In one study, two-thirds of schizophrenia patients and less than one-third of control subjects had histories of obstetrical complications. Hypoxia is one possible result of pregnancy and birth complications that has been shown to disrupt brain development. The hippocampus and some neocortical regions are particularly sensitive to shortfalls in oxygen. Thus, one proposed mechanism for a role of pregnancy and birth complications in the cause of schizophrenia involves hypoxia-mediated damage to these areas. Interestingly, some studies suggest that the rate of obstetric complications are higher in early-onset schizophrenia, occur more often in males, in people with prominent negative symptoms, and no family history of schizophrenia.

### Pathophysiology

Whereas **etiology** refers to the cause of an illness, **pathophysiology** refers to the abnormal processes that mediate the clinical manifestation of the illness. As was the case with etiology, the

brain processes that give rise to schizophrenia are currently not known. However, rapidly converging bodies of neuroanatomical and neurochemical data appear to be closing in on defining the pathophysiology of this illness.

## Neuroanatomical Theories

### Enlarged Ventricles

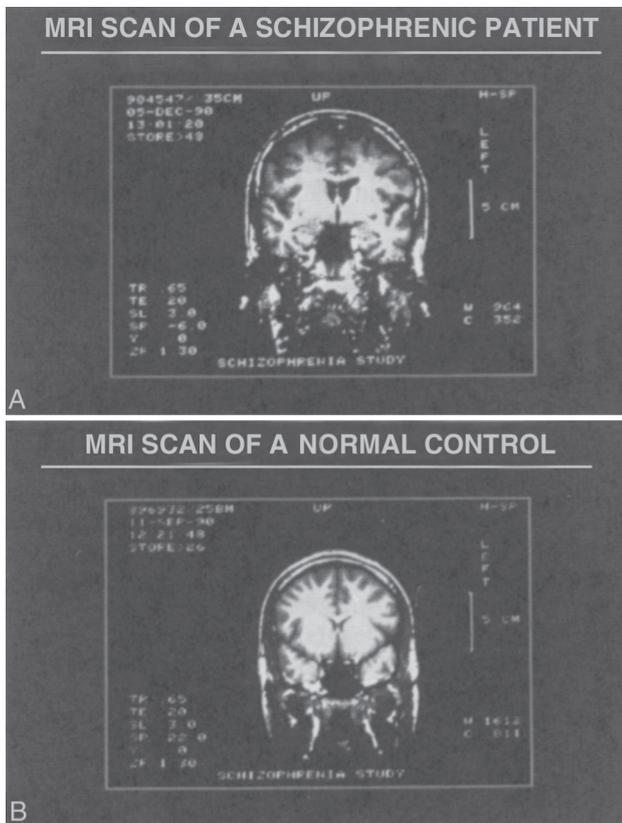

The ventricles are the fluid-filled spaces in the center of the brain. The most consistent morphological finding in the literature of schizophrenia is enlarged ventricles which has been confirmed by a large number of CT and MRI studies. The effect size of ventriculomegaly has been reported to be 0.7 (Raz and Raz, 1990). Seventy-nine percent of the well designed studies report enlargement of lateral ventricles. Lawrie and Abukmeil (1998) report approximately 40% difference in volume between schizophrenia patients and controls across all volumetric MRI studies. It should be noted that although the ventricular increases are statistically significant, the ventricles are not grossly enlarged in most cases. In fact, radiologists most often read CT and MRI scans of patients with schizophrenia as normal. In addition, most studies of ventricular size demonstrate overlap between patients and normal control subjects, indicating that many patients have ventricles in the normal range. Nonetheless, enlargement of the ventricles is the first consistently reported finding confirming a brain abnormality in schizophrenia.

The pathophysiological significance of larger than normal ventricles is unclear. Enlarged ventricles are most likely a secondary manifestation of brain atrophy or some other process resulting in either focal or generalized reductions in brain mass. Indeed, there have been many reports of brain atrophy and reduced mass in the illness (Figure 45.1). Enlarged ventricles have also been reported in first-degree relatives of subjects with schizophrenia (Cannon *et al.*, 1998; Seidman *et al.*, 1997) and in persons suffering from schizotypal personality disorder (Buchsbbaum *et al.*, 1997) raising interesting speculations of whether ventriculomegaly may be an indicator of neurodevelopmental risk for schizophrenia (Lencz *et al.*, 2001).

### Limbic System

The limbic structures that have been implicated in schizophrenia are the hippocampus, entorhinal cortex, anterior cingulate and amygdala. These structures have important functions for memory (hippocampus), attention (anterior cingulate), and emotional expression and social affiliation (amygdala). The entorhinal cortex serves as a “way station” between hippocampus and neocortex in that neurotransmissions between these regions synapse in the entorhinal cortex. The entorhinal cortex, hippocampus and other components of the parahippocampal gyrus are often considered “mesiotemporal” structures because of their close anatomical and functional relationship.

There are more reports of abnormalities in hippocampal and related mesiotemporal structures than other limbic structures in schizophrenia. In fact, mesiotemporal pathology is consistently found in studies of schizophrenia and mesiotemporal structures are leading candidates for the neuroanatomical site of this condition. This region has been implicated by converging brain imaging and postmortem lines of evidence. One of the most consistent MRI morphological findings is reduction in size of the hippocampus. In addition, more than 25 postmortem studies have reported morphological and cytoarchitectural abnormalities in this structure. The findings have included reduced size and

**Figure 45.1** CT scans of a schizophrenic patient (A) and a healthy volunteer (B). Note enlarged ventricular spaces and brain atrophy in the scan of the patient with schizophrenia.

cellular number (white matter reductions, and abnormal cell arrangement. There is a bilateral reduction of approximately 4% hippocampal volume in schizophrenia. However, reduced hippocampal volume is not reported by all studies.

The anterior cingulate has been implicated in schizophrenia largely because of postmortem findings of reduced gamma-aminobutyric acid (GABA) interneurons. In addition, functional imaging studies have demonstrated altered metabolic activity both at rest and during selective attention tasks in the anterior cingulate in patients with schizophrenia. Thirty-one studies evaluated one or more of the medial temporal lobe structures – hippocampus, amygdala, parahippocampal gyrus, entorhinal cortex – with 77% reporting positive findings; this is one of the higher percentages of abnormalities reported in all regions of interest throughout the brain.

### Prefrontal Cortex

The prefrontal cortex is the most anterior portion of the neocortex, sitting behind the forehead. It has evolved through lower species to become one of the largest regions of the human brain, constituting approximately one-third of the cortex. It is responsible for some of the most sophisticated human functions. It contains a heteromodal association area that is responsible for integrating information from all other cortical areas as well as from several subcortical regions for the execution of purposeful behavior. Among its specific functions are working memory, which involves the temporary storage (seconds to minutes) of information, attention and suppression of interference from internal and external sources. The most inferior portion of the

prefrontal cortex, termed the orbital frontal cortex, is involved in emotional expression. Given its unique role, it is not surprising that the prefrontal cortex has been considered in the etiology of schizophrenia.

Indeed, several lines of evidence have implicated the prefrontal cortex in schizophrenia. CT studies have provided evidence for prefrontal atrophy, and some, although not all, MRI studies have found evidence for decreased volume of this structure. One of the earliest observations from functional imaging studies of schizophrenia was reduced perfusion of the frontal lobes. This finding was subsequently replicated by several PET studies suggesting decreased frontal glucose utilization and blood flow, which came to be known as **hypofrontality**. Subsequent functional imaging studies provided further support for hypofrontality by demonstrating that patients with schizophrenia failed to activate their frontal lobes to the same degree as normal control subjects when performing frontal cognitive tasks. This finding has been questioned because patients with schizophrenia typically perform poorly in many cognitive paradigms, so it is unclear whether their lack of frontal activation is a primary frontal deficit or secondary to poor cognitive task performance related to factors such as lack of motivation, inattention, or cognitive impairment stemming from nonfrontal regions. Auditory hallucinations were found to be associated with increases in Broca's area, a portion of the frontal cortex responsible for language production. This finding was of interest because it supported a hypothesis that auditory hallucinations were a form of abnormal "inner speech".

MRI studies employing diffusion tensor imaging have reported changes suggestive of an abnormality in white matter connectivity possibly due to reduced myelination of fiber tracts in patients with schizophrenia (Buchsbaum *et al.*, 1998). Magnetic resonance spectroscopy (MRS) studies have reported reduced levels of neuronal membrane constituents (phosphomonoesters) and/or increased levels of their breakdown products (phosphodiesteres) in patients with schizophrenia, primarily in the frontal cortex. Such abnormalities have been observed in treatment-naïve first episode patients and have been correlated with trait-like negative symptoms and neurocognitive performance.

Though sometimes contradictory, the neuroimaging studies consistently report abnormalities in the orbitofrontal region; often, these abnormalities tend to correlate with severity of schizophrenia symptomatology, show gender differences in relation to spatial localization and the gray matter deficits may be more widespread in chronic, as compared with medication-naïve first episode patients. Additional support for prefrontal cortical involvement in schizophrenia comes from postmortem studies with a range of findings. There have been reports of reduced cortical thickness, loss of pyramidal cells, malformed cellular architecture, loss of GABA interneurons and evidence of failed neuronal migration. A majority of the abnormalities represented a decline in function suggesting a widespread failure of gene expression. Specifically, abnormalities involving the glycoprotein *Reelin* were observed in schizophrenia, a finding reported previously by other postmortem studies. *Reelin*, an extracellular matrix glycoprotein secreted from different GABAergic interneurons during development and adult life, may be important for the transcription of specific genes necessary for synaptic plasticity and morphological changes associated with learning.

### Temporal Lobe

The superior temporal gyrus is involved in auditory processing and, with parts of the inferior parietal cortex, is a heteromodal

association area that includes Wernicke's area, a language center. Because of the important role it plays in audition, it was hypothesized to be involved in auditory hallucinations. Indeed, MRI studies have found the superior temporal gyrus to be reduced in size in schizophrenia and have found a significant relationship between these reductions and the presence of auditory hallucinations. Similarly, Wernicke's area, which is involved in the conception and organization of speech, has been hypothesized to mediate the thought disorder of schizophrenia, particularly conceptual disorganization. Support for this hypothesis comes from a report of a patient with vascular and other lesions of this region that produce Wernicke's aphasia, a disruption in the organization of speech that resembles the thought disorder of schizophrenia. MRI studies have found a relationship between morphological abnormalities in this region and conceptual disorganization in schizophrenia. McCarley and colleagues (1999) reviewed 118 MRI studies published from 1988 to 1998; 62% of the 37 studies of whole temporal lobe showed volume reduction and/or abnormal asymmetry especially in the superior temporal gyrus, the highest percentage of any cortical region of interest.

### Striatum

The striatum, consisting of the caudate, putamen, globus pallidus, substantia nigra and accumbens, is an output center for the cortex and has been traditionally thought to have a primary role in the execution of motor programs. Subsequent studies have demonstrated an important cognitive role for this structure as well. Moreover, in primary diseases of the striatum, such as Parkinson's and Huntington's diseases, clinical manifestations include psychosis and other schizophrenia type behavior, which has contributed to interest in this region in the pathophysiology of schizophrenia.

Two related bodies of data are most frequently cited regarding the role of the striatum in schizophrenia; these concern the mechanism of antipsychotic drugs and postmortem studies of altered dopamine D<sub>2</sub> receptor numbers. The dorsal striatum (caudate and putamen) is the site of the vast majority of D<sub>2</sub> receptors in the brain. All effective antipsychotic drugs antagonize this receptor and thus, by extrapolation, it was reasoned that this region might be central to the pathophysiology of schizophrenia. Moreover, the most consistent postmortem finding in the schizophrenia literature is an increased density of striatal D<sub>2</sub> receptors. However, neuroleptic exposure causes up-regulation of D<sub>2</sub> receptors, which may account for this postmortem finding. A current view of the antipsychotic mechanism is that the dorsal striatum is involved in mediating the extrapyramidal side effects of antipsychotic medications and, based on rodent studies of antipsychotic drug mechanisms, the ventral striatum (nucleus accumbens) may be involved in antipsychotic efficacy. Thus, attention has shifted toward the possible role of the accumbens in mediating the psychosis of schizophrenia.

### Thalamus

The thalamus is a nucleus that receives subcortical input and outputs it to the cortex. One theory posits that the thalamus provides a filtering function for sensory input to the cortex. A deficit in thalamic filtering was proposed to account in part for the experiential phenomena of being overwhelmed by sensory stimuli reported by many patients with schizophrenia. Preclinical studies have demonstrated that antipsychotic drugs modulate thalamic input to the cortex, which has been offered as a model for antipsychotic drug action. Several MRI studies have reported reduced

volume, and functional abnormalities of the thalamus in patients with schizophrenia. Postmortem studies have also found cell loss and reductions in tissue volume in thalamic nuclei. This thalamic tissue reduction is considered as a possible evidence of abnormal circuitry linking the cortex, thalamus and cerebellum.

### Neural Circuits

Because of the large number of different neuroanatomical findings in studies of schizophrenia and the appreciation that brain function involves integration of several brain regions, current thinking about the neuroanatomy of this illness is centered on neural circuits. It is conceivable that an isolated lesion anywhere in a neural circuit could result in dysfunction of the entire network, and therefore spurious conclusions could be drawn by investigating only one component of a neural network. Evidence suggests that schizophrenia may be associated with a decrease in synaptic connectivity of the dorsal prefrontal cortex though this is not reported by all studies. McGlashan and Hoffman (2000) have proposed the Developmentally Reduced Synaptic Connectivity (DRSC) model which proposes that cortical gray matter deficits may arise from either reduced baseline synaptic density due to genetic and/or perinatal factors, or excessive pruning of synapses during adolescence and early adulthood or both. There is regionally specific decreased neuronal size in cortical layer III with cytoplasmic atrophy and generally reduced neuropil. The reduced size and increased density of neurons or glia and decreased cortical thickness suggest that cell processes and synaptic connections are reduced in schizophrenia. This is consistent with reports of decreased concentrations of synaptic proteins (e.g., synaptophysin). These cell processes and synapses could be lost as a consequence of a neurochemically mediated (through dopamine and or glutamate) synaptic apoptosis that would compromise cell function and alter brain morphology without, however, producing serious cell injury (and thus inducing glial reactions). However, McCarley and colleagues (1999) suggest that the main neural abnormality in schizophrenia involves neural connectivity (dendrite/neuropil/gray matter changes) rather than the number of neurons or network size. They suggest that a "failure of inhibition" on the cellular level is present in schizophrenia and may be linked to a "failure of inhibition" at the cognitive level. According to Lafargue and Brasic (2000) abnormalities involving the temporolimbic-prefrontal cerebral circuitry is postulated to underlie the organizational and memory deficits commonly observed in schizophrenia patients. Furthermore, as reviewed by these authors, a possible insult or injury to the mechanism of GABAergic and glutamatergic influence during early corticogenesis may largely contribute to the later manifestation of clinical schizophrenia. Malfunction of the cooperating sensory systems of excitation and inhibition during the early stages of development of the brain could result in the failure of "pioneer neurons" properly to differentiate and migrate to their appropriate cerebral locations. Consequently the later migrating projection neurons may fail to reach or invade their preselected area-specific brain sites. A disturbance of the proper GABAergic and glutamatergic influences would upset NMDA mechanisms and normal cortical development. If such disturbance is actively occurring from the onset of cerebral ontogeny, the affected individual may suffer from the signs and symptoms observed in schizophrenia. A challenge for the future is developing new approaches to examining the brain as an integrated and highly interactive system. An unanswered question is whether the morphological differences reflect hypoplasia (failure to develop) or atrophy (shrinkage).

## Electrophysiology

Electroencephalogram (EEG) records the electrical activity of brain, which may reflect the mental functions carried out by the neurons possibly in “real time”. However, the precise localization of this event in the specific brain region is poor. When EEG activity from repeated presentations of a specific stimulus is summed across trials, some potentials related to the specific processing of the target stimulus can be extracted from the EEG and are referred as **event-related potentials** (ERPs).

The P300 ERP, a positive deflection occurring approximately 300 milliseconds after the introduction of a stimulus, is regarded as a putative biological marker of risk for schizophrenia. The P300 amplitudes are smaller in patients with schizophrenia and is one of the most replicated electrophysiological findings.

## Neurochemical Theories

### Dopamine

Dopamine is the most extensively investigated neurotransmitter system in schizophrenia. In 1973 it was proposed that schizophrenia is related to hyperactivity of dopamine. This proposition became the dominant pathophysiological hypothesis for the next 15 years. Its strongest support came from the fact that all commercially available antipsychotic agents have antagonistic effects on the dopamine D<sub>2</sub> receptor in relation to their clinical potencies (Creese *et al.*, 1975). In addition, dopamine agonists, such as amphetamine and methylphenidate, exacerbate psychotic symptoms in a subgroup of patients with schizophrenia. Moreover, as noted earlier, the most consistently reported postmortem finding in the literature of schizophrenia is elevated D<sub>2</sub> receptors in the striatum.

The dopamine hyperactivity hypothesis and the primacy of D<sub>2</sub> antagonism for antipsychotic drug action were seriously questioned largely because of the advent of clozapine, an atypical antipsychotic drug. Clozapine has proved to be the most efficacious treatment for chronic schizophrenia and yet it has one of the lowest levels of D<sub>2</sub> occupancy of all antipsychotic drugs. This started an extensive search for explanations underlying the extraordinary efficacy of clozapine. However, new information from PET studies has once again highlighted the central role that the dopaminergic system plays in treatment of psychosis. The typical and atypical antipsychotics are effective only when their D<sub>2</sub> receptor occupancy exceeds 65%, reinforcing the importance of D<sub>2</sub> antagonism in producing antipsychotic effects. However, an important difference between typical and atypical antipsychotics is in their affinity for the D<sub>2</sub> receptors. Medications like clozapine attach loosely to and dissociate rapidly from the dopamine D<sub>2</sub> receptors compared with typical antipsychotic agents (like haloperidol) which have strong affinity for and bind tightly to these receptors.

Five subtypes of dopamine receptor have now been discovered, D<sub>1</sub>, D<sub>2</sub>, D<sub>3</sub>, D<sub>4</sub> and D<sub>5</sub>, and interest in dopamine receptors other than the D<sub>2</sub> receptor has arisen. Reduced levels of D<sub>1</sub>-like dopamine receptors in the prefrontal cortex of patients with schizophrenia including in those never exposed to antipsychotic agents have been reported. The D<sub>1</sub> receptors are expressed predominantly by pyramidal neurons on their dendritic spines, where they possibly modulate glutamate-mediated inputs to these neurons – inputs that mainly come from other pyramidal and thalamic neurons. Thus the reduced D<sub>1</sub>-like receptors seen in the prefrontal cortex of schizophrenia patients may underlie aspects of cognitive dysfunction and severity of negative symptoms (Nestler, 1997).

Clinical trials of dopamine agonists have resulted in improvements in the negative symptoms of schizophrenia. A new model of dopamine dysfunction was proposed which stated that deficits in dopamine, perhaps in the prefrontal cortex, may result in negative symptoms and that concomitant dopamine dysregulation in the striatum, perhaps related to faulty presynaptic control of dopamine release, may be involved in positive symptoms. This bidirectional model is under investigation.

The DA hypothesis of schizophrenia has been critical in guiding schizophrenia research for several decades. Until recently, a main shortcoming of this hypothesis was absence of direct evidence linking DA dysfunction to schizophrenia. Sophisticated *in vivo* techniques have provided fascinating data directly implicating dopamine in developing psychosis. It is also becoming clear that dopamine works closely with serotonin, glutamate and other systems such that changes in one system affects the balance of the other systems too.

### Serotonin

Clozapine has a relatively high affinity for specific serotonin (5-hydroxytryptamine [5-HT]) receptors (5-HT<sub>2A</sub> and 5-HT<sub>2C</sub>) and risperidone, has even greater serotonin antagonistic properties. Clozapine, risperidone, olanzapine, quetiapine and ziprasidone, the novel antipsychotic agents, have a greater ratio of serotonin 5-HT<sub>2A</sub> to dopamine D<sub>2</sub> binding affinity. This has led to the hypothesis that the balance between serotonin and dopamine may be altered in schizophrenia. Serotonin 5-HT<sub>2A</sub> (and other serotonin) receptor occupancy by the antipsychotic drugs, depending on the areas of the brain involved, could be associated with improvement in cognition, depression and D<sub>2</sub> receptor mediated EPS.

There has been an explosion of new information about the structure and function of 5-HT receptors. To date, 15 serotonin receptor subtypes have been identified. Two receptors, 5-HT<sub>6</sub> and 5-HT<sub>7</sub>, have been proposed as candidates for atypical drug action and are therefore reasonable targets for pathophysiological studies of schizophrenia. It is clear that the field is in the early stages of understanding the possible involvement of serotonin in schizophrenia.

### Glutamate and N-Methyl-D-aspartate Receptor

Glutamate is a major brain excitatory amino acid neurotransmitter and is critically involved in learning, memory and brain development. Interest in glutamate and the NMDA receptor in schizophrenia arose because of the similarity between phencyclidine (PCP) psychosis and the psychosis of schizophrenia. PCP is a noncompetitive antagonist of the NMDA receptor and produces a psychotic state that includes conceptual disorganization, auditory hallucinations, delusions and negative symptoms. PCP produces more symptoms that are similar to those of schizophrenia than most other pharmacological agents.

PCP and other highly potent NMDA receptor antagonists cause neuronal damage and therefore are not used as research tools in clinical populations. However, ketamine, a widely used dissociative anesthetic, is another noncompetitive NMDA antagonist and, at subanesthetic doses, produces a PCP-like psychosis resembling schizophrenia. The glutamate hypothesis of schizophrenia is one of the most active areas of research currently. The NMDA receptor is reported to play a critical role in guiding axons to their final destination during neurodevelopment. Also, abnormalities with glutamate transmission is reported in many areas of the brain such as frontal cortex, hippocampus, limbic

cortex, striatum and thalamus. Moreover, there are changes reported in the gene expression in these areas, Hypoglutamatergia in schizophrenia may have very important downstream modulatory effects on catecholaminergic neurotransmission and play a critical role during neurodevelopment. It also plays an important role in synaptic pruning and underlies important aspects of neurocognition.

## GABA

GABA is the major inhibitory neurotransmitter in brain. Support for GABA's involvement in schizophrenia comes from two lines of investigation. First, clinical trials have demonstrated that benzodiazepines, administered both in conjunction with antipsychotic drugs and as the sole treatment, are effective at reducing symptoms in subgroups of schizophrenia patients. Benzodiazepines are agonists at GABA<sub>A</sub> receptors. Secondly, postmortem studies have found a deficit in GABA interneurons in the anterior cingulum and prefrontal cortex and decreased GABA uptake sites in the hippocampus. GABAergic neurons are especially vulnerable to glucocorticoid hormones and also to glutamatergic excitotoxicity.

## Peptides

Several peptides have been hypothesized to play a pathophysiological role in schizophrenia. Interest in neurotensin arose because of the discovery that it is colocalized in some dopaminergic neurons and acts as a neuromodulator of this and other neurotransmitters. In preclinical studies, neurotensin was found to have effects that resembled those of antipsychotic drugs (Kasckow and Nemeroff, 1991). In addition, schizophrenia patients were found to have lower cerebrospinal fluid neurotensin levels than healthy control subjects and other patients with neuropsychiatric disorders. Other peptides that are under consideration for a pathophysiological role in schizophrenia are somatostatin, dynorphin, substance P and neuropeptide Y.

## Norepinephrine

Heightened noradrenergic function has been implicated in psychotic relapse in subgroups of schizophrenia patients (van Kammen *et al.*, 1990). In addition, clozapine, but not other neuroleptic drugs, consistently produces increases in central and peripheral indices of noradrenergic function, and one study found a significant relationship between increases in plasma norepinephrine and improvement in positive symptoms.

## The Biochemical Theory

Carlsson and colleagues (2001) provide a multineurotransmitter theory of schizophrenia which improves upon previous biochemical theories of schizophrenia. Accumulating evidence suggests that hyperdopaminergia in schizophrenia is probably secondary to some other phenomena. The data involving glutamatergic system suggests that NMDA receptor antagonism enhances the spontaneous and amphetamine-induced release of dopamine and thus raises the possibility that **hypoglutamatergia** could be related to the **hyperdopaminergia**. Carlsson and colleagues propose that psychotogenesis depends on an interaction between dopamine and glutamate pathways projecting to the striatum from the lower brain stem and cortex respectively. These neurotransmitters are predominantly antagonistic to each other, the former being inhibitory and the latter stimulatory when acting on striatal GABAergic projection neurons. These GABAergic

neurons belong to striathalamic pathways, which exert an inhibitory action on thalamocortical glutamatergic neurons, thereby filtering off part of the sensory input to the thalamus to protect the cortex from a sensory overload and hyperarousal. Hyperactivity of dopamine or hypofunction of the corticostriatal glutamate pathway should reduce this protective influence and could thus lead to confusion or psychosis. As a result, the indirect striathalamic pathways have an inhibitory influence on the thalamus with the corresponding direct pathways exerting an opposite and excitatory influence. Both pathways are controlled by glutamatergic corticostriatal pathways enabling the cortex to regulate the thalamic gating in opposite directions. Thus, according to Carlsson and colleagues they appear to serve as **brakes and accelerators**.

It has been suggested that the activity of the direct pathways is predominantly phasic and of the indirect pathways is mainly tonic. This difference could have important consequences for a different responsiveness of the direct and indirect pathways to drugs. Thus the NMDA receptor antagonists are behavioral stimulants. AMPA receptor antagonists act in the same direction as NMDA antagonists in some and opposite direction in other experiments. The relationship between glutamate and serotonin is very important and interesting. Serotonin appears to play a more important role than dopamine in the behavioral stimulation induced by hypoglutamatergia. Serotonin may play a more prominent role than dopamine in the behavioral stimulation induced by hypoglutamatergia. Schizophrenia is a syndrome of heterogeneous etiology and pathology. If one neurotransmitter is disturbed, it will inevitably have an impact on other neurotransmitters (Carlsson *et al.*, 2001).

## Neurodevelopmental Versus Neurodegenerative Disease Processes

Neurodevelopmental hypotheses of schizophrenia posit that a disruption in normal development causes the illness (Weinberger, 1987). Thus, the "lesion" occurs well before the onset of the illness and interacts with maturation events such as neuronal precursor, glial proliferation and migration; axonal and dendritic proliferation; myelination of axons; programmed cell death and synaptic pruning and is in all likelihood a nonprogressive disease process. Support for the neurodevelopment hypothesis includes the fact that the majority of patients with schizophrenia do not have a course of illness marked by progressive deterioration such as found in dementias. In addition, brain morphological abnormalities commonly found in this illness, such as enlarged ventricles and reduced mesolimbic structures, do not appear to be progressive and, in fact, are present at the onset of the illness. Moreover, gliosis, which occurs during active pathological processes as part of the cellular reparative process in mature brains, is not commonly found in postmortem studies of schizophrenia.

That illness onset typically occurs in the teenage years and early twenties, as opposed to earlier in life when the proposed pathogenic insult occurs, has been explained by the fact that brain regions implicated in this illness, such as prefrontal cortex, are still undergoing myelination during the adolescent years and are therefore not fully functional until that time. Thus, an early lesion involving this region could remain silent until adolescence, when its normal functional capacity is expected to be realized. However, these assumptions have proven to be controversial.

## Clinical Manifestations and Phenomenology

### Positive and Negative Symptoms

There has been an emphasis on positive and negative symptom clusters in some schizophrenia patients. In the psychiatric literature, positive symptoms have come to mean those that are actively expressed, such as hallucinations, thought disorder, delusions and bizarre behavior, whereas negative symptoms reflect deficit states such as avolition, flattened affect and alogia. How these distinct symptom patterns are related in schizophrenia remains unresolved.

That schizophrenia could be divided into a two-syndrome concept was put forth by Crow (1980). According to his theory, type I schizophrenia patients are those who present, often more acutely, with a predominantly positive symptom profile and who have a good response to neuroleptics. In contrast, type II schizophrenia patients are those who have a more chronic illness, more frequent evidence of intellectual impairment and enlarged ventricular size and cortical atrophy as seen on CT or MRI scans, a poorer response to neuroleptics and predominantly negative symptoms. Crow further postulated that type I schizophrenia may be secondary to a hyperdopaminergic state, whereas type II disease may be due to structural abnormality of the brain.

The idea that positive and negative symptoms may be overlapping end points along a single continuum of biological and clinical manifestations has been described by Andreasen and colleagues (1982). In their study of 52 schizophrenia patients, they found that negative symptoms correlated with the presence of ventricular enlargement and that patients with small ventricles were more likely to manifest positive symptoms. In a separate report, Andreasen and Olsen (1982) posited that negative and positive symptoms reflect opposite extremes of a spectrum and that a mixed symptom pattern can exist and may be present 30% of the time. Others have suggested that although the positive and negative characteristics may be part of a continuum, they may not be related to the presence or absence of structural brain abnormalities; rather, there may be a relationship between the symptom pattern and outcome, depending on the clinical course.

A categorical scheme for differentiation of so-called primary and secondary negative symptoms was developed by Carpenter and colleagues (1985). This distinction is based in part on the fact that negative symptoms are not pathognomonic of schizophrenia. The negative symptoms that can be seen in a number of other illnesses, including depression and medical illness, and as a result of positive symptoms themselves or the side effects of medication, particularly extrapyramidal symptoms, are considered “secondary”. The negative symptoms that are a core element of schizophrenia are deemed “primary” or “deficit” symptoms. This distinction enables further exploration of outcome variables and the heterogeneity of this illness and in many ways aids treatment decisions.

Because positive and negative symptoms may be seen differently by individual psychiatrists, valid psychometric scales have become important clinical and research tools. The Brief Psychiatric Rating Scale (BPRS) (Overall and Gorham, 1961), for example, includes subscales for positive and negative symptoms, as does the Positive and Negative Syndrome Scale (PANSS) for schizophrenia (Kay *et al.*, 1988). Others have more broadly defined negative symptoms. Crow (1985) proposed the use of a narrow definition, that is, flattened affect and poverty of speech, for negative symptoms, and Andreasen (1981) supported a broader definition in the widely used Scale for the Assessment of Negative

Symptoms (SANS). This psychometric scale includes categories of alogia and flattened affect as well as items such as anhedonia, asociality, avolition, apathy and deficits in attention.

### Symptom Cluster Analysis

Although the dichotomous positive–negative distinction has gained clinical and research recognition, several reports suggest that this division is incomplete. Much of the current interest in understanding the heterogeneity of schizophrenia has involved a more detailed look at the symptoms of schizophrenia. Sophisticated statistical techniques utilize factor analysis to reduce data to elucidate clusters of symptoms that are most likely to group together or be found independently.

An application of this approach found that there are three, rather than two, symptom dimensions that better subdivide schizophrenia. Correlational relationships between symptoms reveal that positive symptoms can be divided into two distinct groups. The first includes psychotic symptoms such as hallucinations and delusions, and the second includes symptoms of disorganization, consisting of thought disorder, bizarre behavior and inappropriate affect. A third group is that of negative symptoms. Although these patterns of symptoms may be seen in different proportions in individuals and may change over time, they can be shown to have distinct clinical courses and may be related to independent neuropsychological deficits in a given individual (Andreasen *et al.*, 1995).

### Cognitive Impairment

Now it is widely accepted that schizophrenia patients experience neuropsychological deficits that can be characterized by difficulties with attention, information processing, executive function, learning and memory, which leads to a generalized performance deficit. Typically, there is a wide variance with some aspects of performance being more impaired than others. Interestingly, a small subgroup of the patients have cognitive functioning within the normal range. Most patients with schizophrenia have only modest reductions in their IQs with an average of 90 and about 0.67 standard deviation below that of the general population. In contrast, their performance is usually worse even in first episode patients. Usually patients with schizophrenia underperform relative to estimates of their premorbid functioning. Cognitive impairments involving verbal learning, verbal delayed recall, working memory, vigilance and executive functioning have a significant negative impact on social and occupational functioning. Two meta-analysis of 24 and nine studies respectively suggest that treatment with novel antipsychotic agents improve cognitive function compared with typical antipsychotic agents (Keefe *et al.*, 1999; Harvey, 2001).

The degree of cognitive deficit appears to be more strongly associated with severity of negative symptoms, symptoms of disorganization and adaptive dysfunction than with positive symptoms. Verbal fluency is severely impaired in patients with psychotic disorders and the use of atypical antipsychotic medications results in significant improvement. Motor functions (e.g., reaction time, motor and graphomotor speed) improve with clozapine, olanzapine and risperidone. Olanzapine improves motor functions more than either haloperidol or risperidone. Furthermore, motor functions are related to outcome, underscoring the importance of this domain. The symbol–digit and digit–symbol tests have been among the most responsive tests to atypical

antipsychotic treatment. Though the novel antipsychotic agents appear to have beneficial effects on cognition, much work still remains to eliminate biases; also, effect sizes of these improvements are modest (Harvey and Keefe, 2001).

### Information Processing and Attention

The term **information processing** is used to describe the process of taking information and encoding it in such a way that it can be understood and recalled when appropriately cued. This construct is related to neural circuits and a stepwise logical spread of neurochemical messages, which may be impaired in schizophrenia. **Attention**, simply defined, is the ability to focus on a stimulus, either through conscious effort or passively. These two constructs are interrelated, and our understanding of their composite parts has increased in complexity in the past few decades.

Measures of attention were developed from the idea that patients with schizophrenia cannot block out unimportant stimuli in the way that those without schizophrenia can. This phenomenon has come to be called **gating**. Gating is usually seen, for example, when a weak stimulus is delivered before a real stimulus. Normally, the first stimulus would dampen or eliminate the response to the second.

In general, patients with schizophrenia have impairments in information processing, especially when they are exposed to increasing demands on their attentional capabilities, such as under timed conditions or in stressful situations. Therefore, these deficits not only are viewed as trait linked (i.e., a manifestation of the illness itself) but may be compounded when state linked (i.e., when there are increases in symptoms). The trait-linked disturbances in neuropsychological parameters are seen in those at high risk for developing schizophrenia, those who have schizophrenia, and relatives who appear clinically unaffected, which may indicate a genetic vulnerability.

Many of these tests of attention and information processing have been associated with specific symptoms and neuropsychological impairment in schizophrenia. For example, one study showed that impaired prepulse inhibition was related to increased perseveration on neuropsychological tests of higher executive function (Butler *et al.*, 1991). Others have shown that deficits in attention and information processing may be associated with positive and/or negative symptoms (Strauss, 1993). Specifically, deficits in visual processing and motor function (as seen with continuous performance tasks) have been linked to negative symptoms (Nuechterlein *et al.*, 1986), whereas positive symptoms seem to be related to auditory-processing dysfunction (Green and Walker, 1986).

### Learning and Memory

Although there are generally no consistent gross deficits of memory in schizophrenia patients, close examination of certain aspects of learning and memory has revealed striking abnormalities. Schizophrenia patients have been shown to be poorer in recall of word lists if the words are not grouped into categories. Furthermore, unlike normal control subjects, schizophrenia patients do not seem to show an improvement in memory when asked to recall words with latent positive emotional meaning. These findings have been attributed to poor cognitive organization in schizophrenia patients.

Others have reported that patients with chronic schizophrenia had impairment in new learning and short-term memory but

not remote memory possibly indicating temporal–hippocampal dysfunction. These may be more likely in patients with a poor premorbid course and ventricular enlargement.

Working memory is a cognitive system that stores and processes information needed for planning and reasoning for a brief duration. Some cognitive scientists refer to short-term memory as working memory. Working memory consists of verbal and visual memory subsystems with a central principle that manipulates and coordinates information stored in the two systems for problem solving, planning and organizing activities. Separate areas of the prefrontal cortex may underlie different aspects of the working memory. The workspace used for such memory is capacity-limited. Patients with schizophrenia have significant dysfunction in this area and are unable to change an ineffective strategy (i.e., shift sets) even when feedback is provided. This dysfunction occurs (albeit at a lower level) even in subjects with higher intelligence. Conventional antipsychotics do not appear to impair or improve working memory in patients with schizophrenia. Studies involving evaluation of working memory using neuroimaging, pharmacological models of schizophrenia and neurochemical function should further our understanding of this manifestation of schizophrenia.

### Differential Diagnosis

Making an accurate diagnosis of schizophrenia requires high levels of clinical acumen, extensive knowledge of schizophrenia and sophisticated application of the principles of differential diagnosis. It is unfortunately common for patients with psychotic disorders to be misdiagnosed and consequently treated inappropriately. The importance of accurate diagnosis is underlined by an emerging database indicating that early detection and prompt pharmacological intervention may improve the long-term prognosis of the illness.

### Mental Status Examination

There is no specific laboratory test, neuroimaging study, or clinical presentation of a patient that yields a definitive diagnosis of schizophrenia. Schizophrenia can present with a wide variety of symptoms, and a longitudinal history of symptoms and comorbid clinical variables such as medical illness and a history of substance abuse are necessary before a diagnosis can be considered. The Mental Status Examination, much like the physical examination, is an additional clinical tool that aids the psychiatrist in generating a differential diagnosis and appropriate treatment recommendations.

### Appearance

Although a disheveled look is not pathognomonic for schizophrenia, patients with this disorder often present, especially acutely, with a disordered appearance. The description of a patient's appearance is an objective verbal sketch, much like the description of a heart murmur, that can uniquely identify a particular patient.

A person with schizophrenia often has difficulty attending to activities of daily living, either because of negative symptoms (apathy, social withdrawal, or motor retardation) or because of the presence of positive symptoms, such as psychosis, disorganization, or catatonia, that interfere with the ability to maintain personal hygiene. Also, schizophrenia patients often present with odd or inappropriate attire, such as a coat and hat worn during the summer or dark sunglasses worn during an interview. It

is generally thought that the inappropriate dress is a manifestation of symptoms such as disorganization or paranoid ideation. It should be noted that some patients present quite neatly groomed. Thus appearance is noted but is not diagnostic.

### Attitude

Individuals with schizophrenia may be friendly and cooperative, or they may be hostile, annoyed and defensive during an interview. The latter may be secondary to paranoid symptoms, which can make patients quite cautious and guarded in their responses to questions.

### Behavior

Schizophrenic patients can have bizarre mannerisms or stereotyped movements that can make them look unusual. Patients with catatonia can stay in one position for weeks, even to the point of causing serious physical damage to their body; for example, a patient who stands in one place for days may develop stress fractures, peripheral edema and even pulmonary emboli. Patients with catatonia may have waxy flexibility, maintaining a position after someone else has moved them into it. Patients with catatonic excitement exhibit odd posturing or purposeless, repetitive, and often strange movements.

Behaviors seen in schizophrenia patients include choreoathetoid movements, which may be related to neuroleptic exposure but have been reported in patients even before neuroleptic use. Other behaviors or movement disorders may be seen as parkinsonian features, such as a shuffling gait or a pill-rolling tremor.

Psychomotor retardation may be present and may be a manifestation of catatonia or negative symptoms. On close observation, it is usually characterized, in this group of patients, as a lack of motor movements rather than slowed movements.

Patients may present with agitation, ranging from minimal to extreme. This agitation is often seen in the acute state and may require immediate pharmacotherapy. However, agitation may be secondary to neuroleptic medications, as in akathisia, which is felt as an internal restlessness making it difficult for the person to sit still. Akathisia can manifest itself in limb shaking, pacing, or frequent shifting of position. Severely agitated patients may be unresponsive to verbal limits and may require measures to ensure their safety and the safety of others around them.

### Eye Contact

Paranoid patients may look hypervigilant, scanning a room or glancing suspiciously at an interviewer. Psychotic patients may make poor eye contact, looking away, or appear to stare vacuously at the interviewer, making a conversational connection seem distant. Characteristic responding to internal stimuli is seen when a patient appears to look toward a voice or an auditory hallucination, which the patient may hear. A nystagmus may also be observed. This clinical finding has a large differential diagnosis, including Wernicke-Korsakoff syndrome; alcohol, barbiturate, or phenytoin intoxication; viral labyrinthitis; or brain stem syndromes including infarctions or multiple sclerosis.

### Speech

In a Mental Status Examination, one usually comments on the rate, tone and volume of a patient's speech, as well as any distinct

dysarthrias that may be present. Pressured speech is usually thought of in conjunction with mania; however, it can be seen in schizophrenia patients, particularly on acute presentation. This is often difficult to assess, as it may be a normal variant or a cultural phenomenon, because some languages are spoken faster than others.

Tone refers to prosody, or the natural singsong quality of speech. Negative symptoms may include a lack of prosody, resulting in monotonous speech. Furthermore, odd tones may be consistent with neurological disorders or bizarre behavior.

Speech volume is important for a number of reasons. Loud speech can be a measure of agitation; it can occur in conjunction with psychosis, or it could even be an indication of hearing loss. Speech that is soft may be an indication of guardedness or anxiety.

Dysarthrias are notable because they can be idiopathic and longstanding, or they can be an indication of neurological disturbance. In patients who have been exposed to neuroleptics, orobuccal tardive dyskinesia should be considered when there is evidence of slurred speech.

### Mood and Affect

Affect, which is the observer's objective view of the patient's emotional state, is often constricted or flat in patients with schizophrenia. In fact, this is one of the hallmark negative symptoms. Flattened affect may also be a manifestation of pseudoparkinsonism, an extrapyramidal side effect of typical neuroleptics.

Inappropriate affect is commonly seen in patients with more predominant positive symptoms. A smile or a laugh while relating a sad tale is an example. Patients with catatonic excitement or hebephrenia may have bizarre presentations or affective lability, laughing and crying out of context with the situation. Emotional reactivity must alert the clinician to the possibility of neurological impairment as well, as in the case of pseudobulbar palsy.

Mood is based on a patient's subjective report of how he or she feels, emotionally, at the time of the interview. It is not uncommon for patients with schizophrenia to be depressed (especially patients with history of higher premorbid functioning who may have some insight into the losses they are facing) or to be indifferent, with seemingly no emotional awareness of their situation.

### Thought Process

Because actual thoughts cannot be measured, thought processes are assessed by extrapolation from the organization of speech. Thought disorders can be more or less obvious, and a trained listener is one who appreciates the normal logical pattern of flow of words and ideas in speech and can thus sense abnormalities.

There are many different versions of thought disorders: lack of logical connections of ideas (looseness of associations); shift of the original theme because of weak connections of ideas (tangentiality); overinclusiveness to the point of loss of the theme (circumstantiality); use of words and phrases with no relation to grammatical rules (word salad); repetition of words spoken by others (echolalia); use of sounds of other words, such as "yellow bellow, who is this fellow?" (clang associations); use of made-up words (neologisms); and repetition of a particular word or phrase, such as "this and that, this and that" (perseveration).

Other thought disorders are part of a constellation of negative symptoms. Examples would be thoughts that appear to stop abruptly, either because of interruption by an auditory hallucination or because the thought is lost (thought blocking);

absence of thoughts (paucity of thought content); and a delayed response to questions (increased latency of response).

### Thought Content

Although not necessarily present in every patient, characteristic symptoms of schizophrenia include the belief that outside forces control a person's thought or actions. A patient might report that others can insert thoughts into her or his head (thought insertion), broadcast them to others (thought broadcasting), or take thoughts away (thought withdrawal). Other delusions, or fixed false beliefs, may also be prominent. Patients may describe ideas of reference, which is the phenomenon of feeling that some external event or report relates to oneself specifically; for example, a patient may infer special meaning from an image seen on television or a broadcast heard on the radio.

Paranoid ideation may be manifested as general suspiciousness or frank, well-systematized delusions. The themes may be considered bizarre, such as feeling convinced that aliens are sending signals through wires in the patient's ear, or nonbizarre, such as being watched by the Central Intelligence Agency or believing that one's spouse is having an affair. These symptoms can be quite debilitating and lead to a great deal of personal loss, which patients may not understand because the ideas are so real to them.

Patients with schizophrenia commonly express an abundance of vague somatic concerns, and a particular patient might develop a delusion around a real physiological abnormality. Therefore, somatic symptoms should be evaluated appropriately in their clinical context without automatically dismissing them as psychotic. Preoccupations and obsessions are also seen commonly in this population, and certain patients have comorbid obsessive-compulsive disorder.

The mortality rate for suicide in schizophrenia is approximately 10%. It is therefore imperative to evaluate a patient for both suicidal and homicidal ideation. Patients of all diagnoses, and particularly schizophrenia, may not spontaneously articulate suicidal or homicidal ideation and must therefore be asked directly about such feelings. Moreover, psychotic patients may feel compelled by an auditory hallucination telling them to hurt themselves.

### Perceptions

Perceptual disturbances involve illusions and hallucinations. Hallucinations may be olfactory, tactile, gustatory, visual, or auditory, although hallucinations of the auditory type are more typical of schizophrenia. Hallucinations in the other sensory modalities are more commonly seen in other medical or substance-induced conditions. Auditory hallucinations can resemble sounds, background noise, or human voices. Auditory hallucinations that consist of a running dialogue between two or more voices or a commentary on the patient's behavior are typical of schizophrenia. These hallucinations are distinct from verbalized thoughts that most humans experience. They are often described as originating from outside the patient's head, as if they were emanating from the walls or the radiators in the room. Less commonly, a patient with schizophrenia describes illusions or misperceptions of a real stimulus, such as seeing demons in a shadow.

### Consciousness and Orientation

Patients with schizophrenia most likely have a clear sensorium unless there is some comorbid medical illness or substance-

related phenomenon. A schizophrenia patient may be disoriented, but this could be a result of inattentiveness to details or distraction secondary to psychotic preoccupation.

### Attention and Concentration

Studies utilizing continuous performance task paradigms have demonstrated repeatedly that schizophrenia patients have pervasive deficits in attention in both acute and residual phases. On a Mental Status Examination, these deficits may present themselves as the inability to perform mental exercises, such as spelling the word "earth" backward or serial subtractions.

### Memory

Careful assessment of memory in patients with schizophrenia may yield some deficits. Acquisition of new information, immediate recall, and recent and remote memory may be impaired in some individuals. Furthermore, answers to questions regarding memory may lead to idiosyncratic responses related to delusions, thought disorder, or other overriding symptoms of the illness. In general, schizophrenia patients do not show gross deficits of memory such as may be seen in patients with dementia or head trauma.

### Fund of Knowledge

Schizophrenia is not the equivalent of mental retardation, although these syndromes can coexist in some patients. Patients with schizophrenia generally experience a slight shift in intellectual functioning after the onset of their illness, yet they typically demonstrate a fund of knowledge consistent with their premorbid level. Schizophrenia patients manifest a characteristic discrepancy on standardized tests of intelligence, with the nonverbal scores being lower than the verbal scores.

### Abstraction

A classical aberration of mental function in a patient with schizophrenia involves the inability to utilize abstract reasoning, which is similar to metaphorical thinking, or the ability to conceptualize ideas beyond their literal meaning. For example, when the patient is asked what brought him or her to the hospital, a typical answer might be "an ambulance". On a Mental Status Examination, this concrete thinking is best elicited by asking a patient to interpret a proverb or state the similarities between two objects. For example, "a rolling stone gathers no moss" may mean, to the patient with schizophrenia, that "if a stone just stays in one place, the moss won't be able to collect". More profound difficulties in abstraction and executive function, often seen in schizophrenia, such as inability to shift cognitive focus or set, may be assessed by neuropsychological tests.

### Judgment and Insight

Individuals suffering from schizophrenia often display a lack of insight regarding their illness. Whether it is a reflection of a negative symptom, such as apathy, or a constricted display of emotion, patients often appear to be emotionally disconnected from their illness and may even deny that anything is wrong. Poor judgment, which is also characteristic and may be related to lack of insight, may lead to potentially dangerous behavior. For example,

a patient walking barefoot in the snow because of the feeling that her or his shoes could be traced by surveillance cameras would be displaying both poor judgment and poor insight. On a formal Mental Status Examination, judgment is commonly assessed by asking patients what they would do if they saw a fire in a movie theater or if they saw a stamped, addressed envelope on the street. Insight can be ascertained by asking patients about their understanding of why they are being evaluated by a psychiatrist or why they are receiving a certain medication.

## Physical Examination

Although there are no pathognomonic physical signs of schizophrenia, some patients have neurological “soft” signs on physical examination. The neurological deficits include nonspecific abnormalities in reflexes, coordination (as seen in gait and finger-to-nose tests), graphesthesia (recognition of patterns marked out on the palm) and stereognosis (recognition of three-dimensional pictures). Other neurological findings include odd or awkward movements (possibly correlated with thought disorder), alterations in muscle tone, an increased blink rate, a slower habituation of the blink response to repetitive glabellar tap and an abnormal pupillary response.

The exact etiology of these abnormalities is unknown, but they have historically been associated with minimal brain dysfunction and may be more likely in patients with poor premorbid functioning. These neurological abnormalities have been seen in neuroleptic-naïve patients as well as those with exposure to traditional antipsychotic medication. Overall, the literature suggests that these findings may be associated with the disease itself.

Neuroophthalmological investigations have shown that patients with schizophrenia have abnormalities in voluntary saccadic eye movements (rapid eye movement toward a stationary object) as well as in smooth pursuit eye movements. The influence of attention and distraction, neuroleptic exposure and the specificity of smooth pursuit eye movements for schizophrenia have raised criticisms of this area of study, and further investigation is necessary to determine its potential as a putative genetic marker for schizophrenia.

## Other Conditions that Resemble Schizophrenia

### Schizoaffective Disorder

Possibly the most difficult diagnostic dilemma in cases in which a patient has both psychotic symptoms and affective symptoms is in the differentiation between schizophrenia and schizoaffective disorder. There has been some controversy regarding this diagnostic entity. It has been included in studies of both affective disorder and schizophrenia and has at times been considered part of a continuum between the two, which has contributed to some of the diagnostic confusion.

In DSM-IV, schizoaffective disorder is treated as a unique clinical syndrome. A patient with schizoaffective disorder must have an uninterrupted period of illness during which, at some time, they have symptoms that meet the diagnostic criteria for a major depressive episode, manic episode, or a mixed episode concurrently with the diagnostic criteria for the active phase of schizophrenia (criteria A for schizophrenia). Additionally, the patient must have had delusions or hallucinations for at least 2 weeks in the absence of prominent mood disorder symptoms

during the same period of illness. The mood disorder symptoms must be present for a substantial part of the active and residual psychotic period. The essential features of schizoaffective disorder must occur within a single uninterrupted period of illness where the “period of illness” refers to the period of active or residual symptoms of psychotic illness and this can last for years and decades. The total duration of psychotic symptoms must be at least 1 month to meet criteria A for schizophrenia and thus the minimum duration of a schizoaffective episode is also 1 month.

## DSM-IV-TR Criteria 295.70

### Schizoaffective Disorder

An uninterrupted period of

- A. illness during which, at some time, there is either a major depressive episode, a manic episode, or a mixed episode concurrent with symptoms that meet criterion A for schizophrenia.

**Note:** The major depressive episode must include criterion A1: depressed mood.

- B. During the same period of illness, there have been delusions or hallucinations for at least 2 weeks in the absence of prominent mood symptoms.
- C. Symptoms that meet criteria for a mood episode are present for a substantial portion of the total duration of the active and residual periods of the illness.
- D. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

*Specify type:*

**Bipolar type:** if the disturbance includes a manic or a mixed episode (or a manic or a mixed episode and major depressive episodes)

**Depressive type:** if the disturbance only includes major depressive episodes

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

The criteria for a major depressive episode requires a minimum duration of 2 weeks of either depressed mood or markedly diminished interest or pleasure. As the symptoms of loss of pleasure or interest commonly occur in nonaffective psychotic disorders, to meet the criteria for schizoaffective disorder criteria A, the major depressive episode must include pervasive depressed mood. Presence of markedly diminished interest or pleasure is not sufficient to make a diagnosis as it is possible that these symptoms may also occur with other conditions.

### Brief Psychotic Disorder and Schizophreniform Disorder

The distinctions among brief psychotic disorder, schizophreniform disorder and schizophrenia are based on duration of active symptoms. DSM-IV has established the requirement of 6 months of active, prodromal, and/or residual symptoms for a diagnosis

of schizophrenia. Brief psychotic disorder is a transient psychotic state, not caused by medical conditions or substance use, that lasts for at least 1 day and up to 1 month. Schizophreniform disorder falls in between and requires symptoms for at least 1 month and not exceeding 6 months, with no requirement for loss of functioning.

### DSM-IV-TR Criteria 298.8

#### Brief Psychotic Disorder

A. Presence of one (or more) of the following symptoms:

- (1) delusions
- (2) hallucinations
- (3) disorganized speech (e.g., frequent derailment or incoherence)
- (4) grossly disorganized or catatonic behavior

**Note:** Do not include a symptom if it is a culturally sanctioned response pattern.

B. Duration of an episode of the disturbance is at least 1 day but less than 1 month, with eventual full return to premorbid level of functioning.

C. The disturbance is not better accounted for by a mood disorder with psychotic features, schizoaffective disorder, or schizophrenia and is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

*Specify if:*

**With marked stressor(s)** (brief reactive psychosis): if symptoms occur shortly after and apparently in response to events that, singly or together, would be markedly stressful to almost anyone in similar circumstances in the person's culture

**Without marked stressor(s):** if psychotic symptoms do not occur shortly after, or are not apparently in response to events that, singly or together, would be markedly stressful to almost anyone in similar circumstances in the person's culture

**With postpartum onset:** if onset within 4 weeks postpartum

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

### DSM-IV-TR Criteria 295.40

#### Schizophreniform Disorder

A. Criteria A, D, and E of schizophrenia are met.

B. An episode of the disorder (including prodromal, active, and residual phases) lasts at least 1 month but less than 6 months. (When the diagnosis must be made without waiting for recovery, it should be qualified as "provisional.")

*Specify if:*

**Without good prognostic features**

**With good prognostic features:** as evidenced by two (or more) of the following:

- (1) onset of prominent psychotic symptoms within 4 weeks of the first noticeable change in usual behavior or functioning
- (2) confusion or perplexity at the height of the psychotic episode
- (3) good premorbid social and occupational functioning
- (4) absence of blunted or flat affect

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

#### Delusional Disorder

If the delusions that a patient describes are not bizarre (e.g., examples of bizarre delusions include the belief that an outside force or person has taken over one's body or that radio signals are being sent through the caps in one's teeth), it is wise to consider delusional disorder in the differential diagnosis. Delusional disorder is usually characterized by specific types of false fixed beliefs such as erotomanic, grandiose, jealous, persecutory, or somatic types. Delusional disorder, unlike schizophrenia, is not associated with a marked social impairment or odd behavior. Moreover, patients with delusional disorder do not experience hallucinations or typically have negative symptoms.

### DSM-IV-TR Criteria 297.1

#### Delusional Disorder

Nonbizarre delusions (i.e., A. involving situations that occur in real life, such as being followed, poisoned, infected, loved at a distance, or deceived by spouse or lover, or having a disease) of at least 1 month's duration.

B. Criterion A for schizophrenia has never been met.

**Note:** Tactile and olfactory hallucinations may be present in delusional disorder if they are related to the delusional theme.

C. Apart from the impact of the delusion(s) or its ramifications, functioning is not markedly impaired and behavior is not obviously odd or bizarre.

D. If mood episodes have occurred concurrently with delusions, their total duration has been brief relative to the duration of the delusional periods.

E. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

*Specify type* (the following types are assigned based on the predominant delusional theme):

**Erotomanic type:** delusions that another person, usually of higher status, is in love with the individual

**Grandiose type:** delusions of inflated worth, power, knowledge, identity, or special relationship to a deity or famous person

**Jealous type:** delusions that the individual's sexual partner is unfaithful

**Persecutory type:** delusions that the person (or someone to whom the person is close) is being malevolently treated in some way

**Somatic type:** delusions that the person has some physical defect or general medical condition

**Mixed type:** delusions characteristic of more than one of the above types but no one theme predominates

**Unspecified type**

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

### Affective Disorder with Psychotic Features

If the patient experiences psychotic symptoms solely during times when affective symptoms are present, the diagnosis is more likely to be mood disorder with psychotic features. If the mood disturbance involves both manic and depressive episodes, the diagnosis is bipolar disorder. According to DSM-IV, affective disorders that are seen in patients with schizophrenia may fall in the category depressive disorder not otherwise specified or bipolar disorder not otherwise specified.

### Substance-related Conditions

Psychotic disorders, delirium and dementia that are caused by substance use, in DSM-IV, are distinguished from schizophrenia by virtue of the fact that there is clear-cut evidence of substance use leading to symptoms. Examples of psychotomimetic properties of substances include a PCP psychosis that can resemble schizophrenia clinically, chronic alcohol intoxication (Korsakoff's psychosis) and chronic amphetamine administration, which can lead to paranoid states. Therefore, patients who have symptoms that meet criterion A of schizophrenia in the presence of substance use must be reevaluated after a significant period away from the suspected substance, and proper toxicology screens must be performed to rule out recent substance abuse.

### General Medical Conditions

General medical conditions ranging from vitamin B<sub>12</sub> deficiency to Cushing's syndrome have been associated with a clinical

presentation resembling that of schizophrenia. Because the prognosis for the associated medical condition is better than that for schizophrenia and the stigma attached to schizophrenia is significant, it is imperative to provide patients with a thorough medical work-up before giving a diagnosis of schizophrenia. This includes a physical examination; laboratory analyses including thyroid function tests, syphilis screening, and folate and vitamin B<sub>12</sub> levels; a CT or MRI scan; and a lumbar puncture when indicated in new-onset cases.

### Course of Illness

In long-term follow-up studies of 20 years or more, surprisingly favorable outcomes were observed: between 40 and 66% of patients had either recovered or were only mildly impaired at follow-up (Table 45.1). In the Vermont Longitudinal Study of Schizophrenia (Harding *et al.*, 1987a, 1987b), 269 backward patients who were chronically institutionalized in the 1950s were followed up an average of 32 years later. The patients who met rigorously applied retrospective DSM-III diagnostic criteria for schizophrenia disorder ( $N = 118$ ) during their index admission in the 1950s were found on follow-up to have outcomes that varied widely; 82% were not hospitalized in the year of the follow-up, 68% displayed slight or no symptoms, 81% were able to meet their own basic needs, and more than 60% had good social functioning. Thus, these data indicate that the long-term outcome of schizophrenia is heterogeneous, with substantially larger numbers of patients having better outcomes than would have been predicted by the Kraepelinian model that postulated this illness was a dementia and worsened over time.

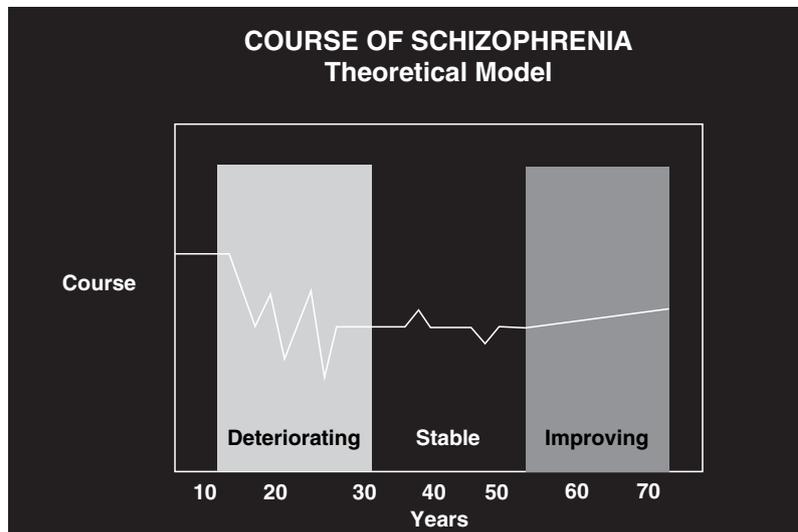

Based on current epidemiological data, a new model of the natural course of schizophrenia has been proposed (Breier *et al.*, 1991). This model has three phases: an early phase marked by deterioration from premorbid levels of functioning; a middle phase characterized by a prolonged period of little change termed the stabilization phase; and the last period, which incorporates the long-term outcome data just cited, which is called the improving phase (Figure 45.2).

### First Episode Schizophrenia

An enormous clinical and research effort is directed internationally towards patients in very early stages of their illness and especially during their first psychotic break with a focus on early and effective intervention. First episode provides a unique opportunity to intervene early and effectively and possibly change the course of illness. It is well known that there is a delay of 1

**Table 45.1** Long-term Follow-up Studies of Schizophrenia

Study	Location	Length of Follow-up (mean, year)	Sample Size ( $N$ )	Recovered or Significantly Improved (%)
DeSisto <i>et al.</i> (1992)	Maine	36	117	45
Harding <i>et al.</i> (1987)	Vermont	32	82	67
Tsuang <i>et al.</i> (1979)	Iowa	35	186	46
Huber <i>et al.</i> (1982)	Bonn	22	502	57
Ciampi <i>et al.</i> (1982)	Lausanne	37	289	53
Bleuler (1987)	Zurich	23	208	53

**Figure 45.2** Model of the lifelong course of illness for schizophrenia. Reprinted with permission from Breier A, Schreiber JL, Dyer J, et al. [1991] National Institute of Mental Health longitudinal study of chronic schizophrenia: Prognosis and prediction of outcome. *Arch Gen Psychiatr* 48, 239–246. Copyright 1991, American Medical Association.

to 2 years on an average between onset of psychosis and starting of treatment. This duration of untreated psychosis (DUP) is recognized by many though not all as an important indicator of subsequent clinical outcome. Larsen and colleagues (2000) examined 1-year outcome in 43 first episode patients and at 1-year follow-up 56% were in remission, 26% were still psychotic and 18% suffered multiple relapses. Both longer DUP and poor premorbid functioning predicted more negative symptoms and poor global functioning. DUP remained a strong predictor of outcome even after controlling for premorbid functioning. Clinical deterioration appears to be correlated with the duration of psychosis and number of episodes of psychosis. The deterioration usually occurs during the first 5 years after onset and then stabilize at a level where they have persistent symptoms and are impaired in their social and vocational function. After that point additional exacerbation may occur but they are not usually associated with further deterioration.

Long-term studies of schizophrenia suggest that negative symptoms tend to be less common and less severe in the early stages of the illness but increase in prevalence and severity in the later stages. Positive symptoms such as delusions and hallucinations are more common earlier on while thought disorganization, inappropriate affect and motor symptoms occur more commonly in the later stages of illness. A possible decline in the prevalence of the hebephrenic and catatonic subtypes of schizophrenia may be attributed to effective treatment and possible arrest of the progression of illness. Thus with effective treatment, and with long-term compliance it is possible to produce favorable outcomes.

Following onset of the illness, patients experience substantial decline in cognitive functions from their premorbid levels. However, it is unclear whether, after the first episode, there is further cognitive decline due to the illness. Some studies even suggest a slight and gradual improvement. Increased number of episodes and the longer duration of untreated psychosis are associated with greater cognitive dysfunction.

Patients with first episode psychosis usually have excellent clinical response to antipsychotic treatment early in their course of illness when compared with chronic multi-episode patients. Effective and early intervention does help achieve clinical

remission and good outcome (Lieberman *et al.*, 1993). Some suggest that atypical antipsychotic medication should be used preferentially in the treatment of first episode patients with psychotic disorders (Lieberman, 1996) as they are a highly treatment responsive group, and may be best able to optimize the outcome. In addition, first episode patients are sensitive to side effects, especially extrapyramidal and weight gain side effects. They require lower doses of medication to achieve therapeutic responses. The issue of treatment adherence is of critical importance in first episode patients. Although these patients respond very well with 1 year remission rates of greater than >80%, the 1-year attrition rates are as high as 60%. This important issue undermines management of first episode patients during this critical period of their illness.

### Treatment

It could be argued that the successful treatment of schizophrenia requires a greater level of clinical knowledge and sophistication than the treatment of most other psychiatric and medical illnesses. It begins with the formation of a therapeutic psychiatrist–patient relationship and must combine the latest developments in pharmacological and psychosocial therapeutics and interventions.

### Psychiatrist–Patient Relationship

The psychiatrist–patient relationship is the foundation for treating patients with schizophrenia. Because of the clinical manifestations of the illness, the formation of this relationship is often difficult. Paranoid delusions may lead to mistrust of the psychiatrist. Conceptual disorganization and cognitive impairment make it difficult for patients to attend to what the psychiatrist is saying and to follow even the simplest directions. Negative symptoms result in lack of emotional expression and social withdrawal, which can be demoralizing for the psychiatrist who is attempting to “connect” with the patient.

It is important for the psychiatrist to understand the ways in which the psychopathology of the illness affects the therapeutic relationship. The psychiatrist should provide constancy to the patient, which helps “anchor” patients in their turbulent world.

The qualities of the relationship should include consistency, acceptance, appropriate levels of warmth that respect the patient's needs for titrating emotional intensity, nonintrusiveness and, most important, caring. "Old-fashioned" family doctors who know their patients well, are easily approachable, have a matter-of-fact style, attend to a broad range of needs, and are available and willing to reach out during crises provide a useful model for the psychiatrist-patient relationship in the treatment of schizophrenia.

## Psychopharmacological Treatment

### Background

The seminal work of Delay and Deniker (1952) provided a pharmacological strategy that would forever change the face of schizophrenia. The implementation of chlorpromazine became the turning point for psychopharmacology. Patients who had been institutionalized for years were able to receive treatment as outpatients and live in community settings. The road was paved for the deinstitutionalization movement, and scientific understanding of the pathophysiology of schizophrenia burgeoned. The introduction of clozapine started the era of antipsychotic agents being referred to as either "typical" (**conventional** or **traditional**) or "atypical" (or **novel**) antipsychotic drugs. If chlorpromazine started the first revolution in the psychopharmacological treatment of schizophrenia, then clozapine ushered in the second and more profound revolution whose impact is felt beyond schizophrenia and its full extent is yet to be realized. Moreover, clozapine has invigorated the psychopharmacology of schizophrenia and rekindled one of the most ambitious searches for new antipsychotic compounds by the pharmaceutical industry. There are now five novel antipsychotics in the USA: risperidone, olanzapine, quetiapine, ziprasidone and aripiprazole.

### Clozapine and the Novel Antipsychotic Agents

Double-blind, controlled studies demonstrated the superior clinical efficacy of clozapine compared with standard neuroleptics, without the associated extrapyramidal symptoms. It is clearly superior to traditional neuroleptics for psychosis. Approximately 50% of patients with chronic and treatment-resistant schizophrenia derive a better response from clozapine than from traditional neuroleptics. Its effect on negative symptoms is somewhat controversial and has started an intense and a passionate debate as to whether the efficacy of the medication is with primary or secondary negative symptoms or both (Meltzer, 1989a). There is substantial evidence that clozapine decreases relapses, improves stability in the community, and diminishes suicidal behavior. There have also been reports that clozapine may cause a gradual reduction in preexisting tardive dyskinesia.

Unfortunately, clozapine is associated with agranulocytosis and, because of this risk, it requires weekly white blood cell testing. Approximately 0.8% of patients taking clozapine and receiving weekly white blood cell monitoring develop agranulocytosis. Women and the elderly are at higher risk than other groups. The period of highest risk is the first 6 months of treatment. These data has led to monitoring of white cell counts less frequently after first 6 months to every other week if a person has a history of white cell counts the within the normal range in the preceding 6 months. Current guidelines state that the medication must be held back if the total white blood cell count is 3000/mm<sup>3</sup> or less or if the absolute polymorphonuclear cell count is 1500/mm<sup>3</sup> or less. Patients who stop clozapine treatment continue to require blood

monitoring for at least 4 weeks after the last dose according to current guidelines. Other side effects of clozapine include orthostatic hypotension, tachycardia, sialorrhea, sedation, elevated temperature and weight gain. Furthermore, clozapine can lower the seizure threshold in a dose-dependent fashion, with a higher risk of seizures seen particularly at doses greater than 600 mg/day.

Clozapine has an affinity for dopamine receptors (D<sub>1</sub>, D<sub>2</sub>, D<sub>3</sub>, D<sub>4</sub> and D<sub>5</sub>), serotonin receptors (5-HT<sub>2A</sub>, 5-HT<sub>2C</sub>, 5-HT<sub>6</sub> and 5-HT<sub>7</sub>), alpha-1- and alpha-2-adrenergic receptors, nicotinic and muscarinic cholinergic receptors and H<sub>1</sub> histaminergic receptors. As clozapine has a relatively shorter half-life, it is usually administered twice a day.

The superior antipsychotic efficacy of clozapine has inspired an abundance of research in the field of modern psychopharmacology for the treatment of schizophrenia. Clozapine and the other novel compounds have an array of biochemical profiles, with affinities to dopaminergic, serotonergic and noradrenergic receptors. Research on the atypical antipsychotic compounds has led to a greater understanding of the biochemical effects of antipsychotic agents, leaving the basic dopamine hypothesis of schizophrenia insufficient to explain schizophrenic symptoms. Clozapine shows selectivity for mesolimbic neurons and does not increase the prolactin level. Binding studies have shown it to be a relatively weak D<sub>1</sub> and D<sub>2</sub> antagonist, compared with traditional neuroleptics (Farde *et al.*, 1989). Clozapine shares the property of higher serotonin 5-HT<sub>2A</sub> to dopamine D<sub>2</sub> blockade ratio reported to impart atypicality. The noradrenergic system may also have a role in the mechanism of action of clozapine (Breier, 1994). Clozapine, but not traditional neuroleptics, causes up to fivefold increases in plasma norepinephrine. Moreover, these increases in norepinephrine correlated with clinical response.

Risperidone is a benzisoxazol compound with a high affinity for 5-HT<sub>2A</sub> and D<sub>2</sub> receptors and has a high serotonin dopamine receptor antagonism ratio. It has high affinity for alpha-1-adrenergic and H<sub>1</sub> histaminergic receptors and moderate affinity for alpha-2-adrenergic receptors. Risperidone is devoid of significant activity against the cholinergic system and the D<sub>1</sub> receptors. The efficacy of this medication is equal to that of other first-line atypical antipsychotic agents and is well tolerated and can be given once or twice a day. It is available in a liquid form as well. The most common side effects reported are drowsiness, orthostatic hypotension, lightheadedness, anxiety, akathisia, constipation, nausea, nasal congestion, prolactin elevation and weight gain. At doses above 6 mg/day EPS can become a significant issue. The risk of tardive dyskinesia at the regular therapeutic doses is low.

Olanzapine, a thienobenzodiazepine compound, has antagonistic effects at dopamine D<sub>1</sub> through D<sub>3</sub> receptors and serotonin 5-HT<sub>2A</sub>, 5-HT<sub>2C</sub> and 5-HT<sub>6</sub> receptors. The antiserotonergic activity is more potent than the antidopaminergic one. It also has affinity for alpha-1-adrenergic, M<sub>1</sub> muscarinic acetylcholinergic and H<sub>1</sub> histaminergic receptors. It differs from clozapine by not having high affinity for the 5-HT<sub>7</sub>, alpha-2-adrenergic and other cholinergic receptors. It has significant efficacy against positive and negative symptoms and also improves cognitive functions. EPS is minimal when used in the therapeutic range with the exception of mild akathisia. As the compound has a long half-life, it is used once a day and as it is well tolerated, it can be started at a higher dose or rapidly titrated to the most effective dose. It is available as a rapidly disintegrating wafer form, which dissolves immediately in the mouth, and as an intramuscular form. The major side effects of olanzapine include significant weight gain, sedation, dry mouth, nausea, lightheadedness, orthostatic

hypotension, dizziness, constipation, headache, akathisia and transient elevation of hepatic transaminases. The risk of tardive dyskinesia and NMS is low. Though used as a once-a-day medication, it is often administered twice a day with the average dose of 15 to 20 mg/day. However, doses higher than 20 mg/day are often used clinically and are thus being evaluated in clinical trials.

Quetiapine, a dibenzothiazepine compound has a greater affinity for serotonin 5-HT<sub>2</sub> receptors than for dopamine D<sub>2</sub> receptors; it has considerable activity at dopamine D<sub>1</sub>, D<sub>5</sub>, D<sub>3</sub>, D<sub>4</sub>, serotonin 5-HT<sub>1A</sub>, and alpha-1-, and alpha-2-adrenergic receptors. Unlike clozapine, it lacks affinity for the muscarinic cholinergic receptors. It is usually administered twice a day due to a short half-life. Quetiapine is as effective as typical agents and also appears to improve cognitive function. Among 2035 patients enrolled in seven controlled studies, quetiapine at all doses used did not have an EPS rate greater than placebo. This is in contrast to olanzapine, risperidone and ziprasidone, where there were dose related effects on EPS levels. The rate of treatment emergent EPS was very low even in high at-risk populations such as adolescent, parkinsonian patients with psychosis and geriatric patients. Major side effects include somnolence, postural hypotension, dizziness, agitation, dry mouth and weight gain. Akathisia occurs on rare occasions. The package insert warns about developing lenticular opacity or cataracts and advises periodic eye examination based on data from animal studies. However, recent data suggest that this risk may be minimal.

Ziprasidone has the strongest 5-HT<sub>2A</sub> receptor binding relative to D<sub>2</sub> binding amongst the atypical agents currently in use. Interestingly, ziprasidone has 5-HT<sub>1A</sub> agonist and 5-HT<sub>1D</sub> antagonist properties with a high affinity for 5-HT<sub>1A</sub>, 5-HT<sub>2C</sub> and 5-HT<sub>1D</sub> receptors. As it does not interact with many other neurotransmitter systems, it does not cause anticholinergic side effects and produces little orthostatic hypotension and relatively little sedation. Just like some antidepressants, ziprasidone blocks presynaptic reuptake of serotonin and norepinephrine. Ziprasidone has a relatively short half-life and thus it should be administered twice a day and along with food for best absorption. Ziprasidone is not completely dependent on CYP3A4 system for metabolism, thus inhibitors of the cytochrome system do not significantly change the blood levels. Ziprasidone at doses between 80 and 160 mg/day is probably the most effective agent for treating symptoms of schizophrenia. To assess the cardiac risk of ziprasidone and other antipsychotic agents a landmark study was designed to evaluate the cardiac safety of the antipsychotic agents, given at high doses alone and with a known metabolic inhibitor in a randomized study involving patients with schizophrenia. This was done to replicate the possible worst-case scenario (overdose or dangerous combination treatment) in the real world. All antipsychotic agents studied caused some degree of QTc prolongation, with the oral form of haloperidol associated with the least and thioridazine with the greatest degree. Major side effects reported with the use of ziprasidone are somnolence, nausea, insomnia, dyspepsia and prolongation of QTc interval. Dizziness, weakness, nasal discharge, orthostatic hypotension and tachycardia occur less commonly.

Ziprasidone should not be used in combination with other drugs that cause **significant** prolongation of the QTc interval. It is also contraindicated for patients with a known history of significant QTc prolongation, recent myocardial infarction, or symptomatic heart failure. Ziprasidone has low EPS potential, does not elevate prolactin levels and causes approximately 1 lb weight gain in short-term studies.

At present, with respect to efficacy, it does not appear that any one of the novel antipsychotic agents (except clozapine) is

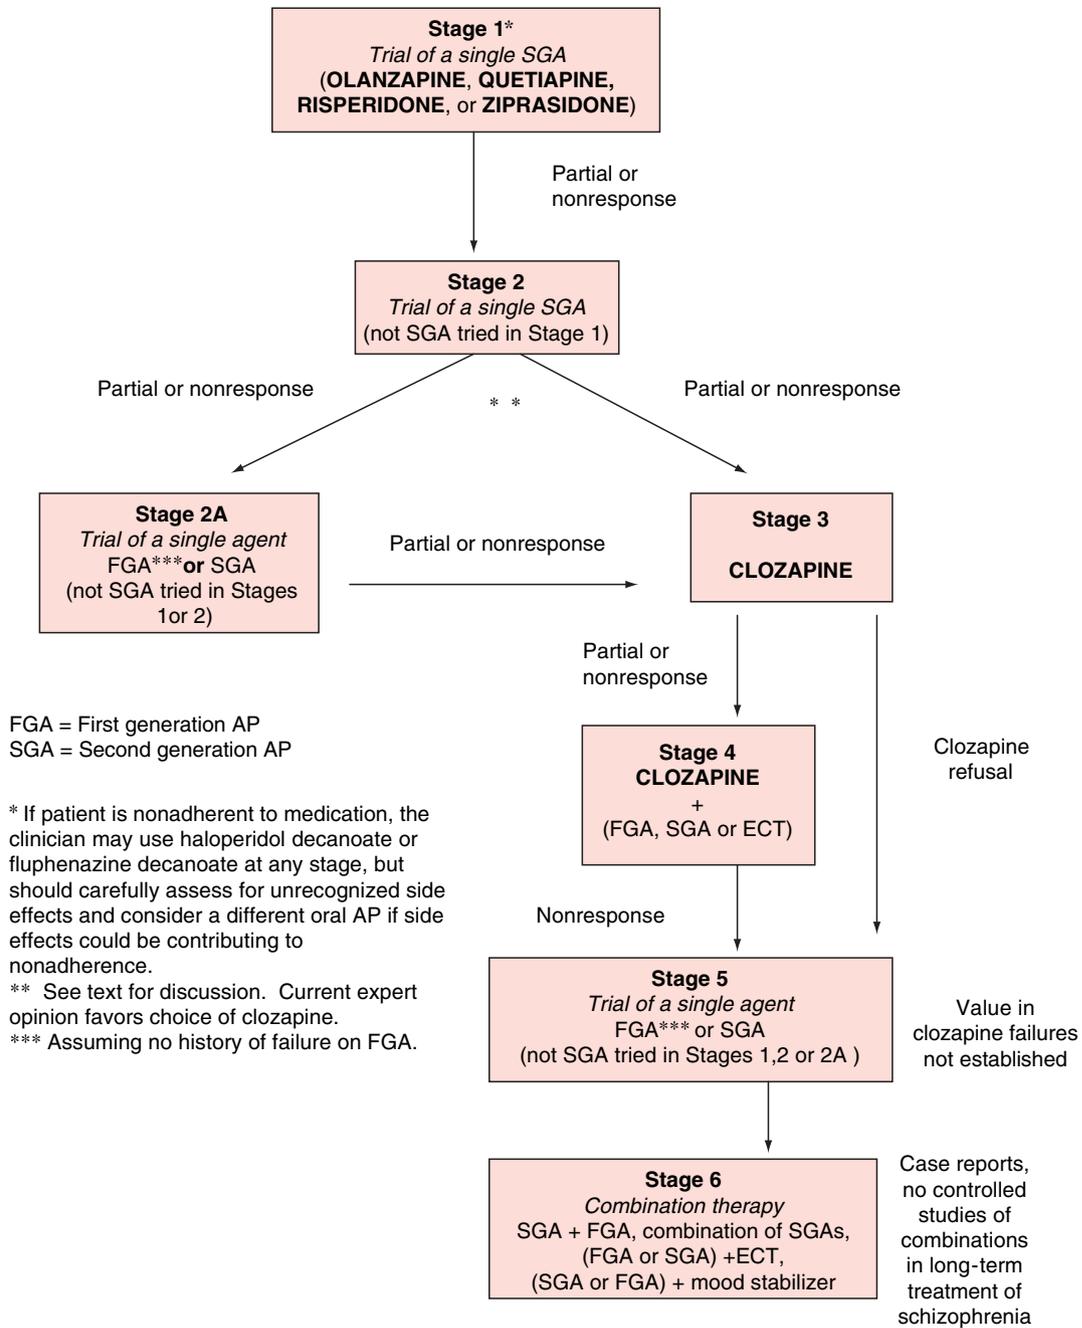

better than another one in treating schizophrenia. The randomized controlled trials suggest that, on average, these antipsychotic agents are each associated with 20% improvement in symptoms. However, clozapine is the only new antipsychotic agent that is more effective than haloperidol in managing treatment resistant schizophrenia. Unfortunately, its potential for treatment-emergent agranulocytosis, seizures and the new warning of myocarditis, precludes its use as a first line agent for schizophrenia. A major difference amongst the newer antipsychotic agents is the side effect profile and its effect on the overall quality of life of the patient.

## Acute Treatment

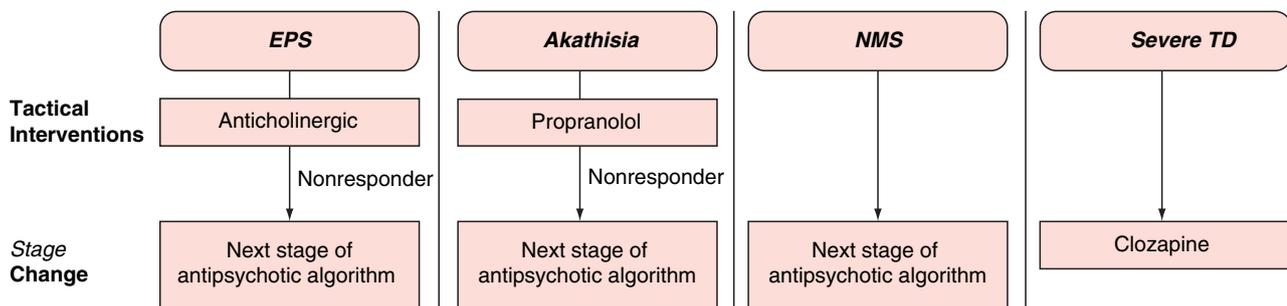

In last few years, the use of novel antipsychotics has surpassed the use of typical ones in the management of acute phase symptoms of schizophrenia, except for the use of parenteral and liquid forms of antipsychotics where typical antipsychotic agents still hold an upper hand. However, this trend will most likely change once the injectable preparations of the novel antipsychotics enter the market. The primary goal of acute treatment is the amelioration of any behavioral disturbances that would put the patient or others at risk of harm. Acute symptom presentation or relapses are heralded by the recurrence of positive symptoms, including delusions, hallucinations, disorganized speech or behavior, severe negative symptoms or catatonia. Quite frequently, a relapse is a result of antipsychotic discontinuation, and resumption of antipsychotic treatment aids in the resolution of symptoms. There is a high degree of variability in response rates among individuals. When treatment is initiated, improvement in clinical symptoms can be seen over hours, days, or weeks of treatment.

Studies have shown that although typical neuroleptics are undoubtedly effective, a significant percentage (between 20 and 40%) of patients show only a poor or partial response to traditional agents. Furthermore, there is no convincing evidence that one typical antipsychotic is more efficacious as an antipsychotic than any other, although a given individual may respond better to a specific drug. Once an informed choice has been made between using a novel or typical antipsychotic medication by the patient and the clinician, selection of a specific antipsychotic agent should be based on efficacy, side-effect profile, history of prior response (or nonresponse) to a specific agent, or history of response of a family member to a certain antipsychotic agent. (For a pharmacotherapy decision tree based on Texas Medication Algorithm Project, see Figure 45.3.) Amongst the typical antipsychotic medications, low-potency, more sedating agents, such as chlorpromazine, were long thought to be more effective for agitated patients, yet there are no consistent data proving that high-potency agents are not equally useful in this context. The low-potency antipsychotics, however, are more associated with orthostatic hypotension and lowered seizure threshold and are often not as well tolerated at higher doses. Higher potency neuroleptics, such as haloperidol and fluphenazine, are safely used at higher doses and are effective in reducing psychotic agitation and psychosis itself. However, they are more likely to cause EPS than the low potency agents.

The efficacy of novel antipsychotic drugs on positive and negative symptoms is comparable to or even better than the typical antipsychotic. The significantly low potential to cause EPS or dystonic reaction and thus the decreased long-term consequences of TD has made the novel agents more tolerable and acceptable in acute treatment of schizophrenia. Other significant advantages adding to the popularity of novel antipsychotics include their beneficial impact on mood symptoms, suicidal risk and cognition. The selection of the first line treatment with novel antipsychotic

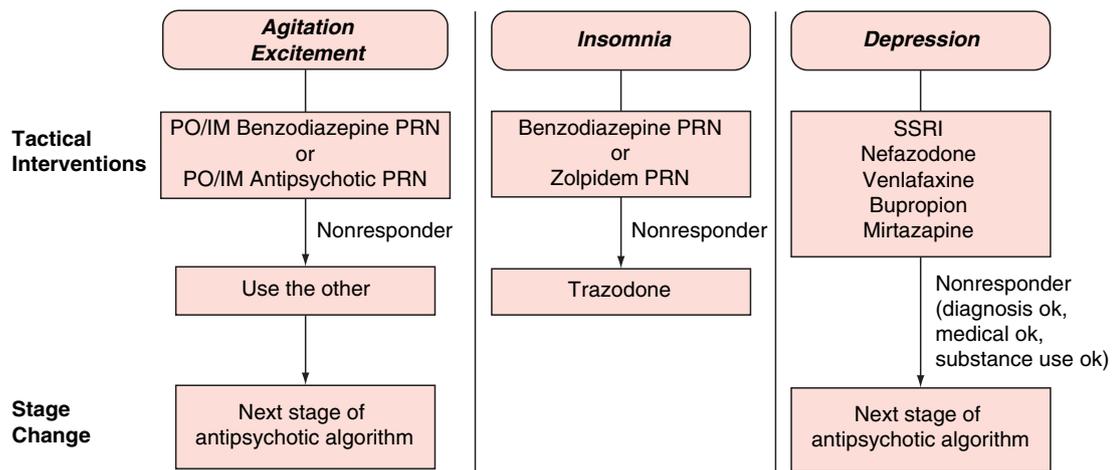

**Side Effects Algorithms**

Continues

## Coexisting Symptoms Algorithms

**Figure 45.3** Selecting antipsychotic treatment using Texas Medication Algorithm for Schizophrenia. Choice of antipsychotic (AP) should be guided by considering the clinical characteristics of the patient and the efficacy and side effect profiles of the medication. Any stage(s) can be skipped depending on the clinical picture or history of antipsychotic failures. Texas Medication Algorithm Project for choosing antipsychotic treatment, managing side-effects and coexisting symptoms. This project is a public-academic collaborative effort to develop, implement, and evaluate medication treatment algorithms for public sector patients. For more information or to view the most current version of the algorithm visit [www.mhmr.state.tx.us/centraloffice/medicaldirector/tmaptoc.html](http://www.mhmr.state.tx.us/centraloffice/medicaldirector/tmaptoc.html).

(and occasionally typical antipsychotic agent) also depends on the circumstances under which the medications are started, for example, extremely agitated or catatonic patients would require intramuscular preparation of the antipsychotic agents which would limit the choice. Except for clozapine, which is not considered first line treatment because of substantial and potentially life threatening side effects, there is no convincing data supporting the preference of one atypical over the other. However, if the patient does not respond to one, a trial with another atypical antipsychotic is reasonable and may produce response.

Once the decision is made to use an antipsychotic agent, an appropriate dose must be selected. Initially, higher doses or repeated dosing may be helpful in preventing grossly psychotic and agitated patients from doing harm. In general, there is no clear evidence that higher doses of neuroleptics (more than 2000 mg chlorpromazine equivalents per day) have any advantage over standard doses (400–600 chlorpromazine equivalents per day).

Some patients who are extremely agitated or aggressive may benefit from concomitant administration of high-potency benzodiazepines such as lorazepam, at 1 to 2 mg, until they are stable. Benzodiazepines rapidly decrease anxiety, calm the person, and help with sedation to break the cycle of agitation. They also help decrease agitation due to akathisia. The use of these medications should be limited to the acute stages of the illness to prevent tachyphylaxis and dependency. Benzodiazepines are quite beneficial in treatment of catatonic or mute patients but the results are only temporary though of enough duration to help with body functions and nutrition.

## Maintenance Treatment

There is by now a great deal of evidence from long-term follow-up studies that patients have a higher risk of relapse and exacerbations if not maintained with adequate antipsychotic regimens. Noncompliance with medication, possibly because of intolerable neuroleptic side effects, may contribute to increased relapse rates. In

a double-blind, placebo-controlled study of relapse rates, 50% of patients in a research ward demonstrated clinically significant exacerbation of their symptoms within 3 weeks of stopping neuroleptic treatment. It is estimated that two-thirds of patients relapse after 9 to 12 months without neuroleptic medication, compared with 10 to 30% who relapse when typical neuroleptics are maintained. Long-term outcome studies showed that persistent symptoms that do not respond to standard neuroleptic therapy are associated with a greater risk of rehospitalization. Nonpharmacological interventions may help decrease relapse rates (discussed later).

Long-term treatment of schizophrenia is a complex issue. It is clear that the majority of patients require maintenance medication. Some patients do well with stable doses of neuroleptics for years without any exacerbations. However, many patients who are maintained with a stable neuroleptic dose have episodic breakthroughs of their psychotic symptoms. The difficulty in tolerating neuroleptic side effects often results in noncompliance with medication. It is therefore prudent to assess patients for medication compliance when signs of relapse are suspected. Prodromal cues may be present before an exacerbation of psychotic symptoms. For example, any recent change in sleep, attention to activities of daily living, or disorganization may be a warning sign of an impending increase in psychosis.

For patients for whom compliance is a problem, long-acting, depot neuroleptics are available in the USA for both traditional and novel antipsychotics. This form of medication delivery guarantees that the medication is in the system of the person taking it and eliminates the need to monitor daily compliance. This alternative should be considered if noncompliance with oral agents has led to relapses and rehospitalization. With these patients, maintenance treatment using long-acting preparations should begin as early as possible. Depot antipsychotic drugs are effective maintenance therapy for patients with schizophrenia.

Many studies have investigated appropriate maintenance doses of standard antipsychotics. Effective maintenance treatment

is defined as that which prevents or minimizes the risks of symptom exacerbation and subsequent morbidity. A series of interesting dose-finding studies were performed by Kane and colleagues (1983, 1985) to determine the minimal dosage required to prevent relapse and to reduce the risk of extrapyramidal symptoms and tardive dyskinesia. This group found that the relapse rate (56%) of patients treated with lower doses of fluphenazine decanoate (1.25–5 mg every 2 weeks) was significantly greater than the relapse rate (14%) of patients receiving standard doses (12.5–50 mg every 2 weeks). Other investigators have found that this low dosage range may appear to prevent relapse for a certain period (Marder *et al.*, 1984) but fails to do so if patients are followed up for more than 1 year (Marder *et al.*, 1987). Unfortunately, no specific dosage reliably prevents relapse, and there is no way to predict future relapse. This is true for the novel antipsychotic agents as well.

### Depression and Schizophrenia

Symptoms of depression occur in a substantial percentage of schizophrenia patients with a wide range of 7 to 75% and a modal rate of 25% and is associated with poor outcome, impaired functioning, suffering, higher rates of relapse or rehospitalization, and suicide. It is important to distinguish depression as a symptom or as a syndrome when it occurs. There is an important overlap of symptoms of depression with the negative symptoms. Differentiating these states can sometimes be difficult especially in patients who lack the interpersonal communication skills to articulate their internal subjective states well. A link between typical antipsychotic use and depression has been suggested with some considering depression to be a form of medication induced akinesia. Many patients have a reaction of disappointment, a sense of loss or powerlessness, or awareness of psychotic symptoms or psychological deficits that contributes to depression. Depression in schizophrenia is heterogeneous and requires careful diagnostic clarification. DSM-IV suggests that the term “postpsychotic depression” be used to describe depression that occurs at any time after a psychotic episode of schizophrenia, even after a prolonged interval. The atypical antipsychotic medications, with less potential to cause motor side effects and different mechanisms of action at receptor levels, themselves may contribute substantially to a decrease in the rate of depression. Moreover, the atypical antipsychotic medications appear to be superior to standard neuroleptics in treatment of negative symptoms. The clear advantage of atypical antipsychotic medications over the typical ones in treatment of psychosis itself can possibly further decrease the rate of depression. The impact of clozapine on the rate of suicide is significantly superior compared with the conventional agents. However, a large number of patients still end up with a depression that will require treatment with an antidepressant.

### Risks and Side Effects of Typical Neuroleptics

Extrapyramidal symptoms are side effects of typical antipsychotic medications that include dystonias, oculogyric crisis, pseudoparkinsonism, akinesia and akathisia. They are referred to collectively as extrapyramidal symptoms or EPS because they are mediated at least in part by dopaminergic transmission in the extrapyramidal system. Prevalence rates vary among the different types of extrapyramidal symptoms. When present, they can be uncomfortable for the patient and a reason for noncompliance.

Dystonias are involuntary muscular spasms that can be brief or sustained, involving any muscle group. They can occur

with even a single dose of medication. When they develop suddenly, these spasms can be quite frightening to the patient and potentially dangerous, as in the case of laryngeal dystonias. They are more likely to be seen in young patients. Pseudoparkinsonism and akinesia are characterized by muscular rigidity, tremor and bradykinesia, much as in Parkinson's disease. On examination patients typically have masked facies, cogwheel rigidity, slowing and decreased arm swing with a shuffling gait. This condition is reported to be more prevalent than the dystonias, presenting with a frequency ranging from 15%.

Akathisia is more common, affecting more than 20% of patients taking neuroleptic medications (Ayd, 1961; Marsden *et al.*, 1986). This clinical entity presents as motor restlessness or an internal sense of restlessness. Often patients experiencing akathisia are unable to sit still during an interview. Akathisia is difficult to differentiate from agitation. The tendency to treat agitation with neuroleptics may exacerbate akathisia, making treatment decisions challenging.

Treatment of EPS can be difficult but usually involves administration of anticholinergic medications. Some advocate the use of prophylactic anticholinergic agents when beginning typical neuroleptic treatment to decrease the incidence of EPS. This option may be appropriate, but it should be used with caution, considering the side effects associated with anticholinergic agents and their potential for abuse. Treatment of acute dystonic reactions usually involves acute intramuscular administration of either an anticholinergic or diphenhydramine. Akathisia may not respond to anticholinergic medications. Both neuroleptic dosage reduction and the use of beta-blocking agents such as propranolol have been found to be efficacious in the treatment of akathisia.

Nonextrapyramidal side effects of the typical antipsychotic agents include those that are secondary to blockade of muscarinic, histaminic and alpha-adrenergic receptors. These side effects, which are more commonly seen with the low-potency neuroleptics, include sedation, tachycardia and anticholinergic side effects such as urinary hesitancy or retention, blurred vision, or constipation. Other nonextrapyramidal side effects include some cardiac conduction disturbances, retinal changes, sexual dysfunction, weight gain, lowered seizure threshold and a risk of agranulocytosis.

Neuroleptic malignant syndrome (NMS) is a relatively rare but serious phenomenon seen in approximately 1% of patients taking neuroleptics. It can be fatal in 15% of cases if not properly recognized and treated. Because the symptoms of NMS may reflect multiple etiologies, making diagnosis difficult, Levenson (1985) has proposed clinical guidelines. According to Levenson, three major or two major and four minor manifestations are indicative of a high probability of NMS. Major manifestations of NMS comprise fever, rigidity, and increased creatine kinase levels, and minor manifestations include tachycardia, abnormal blood pressure, tachypnea, altered consciousness, diaphoresis and leukocytosis. Others do not subscribe to the major–minor manifestation distinctions. In general, NMS is considered to be a constellation of symptoms that usually develops during 1 to 3 days. Although its pathogenesis is poorly understood, it has been associated with all antidopaminergic neuroleptic agents and presents at any time during treatment. It must be distinguished from other clinical entities, including lethal catatonia and malignant hyperthermia.

The mainstay of treatment is cessation of neuroleptic treatment and supportive care, including intravenous hydration, reversal of fever with antipyretics and cooling blankets, and careful monitoring of vital signs because of the risk of cardiac and

respiratory disturbance. Rhabdomyolysis is one of the most serious sequelae of NMS; it can lead to renal failure unless patients are well hydrated. In some cases, dantrolene and bromocriptine have been reported to be effective pharmacological treatments. Though quite rare, NMS has been reported even with the use of novel antipsychotic agents. The decision to rechallenge the patient with neuroleptics after an episode of NMS must be made with caution.

One of the major risks of neuroleptic treatment with the traditional antipsychotic agents is that of tardive dyskinesia, a potentially irreversible syndrome of involuntary choreoathetoid movements and chronic dystonias associated with long-term neuroleptic exposure. These buccal, orofacial, truncal, or limb movements can be exacerbated by anxiety and disappear during sleep. They can present with a range of severity, from subtle tongue movements to truncal twisting and pelvic thrusting movements and even possible respiratory dyskinesias. The prevalence rates for this syndrome range from less than 10 to more than 50%, but it is generally accepted that the risk increases 3 to 5% per year for each year the patient is treated with typical neuroleptics. Older age is a considerable risk factor for tardive dyskinesia, and there is some evidence that women are at increased risk for the development of this condition. Of note, a withdrawal dyskinesia that resembles tardive dyskinesia may appear on cessation of the neuroleptic. The specific mechanism involved in tardive dyskinesia remains unclear, although supersensitivity of dopaminergic receptors has been implicated.

All patients receiving traditional neuroleptic treatment should be monitored regularly for any signs of a movement disorder. DSM-IV now includes a diagnosis of neuroleptic-induced tardive dyskinesia. If tardive dyskinesia is suspected, the benefits of antipsychotic treatment must be carefully weighed against the risk of tardive dyskinesia. This should be discussed with the patient, and the antipsychotic should be removed if clinically feasible or at least maintained at the lowest possible dose that provides antipsychotic effect. This would also be an indication to switch to the novel antipsychotic agents with significantly reduced risk of TD or in the case of clozapine no risk of TD. In many instances, clozapine (and possibly quetiapine or olanzapine) may be the best treatment that can be offered for the TD itself. Unfortunately, there is no specific treatment of tardive dyskinesia, although some investigators have proposed the use of adrenergic agents such as clonidine, calcium channel blockers, vitamin E, benzodiazepines, valproic acid, or reserpine to reduce the spontaneous movements.

Sudden death in psychiatric patients treated with typical antipsychotic drugs has been reported for a long time. Sudden cardiac deaths probably occur from prolongation of the ventricular action potential duration represented as the QT interval (or QTc when corrected for heart rate) on the electrocardiogram resulting in a polymorphic ventricular tachycardia termed *torsades de pointes* that can degenerate into ventricular fibrillation. The incidence of *torsades de pointes* is unknown and the specific duration of the QTc interval at which the risk of an adverse cardiac event is greatest has not been established. QTc prolongation alone does not appear to explain *torsades de pointes*; several other risk factors must be present simultaneously with QT prolongation before *torsades de pointes* occur. These risk factors may include hypokalemia, hypomagnesemia, hypocalcemia, bradycardia, preexisting cardiac diseases (life-threatening arrhythmias, cardiac hypertrophy, heart failure and congenital QT syndrome), female gender, advancing age, baseline QTc interval of more than 460 m/sec and a long list of medications. In some instances, *torsades de pointes* may be associated with an

increase in drug plasma concentrations (e.g., combination with drugs that inhibit the cytochrome P450 systems). Thus, the increase in polypharmacy in psychiatry is especially of concern. The frequency of ECG abnormalities in patients treated with antipsychotic drugs is unclear QTc prolongation has been reported with virtually all antipsychotic drugs. QTc prolongation by more than two standard deviations was reported in 8% of psychiatric patients treated with antipsychotics and especially in those receiving thioridazine (Riley *et al.*, 2000; 2001). Of the typical antipsychotic drugs, haloperidol, chlorpromazine, trifluoperazine, mesoridazine, prochlorperazine, droperidol and fluphenazine have all been reported to cause QTc prolongation and *torsades de pointes*, but thioridazine may be the worst offender. Pimozide, another typical antipsychotic, has also been associated with QTc prolongation, *torsades de pointes* and deaths. A reevaluation by the FDA of the cardiac safety parameters of thioridazine, mesoridazine and droperidol resulted in a black box warning due to significant QTc prolongation. Thus, it is important to monitor QTc interval in the high-risk population to prevent this rare, but potentially fatal side effect.

### Side Effects of Novel Antipsychotic Agents

One of the most significant advantages of the newer antipsychotic agent is the relatively less risk of developing EPS and TD. However, treatment emergent substantial weight gain is a harbinger for long-term health consequences and frequently an important reason for noncompliance with medication. According to a meta-analysis done by Allison and colleagues (1999), clozapine and olanzapine are associated with a weight gain of about 10 lb over 10 weeks and ziprasidone was among the agents with the lowest weight gain at an average of 1 lb over the same period. Risperidone and quetiapine are intermediate with approximately 5 lb. Patients with schizophrenia, independent of the use of antipsychotic agents, are at higher risk of developing diabetes mellitus relative to the general. The data from Patient Outcome Research Team (PORT) suggest that the rate of diabetes mellitus and obesity amongst patients with major mental illness was substantially higher even before the advent of the novel antipsychotic drugs. This was more so in women and nonwhite population. Thakore and colleagues (2002) investigated visceral fat distribution in drug-naïve and drug-free patients with schizophrenia. Compared with controls, patients with schizophrenia had central obesity and significantly higher levels of plasma cortisol. Thus patients with schizophrenia are at a higher risk to develop major medical problems even before they are exposed to antipsychotic medications. However, this risk has been exacerbated with the introduction of the novel antipsychotic agents as seen by the dramatic rise in number of published cases and reports of significant hyperglycemia associated with the use of these medications, particularly olanzapine and clozapine and to a lesser extent with quetiapine and risperidone. The risk of antipsychotic-induced weight gain and secondary diabetes with clozapine and olanzapine may result from changes in glucose metabolism and insulin resistance induced by these agents. In approximately 40% of the cases of hyperglycemia, insulin resistance appears to occur even in absence of significant weight gain raising some interesting questions about how these medications may interact with the insulin-glycemic control. Unfortunately, in the case of clozapine, the risk of developing abnormal glucose and diabetes mellitus appears to be cumulative over the years as reported by Henderson and colleagues (2000). There are no effective countermeasures

available to help with weight gain and hyperglycemia. The substantial increased risk to the health of patients with schizophrenia due to these effects is worrisome and an important shortcoming of these efficacious and important medications.

Amongst the novel agents, risperidone, due to its potent dopamine D<sub>2</sub> blockade, remove the inhibitory dopaminergic tone in the tuberoinfundibular neurons resulting in significant increase in prolactin levels. This increase in prolactin is significantly more than usually seen with the typical antipsychotic agents. It is likely that the serotonin system is also involved along with dopamine in raising the prolactin levels. Clozapine and quetiapine on the other hand, are less potent at the D<sub>2</sub> receptors and thus are unlikely to cause prolactin elevations. In some individuals, these elevations of prolactin lead to amenorrhea, galactorrhea, gynecomastia and may possibly decrease bone mineral density. Ziprasidone and olanzapine, within the therapeutic dose range, do not cause significant increases in prolactin levels.

Cases of sudden death while receiving clozapine therapy (in physically healthy young adults with schizophrenia) from myocarditis and cardiomyopathy led to a black box warning from FDA.

### Treatment Resistance and Negative Symptoms

The concept of treatment resistance has undergone significant modification in recent years. The original concept of treatment refractory applied to the use of typical antipsychotic agents. With the advent of the novel agents, which are generally more effective than the traditional ones, the patient should fail at least one novel antipsychotic agent before initiating a trial of clozapine mainly to avoid its side effects. The definition of the duration of a drug trial has also evolved over the years. It is increasingly appreciated that a 4 to 6 weeks duration of treatment with an antipsychotic agent at therapeutic doses can be considered an adequate trial. The recommended dosing has also undergone changes. The original recommendation considered a trial of 1000 mg equivalent of chlorpromazine as a necessary minimum requirement but this threshold is now reduced to 400 to 600 mg/day equivalent based on the knowledge that these doses block enough dopamine D<sub>2</sub> receptors with higher doses providing no additional benefit. Thus, a 4 to 6 week trial of 400 to 600 mg of chlorpromazine equivalent is accepted as an adequate antipsychotic trial.

In treatment refractory patients, typical antipsychotic use results in less than 5% response rate. Clozapine is the only antipsychotic drug proven more efficacious in rigorously defined treatment refractory groups. However, monitoring of blood counts and fear of its side effects makes it one of most underused effective treatment for schizophrenia.

Risperidone clearly appears to be superior to typical antipsychotics in treatment refractory patients but does not appear to be as efficacious as clozapine. Olanzapine has been reported to have better outcome than haloperidol in the treatment-resistant schizophrenia group. However, when olanzapine was compared with chlorpromazine in a treatment refractory group using a double-blind study design, the outcome with olanzapine was not comparable to what is typically seen with the use of clozapine.

Negative symptoms, such as apathy, amotivational syndrome, flattened affect and alogia, are often the most problematic for patients with schizophrenia, accounting for much of the morbidity associated with this illness. In addition, these symptoms are often the most difficult to treat and do not respond well to traditional neuroleptics. The atypical antipsychotic agents are

more effective against the negative symptoms than are the typical agents. However, the magnitude of the effect of these compounds on primary negative symptoms is not clear. Clearly, one of the goals of psychopharmacological research is to develop new antipsychotic agents with low associated risk, a more effective treatment for negative and cognitive symptoms, a further reduction in positive symptoms, and an improvement in long-term relapse rate for patients with chronic schizophrenia.

### Augmentation of Typical Neuroleptics

When a patient has shown an inadequate response to traditional neuroleptic agents from different classes and there is a good reason for not switching to a novel antipsychotic drug, other strategies may be necessary to ameliorate residual symptoms. Adding a different type of psychotropic medication may augment the neuroleptic response in some individuals. Several neuroleptic augmentation strategies have been studied, including the addition of beta-blockers, thyrotropin-releasing hormone, clonidine and valproic acid, with mixed results. Lithium has been evaluated extensively for its efficacy as an additional treatment of schizophrenia. In one study, lithium seemed to improve psychotic symptoms of patients who had not adequately responded to neuroleptics alone (Small *et al.*, 1975). Although lithium does not seem to affect positive or negative symptoms specifically, it may be beneficial for patients who present at the depressed end of the spectrum (Meltzer, 1992). Similarly, carbamazepine has had mixed results as an augmentation agent although there is evidence that it can improve anxiety, withdrawal and depression. The use of benzodiazepines as augmenting agents in the treatment of schizophrenia has also been extensively studied. There may be some patients who show improvement in psychotic symptoms, and others who show improvement in negative symptoms. Interestingly, there has been a suggestion that the triazolobenzodiazepines may be more effective than other types of benzodiazepines in augmenting the neuroleptic response.

Antidepressant medications have also been considered in the treatment of depression associated with schizophrenia. Although there is some evidence that typical neuroleptics themselves cause depression there undoubtedly are schizophrenic patients who have primary depressive symptoms. Negative symptoms are often difficult to distinguish from depression (both have features of amotivation, apathy and social withdrawal), but those that are secondary to depression may respond to the addition of an antidepressant to the patient's medication regimen.

With electroconvulsive therapy as an adjuvant treatment, it appears the patient may improve initially, but relapse is likely. However, patients with comorbid affective symptoms may have some increased benefit. In general, however, this option should be considered only if the patient is not a candidate for a trial with an atypical antipsychotic agent and only if the patient has severe persistent symptoms.

When agonists of the glycine site of the NMDA receptor were added to typical antipsychotic agents in a placebo-controlled study, significant improvement were reported in negative symptoms and aspects of cognitive functioning (Heresco-Levy *et al.*, 1999). D-cycloserine, a partial agonist at the glycine site produced a selective improvement of negative symptoms at 6 weeks (Goff *et al.*, 1999). Augmentation with another endogenous full agonist, D-serine was associated with significant improvement in negative, positive, and cognitive symptoms when added to conventional agents in an 8-week trial (Tsai *et al.*, 1998).

## Mechanism of Action of the Atypical Antipsychotic Agents

A higher ratio of the serotonin 5-HT<sub>2A</sub> receptor to dopamine D<sub>2</sub> receptor blockade is reported to predict **atypicality**. This, along with other data, formed the basis of the **serotonin–dopamine hypothesis** that explains the possible mechanism of action underlying the efficacy of the atypical antipsychotics. However, studies using PET paradigm failed to detect differences in the serotonin receptor affinities between typical and atypical antipsychotics. Moreover, atypical antipsychotic agents produce high 5-HT<sub>2A</sub> receptor occupancy at doses that are not sufficient to produce antipsychotic effects. This has raised some questions about the importance of 5-HT<sub>2A</sub> blockade for a drug to be either atypical or have antipsychotic efficacy. Though the typical antipsychotics, compared with the atypical ones, show a much higher affinity for the D<sub>2</sub> receptors, both are effective only when their D<sub>2</sub> receptor occupancy exceeds 65%, suggesting that D<sub>2</sub> antagonism is important in producing antipsychotic effects. Thus, some suggest that the major difference between typical and atypical antipsychotic medications may lie in their affinity for the D<sub>2</sub> receptor. **Affinity** is the ratio of the rate at which the drug moves **off** of and **on** to the receptor. Interestingly, Seeman and colleagues found that 99% of the difference in affinity of the antipsychotic was driven by differences in their K<sub>off</sub> at the D<sub>2</sub> receptor. Difference in the K<sub>on</sub> did not account for any significant differences in affinity. Thus, PET studies suggest that all antipsychotics (typical as well as atypical) attach to the D<sub>2</sub> receptor with a similar rate constant but differ in how fast they come off the receptor. Thus, Kapur and Seeman (2001) propose that this relationship between fast K<sub>off</sub> and low receptor affinity of the antipsychotic drug for dopamine D<sub>2</sub> receptor may explain atypicality. Furthermore, *in vivo*, antipsychotic agents modulate dopaminergic transmission and compete with endogenous dopamine. Thus, drugs with fast K<sub>off</sub> (e.g., clozapine, quetiapine, etc.) modulate dopamine transmission differently from drugs with a slow K<sub>off</sub> (e.g., haloperidol). For example, clozapine reaches equilibrium and goes on to and off the receptors significantly faster than haloperidol. When the concentration of endogenous dopamine rises physiologically, drugs like clozapine decrease their D<sub>2</sub> occupancy much faster and accommodate to natural surges of dopamine more readily than haloperidol.

Clinically, a significant difference between the typical and the atypical antipsychotic medications is the extent to which EPS occurs during treatment with therapeutic doses of antipsychotic drugs. PET studies suggest that the threshold for clinical antipsychotic response is lower than that of developing EPS and can be separated based on D<sub>2</sub> receptor occupancy. Specifically, D<sub>2</sub> occupancy of 65% or more significantly predicted clinical response, while D<sub>2</sub> occupancy of 78% or above significantly predicted EPS. Similarly, D<sub>2</sub> occupancy of 72% or higher resulted in prolactin elevation (Kapur *et al.*, 1996, 2000). Risperidone and olanzapine achieve strong antipsychotic activity only at doses that occupy 65% or more D<sub>2</sub> receptors, which is similar to haloperidol (Nordstrom and Farde, 1998). On the other hand, although clozapine and quetiapine show less than 60% D<sub>2</sub> occupancy 12 hours after drug administration (Seeman and Tallerico, 1999) these differences partly reflect a fast decline in D<sub>2</sub> occupancy. For example, quetiapine showed 60 and 20% D<sub>2</sub> occupancy 2 and 12 hours after receiving the medication. Similarly, clozapine showed 71% D<sub>2</sub> occupancy 1 to 2 hours after dose administration with a decline to 55% at 12 hours and 26% at 24 hours. It appears that both typical and atypical antipsychotics block sufficient number of D<sub>2</sub> receptors to achieve antipsychotic effect but differ in the kinetics of receptor occupancy.

It has been proposed that 5-HT<sub>2A</sub> occupancy exerts an attenuating effect on the D<sub>2</sub> related EPS. Antipsychotic agents, both typical and atypical, give rise to EPS only when they exceed 78 to 80% D<sub>2</sub> occupancy; and when they do so, concomitant 5-HT<sub>2A</sub> blockade does not appear to offer protection from these. Since clozapine and quetiapine never exceed this threshold of D<sub>2</sub> occupancy, they do not give rise to EPS. Since olanzapine and risperidone exceed this threshold in a dose-dependent fashion, they give rise to EPS also in a dose-dependent fashion.

## New Directions

Psychopharmacological research has focused on developing compounds with unique combinations of effects at these different neurotransmitter sites. Future strategies for the treatment of schizophrenia are based on novel constructs of its pathophysiology.

One area of interest involves the glutamatergic system. Glutamate, the major excitatory neurotransmitter in the brain, is implicated in information processing and memory, functions that are impaired in schizophrenia. PCP, an NMDA antagonist, causes a syndrome with symptoms clinically similar to those of schizophrenia. These observations have led to the hypothesis that the glutamatergic NMDA receptor is involved in the pathophysiology of schizophrenia. Investigation of compounds that alter NMDA receptor activity is under way to learn more about the clinical significance of this neurotransmitter system.

In another area of drug development, researchers are studying G proteins, ubiquitous proteins found on cell membranes, where they play a critical role in second-messenger systems. These proteins have been found to be related to dopamine receptors in schizophrenic patients and to be involved in the mechanism of action of lithium in the treatment of bipolar disorder. Advanced genetic technology using techniques that could lead to altered receptor function “upstream” is also being explored. Given the enhanced understanding of influential biochemical, genetic and neurodevelopmental interactions, there is promise of developing treatment strategies that would provide a more effective, safe means of ameliorating both the positive and negative symptoms of schizophrenia.

## Nonpharmacological Treatment of Schizophrenia

### Background

Although psychopharmacological intervention has proved to be the foundation on which the treatment of schizophrenia depends, other approaches to the management of these patients serve a critical function. Studies have shown repeatedly that symptoms of schizophrenia have not only a genetic component but also an environmental aspect, and interactions with family and within the community can alter the course of the illness.

For many years, a dichotomous view of treatment options was tenaciously debated as dynamic psychiatry was challenged by developments in the neurosciences. A more unified view is now accepted, as it has become clear that psychopharmacological treatment strategies are most efficacious if combined with some type of psychosocial intervention and vice versa. It can be said that because of the chronic nature of schizophrenia, one or more treatments may be required throughout the illness and they are likely to have to be modified as symptoms change over time.

## Psychosocial Rehabilitation

Bachrach has defined psychosocial rehabilitation as “a therapeutic approach that encourages a mentally ill person to develop his or her fullest capacities through learning and environmental supports” (Bachrach, 2000). According to the author, the rehabilitation process should appreciate the unique life circumstances of each person and respond to the individual’s special needs while promoting both the treatment of the illness and the reduction of its attendant disabilities. The treatment should be provided in the context of the individual’s unique environment taking into account social support network, access to transportation, housing, work opportunities and so on. Rehabilitation should exploit the patient’s strengths and improve his/her competencies. Ultimately, rehabilitation should focus on the positive concept of restoring hope to those who have suffered major setbacks in functional capacity and their self-esteem due to major mental illness. To have this hope grounded in reality, it requires promoting acceptance of one’s illness and the limitations that come with it. While work offers the ultimate in sense of achievement and mastery, it must be defined more broadly for the mentally ill and should include prevocational and nonvocational activities along with independent employment. It is extremely important that work is individualized to the talents, skills, and abilities of the individual concerned. However, psychosocial rehabilitation has to transcend work to encompass medical, social and recreational themes. Psychosocial treatment’s basic principle is to provide comprehensive care through active involvement of the patient in his or her own treatment. Thus, it is important that a holding environment be created where patients can safely express their wishes, aspirations, frustrations and reservations such that they ultimately mold the rehabilitation plan. Clearly, to achieve these goals, the intervention has to be ongoing.

Given the chronicity of the illness, the process of rehabilitation must be enduring to encounter future stresses and challenges. These goals cannot be achieved without a stable relationship between the patient and rehabilitation counselor, which is central to an effective treatment and positive outcome. Thus, psychosocial rehabilitation is intimately connected to the biological intervention and forms a core component of the biopsychosocial approach to the treatment of schizophrenia. In the real world, programs often deviate from the aforementioned principles and end up putting excessive and unrealistic expectations on patients, thus achieving exactly the opposite of the intended values of the program (see Bachrach, 2000 for more details).

## Individual Psychotherapy

Individual therapy in a nontraditional sense can begin on meeting a patient. Even the briefest of normalizing contacts with an agitated, acutely psychotic patient can have therapeutic value. Psychodynamic interpretations are not helpful during the acute stages of the illness and may actually agitate the patient further. The psychiatrist using individual psychotherapy should focus on forming and maintaining a therapeutic alliance (which is also a necessary part of psychopharmacological treatment) and providing a safe environment in which the patient is able to discuss symptoms openly. A sound psychotherapist provides clear structure about the therapeutic relationship and helps the patient to focus on personal goals.

Often, a patient is not aware of or does not have insight into the fact that some beliefs are part of a specific symptom. A psychotherapist helps a patient to check whether his or her reality coincides with that of the therapist. The therapeutic intervention then becomes a frank discussion of what schizophrenia is and how

symptoms may feel to the patient. This objectifying of psychotic or negative symptoms can prove of enormous value in allowing the patient to feel more in control of the illness. A good analogy is to diabetic patients, who know they have a medical illness and are educated about the symptoms associated with exacerbation. Just as these patients can check blood glucose levels, schizophrenia patients can discuss with a therapist their sleep patterns, their interpersonal relationships and their internal thoughts, which may lead to earlier detection of relapses.

Schizophrenia often strikes just as a person is leaving adolescence and entering young adulthood. The higher the premorbid level of social adjustment and functioning, the more devastating and confusing the onset of symptoms becomes. Young male patients with a high level of premorbid function are at increased risk of suicide, presumably in part because of the tremendous loss they face. These feelings can continue for years, with schizophrenia patients feeling isolated and robbed of a normal life. Therefore, a component of individual work (which can also be achieved to some degree in a group setting) with these patients is a focus on the impact schizophrenia has had on their lives. Helping patients to grieve for these losses is an important process that may ultimately help them achieve a better quality of life.

## Group Psychotherapy

Acutely psychotic patients do not benefit from group interaction. As their condition improves, inpatient group therapy prepares patients for interpersonal interactions in a controlled setting. After discharge, patients may benefit from day treatment programs and outpatient groups, which provide ongoing care for patients living in the community.

Because one of the most difficult challenges of schizophrenia is the inherent deficits in relatedness, group therapy is an important means of gathering patients together and providing them with a forum for mutual support. Insight-oriented groups may be disorganizing for patients with schizophrenia, but task-oriented, supportive groups provide structure and a decreased sense of isolation for this population of patients. Keeping group focus on structured topics, such as daily needs or getting the most out of community services, is useful for these patients. In the era of community treatment and brief hospitalizations, many patients are being seen in medication groups, which they attend regularly to discuss any side effects or problems and to obtain prescriptions.

## Psychoeducational Treatment

One of the inherent deficits from which schizophrenia patients suffer is an inability to engage appropriately in social or occupational activities. This debilitating effect is often a lasting feature of the illness, despite adequate psychopharmacological intervention. This disability often isolates patients and makes it difficult for them to advocate appropriate social support or community services. Furthermore, studies have found that there is a correlation between poor social functioning and incidence of relapse. One of the challenges of this area of study is the great deal of variability in individual patients. However, standardized measures have been developed to ascertain objective ratings of social deficits. These assessments have become important tools in the determination of effective nonpharmacological treatment strategies.

The literature suggests that schizophrenia patients can benefit from social skills training. This model is based on the idea that the course of schizophrenia is, in part, a product of the environment, which is inherently stressful because of the social deficits from which these patients suffer. The hypothesis is that

if patients are able to monitor and reduce their stress, they could potentially decrease their risk of relapse. For this intervention to be successful, patients must be aware of and set their own goals. Goals such as medication management, activities of daily living and dealing with a roommate are achievable examples. Social skills and deficits can be assessed by patients' self-report, observation of behavioral patterns by trained professionals, or a measurement of physiological responses to specific situations (e.g., increased pulse when asking someone to dinner). Patients can then begin behavioral training in which appropriate social responses are shaped with the help of instructors.

One example of such a program, discussed by Liberman and colleagues (1985), is a highly structured curriculum that includes a training manual, audiovisual aids and role-playing exercises. Behaviors are broken down into small bits, such as learning how to maintain eye contact, monitor vocal volume, or ameliorate body language. The modules are learned one at a time, with role-playing, homework and feedback provided to the participants. In several studies, Liberman and coworkers (1986) have shown that patients who were treated with social skills training and medication spent less time hospitalized, with fewer relapses than those treated with holistic health measures (e.g., yoga, stress management) on 2-year follow-up. Research such as this in the field of social skills training is growing as the inherent deficits in information processing, executive function and interpersonal skills are further elucidated.

### Social Skills Training

In large number of patients, deficits in social competence persist despite antipsychotic treatment. These deficits can lead to social distress whereas social competence can alleviate distress related to social discomfort. Paradigms using instruction, modeling, role-playing and positive reinforcement are helpful. Controlled studies suggest that schizophrenia patients are able to acquire lasting social skills after attending such programs and apply these skills to everyday life. Besides reducing anxiety, social skills training also improve level of social activity and foster new social contacts. This in turn improves the quality of life and significantly shortens duration of inpatient care. However, their impact on symptom resolution and relapse rates is unclear.

### Cognitive Remediation

Patients with schizophrenia generally demonstrate poor performance in various aspects of information processing. Cognitive dysfunction can be a rate-limiting factor in learning and social functioning. Additionally, impaired information processing can lead to increased susceptibility to stress and thus to an increase risk of relapse. Practice appears to improve some of the cognitive dysfunction. Remediation of cognitive dysfunctions with social skills training has been reported to have positive impact. Various types of cognitive behavioral therapies were particularly effective. Social skills training program, cognitive training program to improve neurocognitive functioning and cognitive behavioral therapy approaches are oriented towards coping with symptoms, the disorder and everyday problems.

### Cognitive Adaptation Training

Cognitive adaptation training (CAT) is a novel approach to improve adaptive functioning and compensate for the cognitive impairments associated with schizophrenia. A thorough functional needs assessment is done to measure current adaptive functioning. Besides measuring adaptive functioning and quantifying

apathy and disinhibition, a neurocognitive assessment using tests to measure executive function, attention, verbal and visual memory, and visual organization is also completed. Treatment plans are adapted to the patient's level of functioning, which includes patient's level of apathy. Interventions include removal of distracting stimuli, use of reminders such as checklists, signs and labels.

### Family Therapy

A large body of literature explores the role of familial interactions and the clinical course of schizophrenia. Many of these studies have examined the outcome of schizophrenia in relation to the degree of expressed emotion (EE) in family members. EE is generally defined as excessive criticism and over involvement of relatives. Schizophrenia patients have been found to have a higher risk of relapse if their relatives have high EE levels. Clearly, a patient's disturbing symptoms at the time of relapse may affect the level of criticism and over involvement of family members, but evidence suggests that preexisting increased EE levels in relatives predict increased risk of schizophrenic relapse and that interventions that decrease EE levels can decrease relapse rates.

Hogarty and colleagues (1986) examined the effectiveness of neuroleptics alone, neuroleptics plus psychoeducational family treatment (based on addressing EE levels), social skills training for neuroleptic-treated patients with schizophrenia, and the combination of all three. Perhaps not surprisingly, they found a decreased relapse rate in the patients treated with medication and family therapy as well as in the group treated with neuroleptic and social skills training. The combination of the treatments had an additive effect and was far superior to medication treatment alone.

Though family intervention studies suffer from methodological limitations, the efficacy of family intervention on relapse rate is fairly well supported. This efficacy was particularly evident when contrasted with low quality or uncontrolled individual treatments. The addition of family intervention to standard treatment of schizophrenia has a positive impact on outcome to a moderate extent. Family intervention effectively reduces the short-term risk of clinical relapse after remission from an acute episode. There is evidence of effect on patient's mental state and social functioning, or on any family-related variables. The elements common to most effective interventions are inclusion of the patient in at least some phases of the treatment, long duration, and information and education about the illness provided within a supportive framework. There is sufficient data only for male chronic patients living with high EE parents. Evidence is limited for recent onset patients, women, and people in different family arrangements and families with low EE. Research in family intervention is still a growing field. Thus, at present it is unclear if the effect seen with family therapy is due to family treatment or more intensive care.

Leff (2000) concluded from his review that family interventions reduced relapse rates by one-half over the first year of combined treatment with medications and family therapy. Medications and family therapy augment each other. Psychoeducation by itself is not enough. It also seems that multiple family groups are more efficacious than single family sessions. Attempts are being made to generalize training of mental health workers in effectively implementing these strategies.

Based on these findings, it is clear that there is a significant interaction between the level of emotional involvement and criticism of relatives of probands with schizophrenia and the outcome of their illness. Identifying the causative factors in familial stressors and educating involved family members about schizo-

phrenia lead to long-term benefits for patients. Future work in this field must examine these interactions with an understanding of modern sociological and biological advances in genetics, looking at trait carriers, social skills assessments, positive and negative symptoms, and medication management with the novel antipsychotic agents.

### Case Management

Assertive Community Treatment (ACT) is a community care model with a caseload per worker of 15 patients or less in contrast to standard case management (SCM) with a caseload of 30 to 35 patients. Intensive clinical case management (ICCM) differs from ACT by the case manager not sharing the caseload. In the ACT model, most services are provided in the community rather than in the office; the caseloads are shared across clinicians rather than individual separate caseloads. These are time unlimited services provided directly by the ACT team and not brokered out and 24-hour coverage is provided. Research on the ACT model confirms that it is successful in making patients comply with treatment and leads to less inpatient admissions. ACT also improves housing conditions (fewer homeless patients, more patients in stable housing), employment, quality of life and patient satisfaction. No clear differences between ACT and standard or intensive clinical case management are reported with mental condition, social functioning, self-esteem, or number of deaths.

### Combining Pharmacological and Psychosocial Treatments

The combination of pharmacological and psychosocial interventions in schizophrenia can have complex interactions. For example, psychotherapies improve medication compliance on one hand but are more effective in the presence of antipsychotic treatment. Family psychoeducation has been reported to decrease the level of expressed emotion in the family resulting in better social adjustment and a need for lower dose of antipsychotic medications. Marder and colleagues (1996) found in their study that pharmacological and psychosocial treatments affect different outcome dimensions. Medications affect relapse risk whereas skills training affect social adjustment. The VA cooperative study by Rosenheck and colleagues (1998) found that patients who received clozapine were more likely to participate in these treatments and led to improved quality of life. The qualitative differences in the interactions between the newer antipsychotic agents and psychotherapy suggest a hopeful trend of better utilization of psychosocial treatments.

### Self-directed Treatment

Groups such as the National Alliance for Mentally Ill (NAMI) and the Manic–Depressive Association offer tremendous resources to psychiatric patients and their relatives. They provide newsletters, neighborhood meetings and support groups to interested persons. These nonprofessional self-help measures may feel less threatening to patients and their families and provide an important adjunct to professional settings.

Structured self-help clubs have also been effective means of bolstering patients' social, occupational and living skills. The Fountain House was the first such club aimed at social rehabilitation (Beard *et al.*, 1982). Patients who are involved are called members of the club, giving them a sense of belonging to a group. They are always made to feel welcome, useful, and productive members of the club community.

The clubhouse model has expanded to provide services such as transitional employment programs, apartment programs, outreach programs, and medication management and consultation services, to name a few. A self-supportive rehabilitation program for mentally ill patients is an important option for many schizophrenic patients who might otherwise feel isolated and out of reach.

### Stigma

Though tremendous progress has occurred in understanding and treatment of schizophrenia, stigmatizing attitudes still prevail (Crisp *et al.*, 2000); in a survey, schizophrenia elicited the most negative opinions and over 70% of those questioned thought that schizophrenia patients were dangerous and unpredictable. Thus, stigma surrounding schizophrenia can cause people suffering from the illness to develop low self-esteem, disrupt personal relationships and decrease employment opportunities. The World Psychiatric Association (WPA) has initiated an international program aimed at developing tools to fight stigma and discrimination (Sharma, 2001).

---

#### Clinical Vignette 1

Mr A first sought psychiatric help at the age of 19 years. During his first year of college he had a difficult adjustment. He had never had close friends, but at school he felt isolated from his family. Although he had always been a good student, averaging As and Bs in high school, he was unable to achieve the same level of academic performance. He became increasingly distressed by his sense of isolation and his inability to maintain an adequate grade point average. Around the middle of his first year of college he saw a psychiatrist, who thought he was having an adjustment reaction to his new surroundings. He was not given medication at the time but was referred for supportive psychotherapy. After two appointments with his therapist, he decided it was not helpful.

Shortly thereafter, he began to feel that the other students were staring at him and laughing at him behind his back. Then he began to feel as if they were playing tricks on him, sending secret messages to him over the radio to torment him. This experience lasted over 6 months. He also began hearing two voices, which he did not recognize. These voices would comment on his behavior and criticize his actions. They began to tell him to stay out of his dormitory room at night. The voices also warned him that the dormitory food was poisoned. One night, he was picked up by police for loitering and was brought to an emergency department.

The emergency department psychiatrist saw him as a disheveled, unshaven man who was agitated during the interview, pacing across the examining room. He was wearing dark sunglasses, although it was the middle of the night, and he said he did not want the examiner to read his mind by looking into his eyes, so he kept the sunglasses on throughout the interview. His speech was of normal rate and prosody, although there were long pauses in some of his responses. He was able to respond to questions clearly, and his thought processes were logical, although he repeatedly spoke angrily as if responding to voices. He did say that the voices had been telling him to kill himself for the past two nights, although he said he was trying not to listen to them. The patient showed only some difficulty

**Clinical Vignette 1** *continued*

in concentration on a cognitive examination. His judgment was fair in that he recognized his need for some help, but he showed no insight into his symptoms.

The psychiatrist felt that the patient was potentially dangerous to himself because of the command auditory hallucinations and required hospitalization. Mr A did not agree to come into the hospital, and the psychiatrist sought involuntary hospitalization through appropriate procedures. In the hospital, the patient was initially quite agitated, requiring intramuscular haloperidol and lorazepam. Almost immediately his behavior calmed, and he was able to agree to hospitalization and treatment. He was treated with risperidone, and the dose was titrated up to 3 mg/day by mouth at bedtime. After 1 week with this medication regimen, he began to experience a decrease in his auditory hallucinations and paranoid ideation. He was sleeping better and was no longer concerned about the foods he was eating.

**Other Psychoses****Schizoaffective Disorder**

Over the decades, these patients were often classified as having atypical schizophrenia, good prognosis schizophrenia, remitting schizophrenia, or cycloid psychosis. Inherent within these diagnoses was the implication that they shared similarities to schizophrenia and also appeared to have a relatively better course of illness. With the advent of effective treatment of bipolar disorder with lithium salts, some of these patients started responding to lithium, and the term schizoaffective disorder gained further momentum and evolved in the direction of bipolar disorder. Unfortunately, this lack of diagnostic clarity has plagued the diagnosis of schizoaffective disorder such that there is much that is unknown about the illness.

**Epidemiology**

The diagnosis of schizoaffective disorder has undergone numerous changes through the decades making it difficult to get reliable epidemiology information. When data was pooled together from various clinical studies, approximately 2 to 29% of those patients diagnosed to have mental illness at the time of the study were suffering from schizoaffective disorder with women having a higher prevalence (Keck *et al.*, 2001). This could possibly be explained by a higher rate of depression in women. Relatives of women suffering from schizoaffective disorder have a higher rate of schizophrenia and depressive disorders compared with relatives of male schizoaffective subjects. The estimated lifetime prevalence of schizoaffective disorder is possibly in the range of 0.5 to 0.8%. In the inpatient settings of New York State psychiatric hospitals, approximately 19% of 6000 patients had a diagnosis of schizoaffective disorder (Levinson *et al.*, 1999).

**Gender and Age**

The depressive type of schizoaffective disorder appears to be more common in older people while the bipolar type probably occurs more commonly in younger adults. The higher prevalence of the disorder in women appears to occur particularly amongst

those who are married. As in schizophrenia, the age of onset for women is later than that for men. Depression tends to occur more commonly in women.

**Etiology**

The etiology of schizoaffective disorder is unknown. There is a dearth of data relating to this illness. Studies involving families of schizoaffective probands suggest that they have significantly higher rates of relatives with mood disorder than families of schizophrenia probands. It is possible that some of the same environmental theories that apply to schizophrenia and bipolar disorder may also apply to schizoaffective disorder. It is most likely that schizoaffective disorder is a heterogeneous condition. Thus, depending on the type of schizoaffective disorder studied an increased prevalence of either schizophrenia or mood disorders may be found in their relatives. As a group, patients with schizoaffective disorder have a prognosis intermediate between mood disorders and schizophrenia. Thus, on an average they have a better course than those suffering from schizophrenia, respond to mood stabilizers more often and tend to have a relatively nondeteriorating course.

**Diagnosis**

Schizoaffective disorder criteria have evolved over the years and undergone major changes. According to the DSM-IV, a patient with schizoaffective disorder must have an uninterrupted period of illness during which, at some time, they meet the diagnostic criteria for a major depressive episode, manic episode, or a mixed episode concurrently with the diagnostic criteria for the active phase of schizophrenia (criteria A for schizophrenia). Additionally, “the patient must have had delusions or hallucinations for at least 2 weeks in the absence of prominent mood disorder symptoms” during the same period of illness. The mood disorder symptoms must be present for a substantial part of the active and residual psychotic period. The essential features of schizoaffective disorder must occur within a single uninterrupted period of illness where the “period of illness” refers to the period of active or residual symptoms of psychotic illness and this can last for years and decades. The total duration of psychotic symptoms must be at least 1 month to meet the criteria A for schizophrenia and thus, the minimum duration of a schizoaffective episode is also 1 month.

The criteria for major depressive episode requires a minimum duration of 2 weeks of either depressed mood or markedly diminished interest or pleasure. As the symptoms of loss of pleasure or interest commonly occur in nonaffective psychotic disorders, to meet the criteria for schizoaffective disorder criteria A, the major depressive episode must include pervasive depressed mood. Presence of markedly diminished interest or pleasure is not sufficient to make a diagnosis as it is possible that these symptoms may occur with other conditions too.

The DSM-IV diagnosis of schizoaffective disorder can be further classified as schizoaffective disorder **bipolar type** or schizoaffective disorder **depressive type**. For a person to be classified as having the bipolar subtype he/she must have a disorder that includes a manic or mixed episode with or without a history of major depressive episodes. Otherwise the person is classified as having depressive subtype having had symptoms that meet the criteria for a major depressive episode with no history of having had mania or mixed state.

**Clinical Features**

The clinical signs and symptoms of schizoaffective disorder include all the signs and symptoms of schizophrenia, and a

manic episode and/or a major depressive episode. The schizophrenia and mood symptoms may occur together or in an alternate sequence. The clinical course can vary from one of exacerbations and remissions to that of a long-term deterioration. Presence of mood-incongruent psychotic features – where the psychotic content of hallucinations or delusions is not consistent with the prevailing mood – more likely indicate a poor prognosis.

### Differential Diagnosis

The possible differential diagnosis consists of bipolar disorder with psychotic features, major depressive disorder with psychotic features and schizophrenia. Clearly, substance induced states and symptoms caused by coexisting medical conditions should be carefully ruled out. All conditions listed in differential diagnosis of schizophrenia, bipolar disorder and major depressive disorder should be considered including but not limited to those patients undergoing treatment with steroids, those abusing substances such as PCP and medical conditions such as temporal lobe epilepsy. In circumstances where there is ambiguity, it may be prudent to delay making a final diagnosis until the most acute symptoms of psychosis have subsided and time is allowed to establish a course of illness and collect collateral information.

### Course and Prognosis

Due to the evolving nature of the diagnosis and limited studies done thus far much remains unknown. However, to the extent that this illness has symptoms from both a major mood disorder and schizophrenia, theoretically one can confer a relatively better prognosis than schizophrenia and a relatively poorer prognosis than bipolar disorder. The following variables are harbingers of a poor prognosis:

1. a poor premorbid history;
2. an insidious onset;
3. absence of precipitating factors;
4. a predominance of psychotic symptoms, especially deficit or negative ones;
5. an early age of onset;
6. an unremitting course, and;
7. a family history of schizophrenia.

The corollary would be that the opposite of each of these characteristics would suggest a better prognosis. Interestingly, the presence or the absence of Schneiderian first-rank symptoms does not seem to predict the course of illness. The incidence of suicide in patients with schizoaffective disorder is at least 10%. Some data indicate that the suicidal behavior may be more common in women than men.

In one study, 82% of those patients who were suffering from a first episode of schizoaffective disorder, and had recovered, experienced psychotic relapse within 5 years. These patients had high rates of second and third relapses despite careful monitoring. Medication discontinuations in first episode patients who are stable for 1 year substantially increase relapse risks. Aside from medication status, premorbid social adjustment was the only predictor of relapse in their study. Poor adaptation to school and premorbid social isolation predicted initial relapse independent of medication status. Thus, like schizophrenia, the risk of relapse is diminished by antipsychotic maintenance treatment (Robinson *et al.*, 1999).

### Treatment

With the shifting definitions of schizoaffective disorder, evaluating the treatment of schizoaffective disorder is not easy. Mood stabilizers, antidepressants and antipsychotic medications clearly have a role in management of these patients. The presenting symptoms, their duration and intensity, and patient choices need to be incorporated into deciding what treatment(s) to choose.

### Antipsychotic Medications

Atypical antipsychotic medications are reported to be more effective than the typical ones in the treatment of schizoaffective disorder. They appear to have a more broad-spectrum effects than the typical agents. Optimizing antipsychotic treatment, especially with the novel agents, is more likely to be effective than the routine use of adjunctive antidepressants or mood stabilizers. However, when indicated, the use of antidepressants is well supported in schizoaffective patients who present with a full depressive syndrome after stabilization of psychosis.

Olanzapine, ziprasidone and risperidone appear to be effective against symptoms of psychosis, mania and depression. Clozapine use may be beneficial in the treatment of refractory schizoaffective disorder as it has both mood stabilizing and antipsychotic properties, a substantial advantage.

### Mood Stabilizers

A small number of studies suggest that valproic acid, lithium and lamotrigine are effective in treating the manic symptoms associated with schizoaffective disorder, bipolar type.

**Antidepressants** The novel antipsychotic agents are often efficacious against depression in patients who suffer from both depression and psychosis negating the need for routine use of antidepressants. However, there are patients who remain depressed even with optimal antipsychotic and mood stabilizer treatment. SSRIs are widely used in patients who present with schizoaffective disorder with depression. If the SSRIs and newer antidepressants do not show efficacy, tricyclic antidepressants do have a role. Interestingly, chlorpromazine in combination with amitriptyline was reported to be as effective as chlorpromazine alone. Many studies suggest that addition of antidepressants helps in effective treatment of depression in schizoaffective disorder. Occasionally, antidepressants may worsen the course. For patients suffering from depression where they are not responding adequately and are at risk for suicide, ECT is an effective alternative.

**Psychosocial Treatment** To the extent that schizoaffective disorder shares symptoms with schizophrenia, most of the psychosocial treatments used in the treatment of schizophrenia are likely to be useful in the treatment of schizoaffective disorder. Specifically, patients benefit from individual supportive therapy, family therapy, group therapy, cognitive-behavioral therapy and social skills training. Many patients would be suitable candidates for assertive community therapy (ACT). Depending on the level of recovery, some of the patients may need rehabilitation services to assist them with either developing skills for some form of employment or assistance to maintain a job. Family members benefit from support groups such as NAMI or MDA groups.

### Brief Psychotic Disorder

Brief psychotic disorder is defined by DSM-IV-TR as a psychotic disorder that lasts more than 1 day and less than a month.

Moreover, the disorder may develop in response to severe psychosocial stressors or group of stressors. European and Scandinavian countries have traditionally diagnosed this type of psychosis as **psychogenic psychoses**, **reactive psychosis**, or **brief reactive psychosis**.

### Epidemiology

This illness is not uncommon, but, unfortunately, reliable estimates of the incidence, prevalence, sex ratio and average age of onset are not available. It is believed that this disorder is more common among young people with occasional cases involving older people. This disorder may be seen more commonly in patients from low socioeconomic classes and in those with personality disorders such as histrionic, paranoid, schizotypal, narcissistic and borderline. Though immigrants and people who have experienced major disasters are reported to be at a higher risk, well-controlled studies have failed to show this.

### Diagnosis

The DSM-IV diagnostic criteria specify the presence of at least one clear psychotic symptom lasting a minimum of 1 day to a maximum of 1 month. Furthermore, DSM-IV allows the specification of two additional features: the presence or the absence of one or more marked stressors and a postpartum onset. DSM-IV describes a continuum of diagnosis for psychotic disorder based primarily on duration of the symptoms. Once the duration criteria are met, other conditions such as etiological medical illnesses and substance-induced psychosis need to be excluded. In those cases where the duration of psychosis lasts more than 1 month, appropriate diagnosis to be considered are other psychotic conditions based on reevaluation of the clinical features, duration of psychosis and presence of mood symptoms.

### Clinical Features

People suffering from this disorder usually present with an acute onset, manifest at least one major symptom of psychosis, and do not always include the entire symptom constellation seen in schizophrenia. Affective symptoms, confusion and impaired attention may be more common in brief psychotic disorders than in chronic psychotic conditions. Some of the characteristic symptoms include emotional lability, outlandish behavior, screaming or muteness and impaired memory for recent events. Some of the symptoms suggest a diagnosis of **delirium** and may warrant a more complete medical workup. The symptom patterns include acute paranoid reactions, reactive confusions, excitations and depressions.

### Precipitating Stressors

The precipitating stressors most commonly encountered are major life events that would cause any person significant emotional turmoil. Such events include the death of a close family member or severe accidents. Rarely, it could be accumulation of many smaller stresses.

### Differential Diagnosis

Although the classical presentation may be short in duration and associated with stressors, a thorough and careful evaluation is necessary. Additional information is critical to rule out other major psychotic conditions as temporal association of stressors to the acute manifestation of symptoms may be coincidental and thus misleading. Other conditions to be ruled out include psychotic disorder due to a general medical condition, substance-induced psychosis, factitious disorder with predominantly psychological

signs and symptoms, and malingering. Patients with epilepsy and delirium may also present with similar symptoms. Additional conditions to be considered are dissociative identity disorder and psychotic episodes associated with borderline and schizotypal personality disorder that may last for less than a day.

### Course and Prognosis

As defined by DSM-IV, the duration of the disorder is less than 1 month. Nonetheless, the development of such a significant psychiatric disorder may indicate a patient's mental vulnerability. An unknown percentage of patients who are first classified as having brief psychotic disorder later display chronic psychiatric syndromes such as schizophrenia and bipolar disorder. Patients with brief psychotic disorders generally have good prognosis, and European studies indicate that 50 to 80% of all patients have no further major psychiatric problems.

The length of the acute and residual symptoms is often just a few days. Occasionally, depressive symptoms follow the resolution of the psychosis. Suicide is a concern during both the psychotic phase and the postpsychotic depressive phase. Indicators of good prognosis are good premorbid adjustment, few premorbid schizoid traits, severe precipitating stressors, sudden onset of symptoms, confusion and perplexity during psychosis, little affective blunting, short duration of symptoms and absence of family history of schizophrenia.

### Treatment

These patients may require short-term hospitalizations for a comprehensive evaluation and safety. Antipsychotic drugs are often most useful along with benzodiazepines. Long-term use of medication is often not necessary and should be avoided. If maintenance medications are necessary, the diagnoses may need to be revised. Clearly, the newer antipsychotic agents have a better neurological side effect profile and would be preferred over the typical agents.

Psychotherapy is necessary to help the person reintegrate the experience of psychosis and possibly the precipitating trauma. Individual, family and group therapies may be necessary in some individuals. Many patients need help to cope with the loss of self-esteem and confidence.

### Schizophreniform Disorder

Gabriel Langfeldt (1939) suggested the term **Schizophreniform Disorder** in 1937 for a heterogeneous group of patients characterized by the similarity of their symptoms to those of schizophrenia albeit with a good clinical outcome. Langfeldt observed that those patients whose diagnosis was questionable as schizophrenia had a much better outcome than those whose diagnosis was confirmed as schizophrenia; these patients were thus classified as having schizophreniform psychosis. Langfeldt also noted that these patients often had good premorbid adjustment, an abrupt onset of symptoms, frequent presence of psychosocial stressor(s) and a good prognosis.

### Family History

Several studies suggest that the relatives of patients with schizophreniform psychosis are at a high risk of having psychiatric disorders. The relatives of patients with schizophreniform psychosis are more likely to have mood disorders than are the relatives of patients with schizophrenia. In addition, the relatives of patients with schizophreniform disorder are more likely to have a diagnosis of a psychotic mood disorder than are the relatives of patients with bipolar disorders.

## Biological Measures

Although brain-imaging studies suggest a similarity between schizophreniform disorder and schizophrenia, one study of electrodermal activity has indicated a difference. Patients with schizophrenia born during the winter and spring months had hyporesponsive skin conductances, but this association was absent in patients with schizophreniform disorder. Though the significance of this one study would be difficult to interpret, the results do suggest caution in assuming similarity between patients with schizophrenia and those with schizophreniform disorder. Data from a study of eye tracking in the two groups also indicate that there are differences on some biological measures between schizophrenia and schizophreniform psychosis.

## Diagnosis

Schizophreniform disorder shares a majority of the DSM-IV-TR diagnostic features with schizophrenia (see diagnostic criteria above) except the following two criteria: 1) the total duration of the illness which includes the prodrome, active, and residual phases is at least 1 month but less than 6 months in duration; and 2) though impairment in social and occupational functioning may occur during the illness, it is not required or necessary. Thus, the duration of more than 1 month eliminates brief psychotic disorder as a possible diagnosis; if the illness lasts or has lasted for more than 6 months, the diagnosis has to be reevaluated for other possible conditions including schizophrenia. Therefore, the diagnosis of schizophreniform disorder is intermediate between brief psychotic disorder and schizophrenia. Hence, those patients whose duration of episode lasted more than a month and less than 6 months, and have recovered, would be diagnosed as having schizophreniform disorder. On the other hand those patients who have not recovered from an episode, which is less than 6 months but more than one month in duration, and are likely to have schizophrenia would be diagnosed as having schizophreniform disorder until the 6 months criteria is met for schizophrenia. The diagnosis of 'provisional' schizophreniform disorder is made while the clinician monitors the evolving course of the illness, waits for the symptoms to resolve, or when the clinician cannot obtain a reliable history from a patient about the duration of the symptoms.

## Specifiers for Prognostic Features

The DSM-IV has specifiers for the presence or absence of good prognostic features. These features include a rapid onset (within 4 weeks) of prominent psychotic symptoms, presence of (psychogenic) confusion or perplexity at the height of the psychotic episode, good premorbid adjustment as evidenced by social and occupational functioning, and the absence of deficit symptoms such as blunted or flat affect.

## Clinical Features

The clinical signs and symptoms and the Mental Status Examination of the patient with schizophreniform disorder are often similar to those with schizophrenia, but the presence of affective symptoms usually predict a favorable course. Alternatively, a flat or blunted affect may predict an unfavorable course.

## Differential Diagnosis

This is similar to schizophrenia. Psychotic disorder caused by a general medical condition and substance-induced psychotic disorder must be ruled out. General medical conditions to be considered are HIV infection, temporal lobe epilepsy, CNS tumors

and cerebrovascular disease, all of which can also be associated with relatively short-lived psychotic episodes. The increasing number of reports of psychosis associated with the use of anabolic steroids by young men who are attempting to build up their muscles to perform better in athletic activities require careful history. Factitious disorder with predominantly psychological signs and symptoms and malingering may need to be ruled out in some instances.

## Course and Prognosis

This is, as anticipated, variable. The DSM IV specifiers "with good prognostic features" and "without good prognostic features" though helpful in guiding the clinician, require further validation. However, confusion or perplexity at the height of the psychotic episode is the feature best correlated with good outcome. Also, the shorter the period of illness, the better the prognosis is likely to be. There is a significant risk of suicide in these patients. Postpsychotic depression is quite likely and should be addressed in psychotherapy. Psychotherapy may help speed the recovery and improve the prognosis. By definition, schizophreniform disorder resolves within 6 months with a return to baseline mental functioning.

## Treatment

Hospitalization is often necessary and allows for effective assessment, treatment and supervision of a patient's behavior. The psychotic symptoms, usually treated with a 3- to 6-month course of antipsychotic drugs, respond more rapidly than in patients with schizophrenia. One study found that 75% of the patients with schizophreniform psychosis compared with 20% of those with schizophrenia responded to antipsychotic agents within 8 days. ECT may be indicated for some patients, especially those with marked catatonic features or depression. If a patient has recurrent episodes, trials of lithium carbonate, valproic acid, or carbamazepine may be warranted for prophylaxis. Psychotherapy is usually necessary to help patients integrate the psychotic experience into their understanding of their minds, brains and lives.

## Delusional Disorder

Delusional disorder refers to a group of disorders, the chief feature of which is the presence of **nonbizarre** delusions. People suffering from this illness do not regard themselves as mentally ill and actively oppose psychiatric referral. Because they may experience little impairment, they generally remain outside hospital settings, appearing reclusive, eccentric, or odd, rather than ill. They are more likely to have contacts with professionals such as lawyers and other medical specialists for health concerns. The current shift in diagnosis from **paranoid** to **delusional** helps avoid the ambiguity around the term "paranoid". This also emphasizes that other delusions besides the paranoid ones are included in this diagnosis. It is important to understand the definition of nonbizarre delusion so as to reach an unambiguous diagnosis. Nonbizarre delusions typically involve situations or circumstances that can occur in real life (e.g., being followed, infected, or deceived by a lover) and are believable.

## Diagnostic Criteria

According to DSM-IV-TR, the diagnosis of delusional disorder can be made when a person exhibits nonbizarre delusions of at least 1 month's duration that cannot be attributed to other psychiatric disorders. Nonbizarre delusions must be about phenomena that, although not real, are within the realm of being possible. In

general, the patient's delusions are well systematized and have been logically developed. If the person experiences auditory or visual hallucinations, they are not prominent except for tactile or olfactory hallucinations where they are tied in to the delusion (e.g., a person who believes that he emits a foul odor might experience an olfactory hallucination of that odor). The person's behavioral and emotional responses to the delusions appear to be appropriate. Usually the person's functioning and personality are well preserved and show minimal deterioration if at all.

### Epidemiology

Though the existence of delusional disorder has been known for a long time, relatively little is known about the demographics, incidence and prevalence. Unfortunately, people suffering from this illness function reasonably well in the community and lack insight resulting in minimal or no contact with the mental health system. However, the crude incidence is roughly 0.7 to 3.0 per 100 000 with a more frequent occurrence in females.

### Etiology

Etiology of the delusional disorder is unknown. Risk factors associated with the disorder include advanced age, sensory impairment/isolation, family history, social isolation, personality features (e.g. unusual interpersonal sensitivity) and recent immigration. Some have reported higher association of delusional disorder with widowhood, celibacy and history of substance abuse. Age of onset is later than schizophrenia and earlier in men compared with women.

### Subtypes

#### Persecutory Type

This is the most common form of delusional disorder. Here the person affected believes that he or she is being followed, spied on, poisoned or drugged, harassed, or conspired against. The person affected may become preoccupied by small slights that can become incorporated into the delusional system. These individuals may resort to legal actions to remedy perceived injustice. Individuals suffering from these delusions often become resentful and angry with a potential to become violent against those believed to be against them.

#### Jealous Type

Individuals with this subtype have the delusional belief that their spouses/lovers are unfaithful. This is often wrongly inferred from small bits of benign evidence which is used to justify the delusion. Delusions of infidelity have also been called **conjugal paranoia**. The term **Othello syndrome** has been used to describe morbid jealousy. This delusion usually affects men, with no history of prior psychiatric problems. The condition is difficult to treat and may diminish only on separation, divorce or death of the spouse. Marked jealousy (pathological jealousy or morbid jealousy) is a symptom of many disorders including schizophrenia and not unique to delusional disorder. Jealousy is a powerful emotion and when it occurs in delusional disorder or as part of another condition, it can be potentially dangerous and has been associated with violence including suicidal and homicidal behavior.

#### Erotomaniac Type

These patients have delusions of secret lovers. Most frequently, the patient is a woman, though men are also susceptible to these delusions. The patient believes that a suitor, usually more socially

prominent than herself, is in love with her. This can become central focus of the patient's existence and the onset can be sudden. Erotomania is also referred to as **de Clerambault's syndrome**. Again, these delusions can occur as part of other disorders too. Generally women (but not exclusively so), unattractive in appearance, working at a lower-level jobs, who lead withdrawn, lonely single lives with few sexual contacts are reported to be more prone to develop this condition. They select lovers who are substantially different from them. They exhibit what has been called paradoxical conduct, the delusional phenomenon of interpreting all denials of love no matter how clear as secret affirmations of love. Separation from the love object may be the only satisfactory means of intervention. When it affects men, it can manifest with more aggressive and possibly violent pursuit of love. Thus, such people are often in the forensic system. The object of aggression is often companions or protectors of the love object who are viewed as trying to come between the lovers. However, resentment and rage in response to an absence of reaction from all forms of love communication may escalate to a point that the love object may be in danger too.

Approximately 10% of stalkers have a primary diagnosis of erotomania. Menezies and colleagues (1995) conducted the first predictive study of violence among erotomaniac males and found that serious antisocial behavior (a criminal history) unrelated to the delusion and concurrent multiple objects of fixations discriminated between the dangerous and the nondangerous men. In a review by Meloy (1996), if violence occurred the object of love was target at least 80% of the time. The next most likely target was a third party perceived as impeding access to the object. He referred to this latter behavior as **triangulation**. Triangulation when present in jealousy, whether delusional or not, is motivated by a perceived competition for the love object.

#### Somatic Type

Delusional disorder with somatic delusions has been called **monosymptomatic hypochondriacal psychosis**. This disorder differs from other conditions with hypochondriacal symptoms in degree of reality impairment Munro (1991) has described the largest series of cases and has used content of delusions to define three main types.

**Delusions of Infestations (Including Parasitosis)** Delusional parasitosis is one of the most common presentations of monohypochondriacal psychosis, which occurs in absence of other psychiatric illness. The onset is insidious and chronic.

**Matchbox sign** describes the common phenomenon that occurred not so long ago in patients suffering from this condition. During their clinic visit, the patient would present with peeled skin, and other substances connected to delusional thinking in an empty old-fashioned matchbox as evidence that they were infested with insects. Delusional parasitosis has been described in association with many physical illnesses such as vitamin B12 deficiency, pellagra, neurosyphilis, multiple sclerosis, thalamic dysfunction, hypophyseal tumors, diabetes mellitus, severe renal disease, hepatitis, hypothyroidism, mediastinal lymphoma and leprosy. Use of cocaine and presence of dementia has also been reported.

Psychogenic parasitosis was also known as Ekbohm's syndrome before being referred to as **delusional parasitosis**. Females experienced this disorder twice as often as males. Entomologists, pest control specialists and dermatologists had often seen the patient before seen by a psychiatrist. All investigators have been impressed by the concurrent medical illnesses associated with

this condition. Others have attempted to distinguish between delusional and nondelusional aspects of presentation to establish clearer diagnosis and thus management.

**Delusions of Dymorphophobia** This condition includes delusions such as of misshapeness, personal ugliness, or exaggerated size of body parts.

**Delusions of Foul Body Odors or Halitosis** This is also called **olfactory reference syndrome**.

The frequency of these conditions is low, but they may be under diagnosed because patients present to dermatologists, plastic surgeons and infectious disease specialists more often than to psychiatrists. Patients with these conditions do respond to pimozide, a typical antipsychotic medication and also to SSRIs. Usually prognosis is poor without treatment. It affects both sexes equally. Suicide apparently motivated by anguish is not uncommon.

### Grandiose Type

This is also referred to as **megalomania**. In this subtype, the central theme of the delusion is the grandiosity of having made some important discovery or having great talent. Sometimes there may be a religious theme to the delusional thinking such that the person believes that he or she has a special message from god.

### Mixed Type

This subtype is reserved for those with two or more delusional themes. However, it should be used only where it is difficult to clearly discern one theme of delusion.

### Unspecified Type

This subtype is used for cases in which the predominant delusion cannot be subtyped within the above mentioned categories. A possible example is certain delusions of misidentification, for example, **Capgras's syndrome**, named after the French psychiatrist who described the 'illusions of doubles'. The delusion here is the belief that a familiar person has been replaced by an imposter. A variant of this is **Fregoli's syndrome** where the delusion is that the persecutors or familiar persons can assume the guise of strangers and the very rare delusion that familiar persons could change themselves into other persons at will (intermetamorphosis). Each disorder is not only a rare delusion but is highly associated with other conditions such as schizophrenia and dementia.

### Course and Prognosis

Though the onset can occur in adolescence, generally it begins from middle to late adulthood with variable patterns of course, including lifelong disorder in some cases. Delusional disorder does not lead to severe impairment or change in personality, but rather to a gradual, progressive involvement with the delusional concern. Suicide has often been associated with this disorder. The base rate of spontaneous recovery may not be as low as previously thought, especially because only the more severely afflicted are referred for psychiatric treatment. The more chronic forms of the illness tend to have their onset early in the fifth decade. Onset is acute in nearly two-thirds of the cases and gradual in the remainder. In almost half of the cases the delusion disappears at follow-up, improves in 10%, and is unchanged in 31%. In the more acute forms of the illness, the age of onset is in the fourth decade, a lasting remission occurs in over half of the patients and a pattern of chronicity develops in only 10%; a relapsing course has been observed in 37%. Thus, the more acute and earlier the onset of the illness, the more favorable the prognosis.

The presence of precipitating factors, married status and female gender are associated with better outcome. The persistence of delusional thinking is most favorable for cases with persecutory delusions and somewhat less favorable for delusions of grandeur and jealousy. However, the outcome in terms of overall functioning appears somewhat more favorable for the jealous subtype.

### Comorbidity

Depression occurs frequently and is often an independent disorder in these patients.

### Treatment

Though generally considered resistant to treatment and interventions, the management is focused on managing the morbidity of the disorder by reducing the impact of the delusion on the patient's (and family's) life. However, in recent years the outlook has become less pessimistic or restricted in planning effective treatment for these conditions. An effective and therapeutic clinician-patient relationship is important but difficult to establish.

### Somatic Treatment

Overall, treatment results suggest that 80.8% of cases recover either fully or partially. Pimozide, the most frequently reported treatment produced full remission in 68.5% and partial recovery in 22.4% ( $N = 143$ ). There are reports of treatment with other typical antipsychotic agents with variable success in small number of subjects. SSRIs have been used and reported to be helpful. The newer atypical antipsychotic agents have been used in small number of cases with success but the data is anecdotal. Bhatia and colleagues (2000) report that pimozide, fluoxetine and amitriptyline were used in their study with pimozide showing good response.

### Psychosocial Treatment

As mentioned earlier, developing a therapeutic relationship is very important and yet significantly difficult, and requires a frank and supportive attitude. Supportive therapy is very helpful in dealing with emotions of anxiety and dysphoria generated because of delusional thinking. Cognitive therapy, when accepted and implemented, is helpful. Confrontation of the delusional thinking usually does not work and can further alienate the patient.

### Shared Psychotic Disorder

Shared psychotic disorder is a rare disorder, which is also referred to as **shared paranoid disorder, induced psychotic disorder, folie a deux** and **double insanity**. In this disorder, the transfer of delusions takes place from one person to another. Both persons are closely associated for a long time and typically live together in relative social isolation. In its more common form, **folie imposee**, the individual who first has the delusion is often chronically ill and typically is the influential member of the close relationship with another individual, who is more suggestible and who develops the delusion too. The second individual is frequently less intelligent, more gullible, more passive, or more lacking in self-esteem than the primary case. If the two people involved are separated, the second individual may abandon the delusion. However, this is not seen consistently. Other forms of shared psychotic disorder reported are **folie simultanee**, where similar delusional systems develop independently in two closely associated people. The most common dyadic relationships who develop this disorder are sister-sister, husband-wife and mother-child. Almost all cases involve members of a single family.

## Epidemiology

More than 95% of all cases of shared psychotic disorder involve two members of the same family. About a third of the cases involve two sisters, another one-third involve husband and wife or a mother and her child. The dominant person is usually affected by schizophrenia or a similar psychotic disorder. In 25% of all cases, the submissive person is usually affected with physical disabilities such as deafness, cerebrovascular diseases, or other disability that increases the submissive person's dependence on the dominant person. This condition is more common in people from low socioeconomic groups and in women.

## Etiology

There is some data that suggest that people suffering from shared psychotic disorder may have a family history of schizophrenia. The dominant person suffering from this illness often has schizophrenia or a related psychotic illness. The dominant person is usually older, more intelligent, better educated and has stronger personality traits than the submissive person, who is usually dependent on the dominant person. The affected individuals usually live together or have an extremely close personal relationship, associated with shared life experiences, common needs and hopes, and, often, a deep emotional rapport with each other. The relationship between the people involved is usually somewhat or completely isolated from external societal cultural inputs. The submissive person may be predisposed to a mental disorder and may have a history of a personality disorder with dependent or suggestible qualities as well as a history of depression, suspiciousness and social isolation. The dominant person's psychotic symptoms may develop in the submissive person through the process of identification. By adopting the psychotic symptoms of the dominant person, the submissive person gains acceptance by the other.

## Diagnosis

An important feature in the diagnosis is that the person with shared psychotic disorder does not have a preexisting psychotic disorder. The delusions arise in the context of a close relationship with a person who suffers from delusional thinking and resolve on separation from that person.

## Clinical Features

The key symptom of shared psychosis is the unquestioning acceptance of another person's delusions. The delusions themselves are often in the realm of possibility and usually not as bizarre as those seen in patients with schizophrenia. The content of the delusion is often persecutory or hypochondriacal. Symptoms of a coexisting personality disorder may be present, but signs and symptoms that meet criteria for schizophrenia, mood disorders and delusional disorder are absent. The patient may have ideation about suicide or pacts about homicide; clinicians must elicit this information during the interview.

## Differential Diagnosis

Malingering, factitious disorder with predominantly psychological sign and symptoms, psychotic disorder due to a general medical condition and substance-induced psychotic disorder must be considered.

## Course and Prognosis

Though separation of submissive person from the dominant person should resolve the psychosis, this probably occurs only in 10

to 40% of the cases. Unfortunately, when these individuals are discharged from hospital, they usually move back together.

## Treatment

The initial step in treatment is to separate the affected person from the source of the delusions, the dominant individual. Antipsychotic agents may be used if the symptoms have not abated in a week after separation. Psychotherapy with the nondelusional members of the patient's family should be undertaken, and psychotherapy with both the patient and the person sharing the delusion may be indicated later in the course of treatment. To prevent redevelopment of the syndrome the family may need family therapy and social support to modify the family dynamics and to prevent redevelopment of the syndrome. Steps to decrease the social isolation may also help prevent the syndrome from reemerging.

## Comparison of DSM-IV/ICD-10 Diagnostic Criteria

The ICD-10 and DSM-IV-TR criteria sets for schizophrenia are similar in many important ways although not identical. The ICD-10 Diagnostic Criteria for Research provide two ways to satisfy the criteria for schizophrenia: having one Schneiderian first-rank symptom or having at least two of the other characteristic symptoms (hallucinations accompanied by delusions, thought disorder, catatonic symptoms and negative symptoms). In contrast to DSM-IV-TR which requires 6 months of symptoms (including prodromal, active and residual phases), the ICD-10 definition of schizophrenia requires only a 1-month duration thereby encompassing the DSM-IV-TR diagnostic categories of both schizophrenia and schizophreniform disorder. Thus, cases of DSM-IV-TR schizophreniform disorder are diagnosed in ICD-10 as schizophrenia.

The DSM-IV-TR and ICD-10 definitions of schizoaffective disorder differ with regard to the relationship of the schizoaffective disorder category with the category mood disorder with psychotic features. In DSM-IV-TR, the differentiation depends on the temporal relationship between the mood and psychotic symptoms (i.e., mood disorder with psychotic features is diagnosed whenever the psychotic symptoms occur only in the presence of a mood episode, regardless of the characteristics of the psychotic symptoms). In contrast, the ICD-10 definition of schizoaffective disorder is much broader. It includes situations in which certain specified psychotic symptoms (i.e., thought echo, insertion, withdrawal, or broadcasting; delusions of control or passivity; voices giving a running commentary; disorganized speech, catatonic behavior) occur even if they are confined to a mood episode. Therefore, many cases of DSM-IV-TR mood disorder with mood-incongruent psychotic features would be considered to be schizoaffective disorder in ICD-10. Furthermore, the ICD-10 definition suggests that there should be an "approximate balance between the number, severity, and duration of the schizophrenic and affective symptoms". For delusional disorder, the ICD-10 Diagnostic Criteria for Research specify a minimum 3-month duration in contrast to the 1-month minimum duration in DSM-IV-TR.

In contrast to the single DSM-IV-TR category brief psychotic disorder, ICD-10 has a much more complex way of handling brief psychotic disorders. It includes criteria sets for four specific brief psychotic disorders that differ based on types of symptoms (i.e., with or without symptoms of schizophrenia)

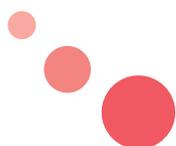

and course (i.e., whether they change rapidly or not). Furthermore, the maximum duration of these brief psychotic episodes varies depending on the type of symptoms (i.e., 1 month for schizophrenia-like symptoms and 3 months for predominantly delusional). In contrast, DSM-IV-TR has a single criteria set and a maximum 1-month duration.

Finally, the ICD-10 and DSM-IV-TR definitions of shared psychotic disorder are almost identical.

### Definition

The depressive disorders are characterized by lifelong vulnerability to episodes of disease, involving depressed mood or loss of interest and pleasure in activities. Individuals may demonstrate ongoing potential for cycling of mood from euthymia to depression to recovery and sometimes to hypomania or mania. When individuals cycle to hypomania or mania, then a diagnosis of bipolar II (in the case of hypomania) or bipolar I (in the case of mania) is made. When the mood disorder is severe, assessment for psychosis is essential.

In most definitions of depression, a distinction is drawn between a feeling state of dejection, sadness, or unhappiness, which may be brief in duration, and a clinical syndrome characterized by persistent sadness, profound discouragement, or despair which persists two weeks or more and is associated with a change from previous functioning. This clinical syndrome invariably involves alterations in mood experienced by an individual as a feeling of sadness, irritability, dejection, despair, or loss of interest or pleasure. Associated neurovegetative or biological signs of depression include impairment in sleep, appetite, energy level, libido and psychomotor activity. Cognitive manifestations of the depressive syndrome include distortions about oneself, one's experience in the world and the future, accompanied by self-blame and indecision. These core symptoms of depression are evident in children or adolescents with MDD although the depressed mood may be manifested by irritability or social withdrawal. Older adults may show a preponderance of somatic preoccupation and memory impairment in association with the signs of MDD. The current DSM-IV-TR criteria (A) for MDD are noted below.

The use of the term melancholia to refer to the depressive syndrome became less common as depression and manic-depressive disease were used more frequently in the early 20th century. Currently, the specifier with melancholic features is applied to the diagnosis of MDD if it is associated with a profound loss of interest and lack of reactivity to favorable external events. Other symptoms characteristic of melancholia include a distinct quality to the depressive mood characterized by marked worsening in the morning, early morning awakening, psychomotor retardation or agitation, significant anorexia and excessive guilt. These melancholic features are noted as a modifier of MDD in III-R, and in DSM-IV (American Psychiatric Association, 1994).

### Suicidal Phenomena

Our current definitions of MDD emphasize suicidal ideation, thoughts of death and suicide attempts as a cardinal criterion symptom of the disorder. Suicidality is the feature of depressive disorder that poses substantial risk of mortality in the disease. Prevention of suicide, more than any other treatment goal,

requires immediate intervention and may require hospitalization. The risk for subsequent completed suicide for an individual hospitalized for an episode of severe MDD is estimated to be 15%.

### Epidemiology

#### Prevalence and Incidence

Across epidemiologic studies, MDD is found to be a common psychiatric disorder. The lifetime risk for MDD in community samples vary from 10 to 25% for women and 5 to 12% for men (American Psychiatric Association, 2000). The point prevalence of MDD for adults in community samples has varied from 5 to 9% for women and from 2 to 3% for men (American Psychiatric Association, 2000). While the incidence rates of MDD in prepubertal boys and girls are equal, women over the course of their lifetime are two to three times more likely to have MDD after puberty. Whereas a strong relationship exists between low social class and schizophrenia, a weaker but nevertheless meaningful relationship may exist between low income status and the occurrence of MDD. Analyses of the Epidemiological Catchment Area (ECA) data indicated that the lowest income group manifested twice the risk of MDD than the highest income group while the National Comorbidity Survey (NCS) concluded that individuals with low socioeconomic status demonstrate higher risk for MDD than individuals who are economically well-off. The rates of MDD may also be influenced by childhood adversity including severe physical abuse, sexual abuse, neglect and poor care (Harkness and Monroe, 2002). The NCS identified the risk factors associated with having MDD comorbid with another mental disorder as opposed to MDD alone. These risk factors include younger age, lower level of education and lower income.

#### Lifetime Risk and Lifetime Prevalence

Lifetime risk refers to the proportion of individuals being studied who would go on to develop the disorder during their lifetime. Estimates of lifetime risk of MDD in community samples vary from 20 to 25% for women and 7 to 12% for men (Depression Guideline Panel, 1993). Lifetime prevalence refers to those individuals who, up to the time of assessment, have had symptoms that met diagnostic criteria at some point in their lives. The NCS estimated overall lifetime prevalence of MDD as 17.1%. The estimated prevalence was twice as high in females than males. The ECA study and NCS identified higher lifetime prevalence in younger age groups consistent with the birth cohort effect and possible recall bias. In the survey replication of the NCS (NCS-R) (Kessler *et al.*, 2005), the lifetime prevalence estimate of major depression was 16.6%. Lifetime prevalence for all mood disorders was 20.8%. Both of these estimates were considered to be conservative.

**DSM-IV-TR Criteria** 296.xx**Major Depressive Episode**

Five (or more) of the following symptoms have A. been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure. **Note:** Do not include symptoms that are clearly due to a general medical condition, or mood-incongruent delusions or hallucinations.

- (1) Depressed mood most of the day, as indicated by either subjective report (e.g., feels sad or empty) or observation made by others (e.g., appears tearful). **Note:** In children and adolescents, can be irritable mood.
- (2) Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation made by others).
- (3) Significant weight loss when not dieting or weight gain (e.g., a change of more than 5% of body weight in a month), or decrease or increase in appetite nearly every day. **Note:** In children, consider failure to make expected weight gains.
- (4) Insomnia or hypersomnia nearly every day.
- (5) Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down).
- (6) Fatigue or loss of energy nearly every day.
- (7) Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick).
- (8) Diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others).
- (9) Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide.

B. The symptoms do not meet criteria for a mixed episode.

C. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

D. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hypothyroidism).

The symptoms are not better accounted for by E. bereavement, i.e., after the loss of a loved one, the symptoms persist for longer than 2 months or are characterized by marked functional impairment, morbid preoccupation with worthlessness, suicidal ideation, psychotic symptoms, or psychomotor retardation.

**Point Prevalence**

Point prevalence or current prevalence refers to the proportion of the individuals that have the disorder being studied at a designated time. The specific point prevalence of MDD in community samples has ranged from 5 to 9% for women and 2 to 3% for men. The current point prevalence estimates in the NCS were 4.9%. Of the more prevalent 12 month disorders, the NCS-R found that major depressive disorder was the third most common disorder (6.7%). Although more than one third of cases were found to be mild, the prevalence of moderate and serious cases was 14% of this population and mood disorders was considered the second most common disorder of those serious cases. The point prevalence of MDD in primary care outpatient settings ranges from 4.8 to 8.6% (Depression Guideline Panel, 1993a). In hospitalized patients for all medical conditions, more than 14% had MDD.

**Children and Adolescents**

For preschool children, the point prevalence is thought to be of 0.8% (Depression Guideline Panel, 1993). Point prevalences of major and minor depressive disorder of 1.8 and 2.5%, respectively, were found in a sample of 9-year-old children from the general population, based upon the use of a semistructured diagnostic instrument (Kashani *et al.*, 1983). A semistructured diagnostic instrument was used to find a 4.7% point prevalence

rate of major depression in a community sample of 150 adolescents. Those adolescents diagnosed with MDD had symptoms that met criteria for dysthymia as well. A point prevalence rate of 3.3% was found for dysthymia. Weller and Weller (1990) have shown the prevalence of MDD in clinical samples of children and adolescents to be 58% in educational clinics, 28% in outpatient psychiatric clinics and 40 to 60% in psychiatric hospitals. By comparison, a prevalence of 7% is found in hospitalized pediatric patients. Emslie *et al.*, (1990) assessed depressive symptoms by self-report in a large sample of high school students of mixed ethnic background in an urban school district. They found that hispanic females reported more severe depression whereas white males reported the least severe scores of depression. For males and females, African-Americans and hispanics reported significantly more depression than whites. Female gender, being behind in school and nonwhite ethnicity predicted higher self-report scores of depressive symptoms.

**Older Adult**

Weissman and colleagues (1991) found a 1% prevalence of MDD in adults 65 years and older who lived in the community. The data indicate that a lower lifetime prevalence of MDD was found in the oldest age group ( $\geq$  age 65) in comparison to younger age groups. Women manifest an increased prevalence

of MDD in comparison to men and no significant differences were found across racial or ethnic groups. However, other community samples of older adults were found to have a high prevalence (8–15%) of clinically significant depressive symptoms (but not a formal diagnosis of MDD). In a recent Stockholm group, the frequency of MDD was 5.9% and the rate of DD was 8.3% (Forsell *et al.*, 1994).

In comparison to community settings, higher prevalence rates for MDD are found in treatment settings for older adults: 11% in hospitals, 5% in outpatient nonpsychiatric clinics and 12% in long-term care settings. There is also a higher prevalence rate in treatment settings of clinically significant depression that is not severe enough to warrant a formal diagnosis of MDD: 25% prevalence in hospitals and 30.5% in long-term care facilities.

### Birth Cohort

Klerman and Weissman (1989) as well as The Cross-National Collaborative Group (1992) called attention to a changing rate of MDD for recent birth cohorts found in: North America, Puerto Rico, Western Europe, Middle East, Asia and the Pacific Rim. Specifically, earlier age of onset and increased rate of depression occur in individuals born in more recent decades. This finding was supported in NCS-R as well. Historical, social, economic, or biological events most likely account for the variability in rate of depression noted in different countries included in the study. However, an overall increase in the rate of depression was noted across many of the geographic locations.

Older adults continue to manifest a higher suicide rate than in younger age groups. However, suicide rates have increased in younger age groups as the changing rate of MDD is observed in younger cohorts. In keeping with the birth cohort effect, recurrences of MDD in late life may become a significant health concern as the population ages.

### Risk Factors

Familiarity with risk factors for MDD may help the clinician recognize or diagnose this common and serious psychiatric illness. Accordingly, The Depression Guideline Panel (1993) enumerated 10 primary risk factors for depression:

1. History of prior episodes of depression;
2. Family history of depressive disorder especially in first-degree relatives;
3. History of suicide attempts;
4. Female gender;
5. Age of onset before age 40;
6. Postpartum period;
7. Comorbid medical illness;
8. Absence of social support;
9. Negative, stressful life events;
10. Active alcohol or substance abuse.

In the NCS, 4.9% of subjects were diagnosed as having a current episode of MDD. Of the subjects with depression, 43.7% had noncomorbid depression while 56.3% had comorbid conditions. This distribution of comorbid versus noncomorbid conditions is consistent with other reports of community and clinical samples examining the extent of cooccurrence. In the NCS, certain risk factors, including: 1) younger age, 2) lower level of education, and 3) lower income, were more associated with comorbid depression than noncomorbid depression.

## Comorbidity Patterns: General Medical Conditions

Whereas a 4 to 5% current prevalence rate of MDD exists in community samples, symptoms of depression are found in 12 to 36% of patients with a general medical condition (Depression Guideline Panel, 1993). The rate of depression may be higher in patients with a specific medical condition. MDD is identified as an independent condition and calls for specific treatment when it occurs in the presence of a general medical condition.

The Depression Guideline Panel includes four possible relationships between depression and a general medical condition: 1) depression is biologically caused by the general medical condition; 2) an individual who carries a genetic vulnerability to MDD manifests the onset of depression triggered by the general medical condition; 3) depression is psychologically caused by the general medical condition; and 4) no causal relationship exists between the general medical condition and mood disorder. The first two cases warrant initial treatment directed at the general medical disorder. Treatment is advocated for persistent depression upon stabilization of the general medical condition. When the general medical condition causes depression, specific treatment for the former condition is optimized, while psychiatric management, education and antidepressant medication are administered to treat the depression. In cases where the two conditions are not etiologically related, appropriate treatment is indicated for each disorder.

### Stroke

Some poststroke patients manifest depression due to cerebrovascular disease related to cerebral infarction in left frontal and left subcortical brain regions. Mood disorder due to cerebrovascular disease is diagnosed when an individual manifests a recent stroke and has significant symptoms of depression. A point prevalence of mood disorder due to cerebrovascular disease in poststroke patients between 10 and 27% has been documented, with an average duration of depression lasting approximately 1 year. Case reports of mood disorder due to cerebrovascular disease in poststroke patients suggest poor treatment compliance, irritability and personality change (Ross and Rush, 1981).

### Dementia

According to DSM-IV-TR, when symptoms of clinically significant depressed mood accompany dementia of the Alzheimer's Type and, in the clinician's judgment, the depression is due to the direct physiological effects of the Alzheimer's disease, mood disorder due to Alzheimer's disease is diagnosed. When dementia consistent with cerebrovascular disease leads to prominent cognitive deficits, focal neurological signs and symptoms, significant impairment in functioning as well as predominant depressed mood, vascular dementia with depressed mood is diagnosed. The distinction between depressive disorders and dementing disorders is often complicated because depression and dementia commonly cooccur. Treatment of cooccurring depressive features may relieve symptoms and improve overall quality of life.

### Parkinson's Disease

Fifty percent of patients with Parkinson's disease experience a MDD during the course of the illness. When depression occurs in this context, one diagnoses mood disorder due to Parkinson's disease. Active treatment of the depressive disorder may result in improvement in the signs and symptoms of depression without alleviation of the involuntary movement disorder or cognitive

changes associated with subcortical brain disease. The underlying etiology of associated dementia and depressive disorder in Parkinson's disease appears to involve physiologic changes in subcortical brain regions.

### Diabetes

It is estimated that the prevalence of depression in treated patients with diabetes is three times as frequent as in the general population. Further, there is no difference in the prevalence rate of depression in patients with insulin-dependent diabetes mellitus (Type I) in comparison to patients with noninsulin-dependent diabetes mellitus (Type II). The symptomatic presentation of MDD in patients with diabetes is similar to patients without diabetes. Consequently, full assessment of and treatment for MDD is recommended in patients who become depressed during the course of diabetes. The relatively high point prevalence rate may be due to higher detection rate in this treated population, having a chronic illness, as well as metabolic and endocrine factors.

### Coronary Artery Disease

When MDD is present, increased morbidity and mortality is reported in postmyocardial infarction patients as well as in patients having coronary artery disease without myocardial infarction (MI). Therefore, treatment of MDD in patients with coronary artery disease is indicated. Prevalence estimates of MDD in postmyocardial infarction range from 40 to 65%. Over a 15-month period, patients 55 years or older who had mood disorder evidenced a mortality rate four times higher than expected, and coronary heart disease or stroke accounted for 63% of the deaths. Depression may promote poor adherence to cardiac rehabilitation and worse outcome. During the first year following MI, depression is considered to be associated with a three- to fourfold increase in subsequent cardiovascular morbidity and mortality. Depression in patients with coronary artery disease is associated with more social problems, functional impairment and increased health care utilization. Recent studies of erectile dysfunction, cardiovascular disease and depression demonstrate that all three conditions share many of the same risk factors.

### Cancer

MDD occurs in 25% of patients with cancer at some time during the illness. MDD should be assessed and treated as an independent disorder. The intense reaction in patients diagnosed with cancer may lead to dysphoria and sadness without evolving a full syndrome of MDD. The consulting psychiatrist must evaluate the patient's response to chemotherapy, side effects of the treatment, and medication interactions in the overall assessment of the patient. Among patients with cancer, MDD is typically characterized by heightened distress, impaired functioning and decreased capacity to adhere to treatment. Treating comorbid MDD with psychotherapy or pharmacotherapy may improve the overall outcome in patients with cancer and mitigate complications of MDD.

### Chronic Fatigue Syndrome

Lifetime rates of MDD in patients with chronic fatigue syndrome range from 46 to 75%. Comorbid anxiety and somatization disorders are also common in patients with chronic fatigue. According to the Centers for Disease Control (CDC) criteria, the diagnosis of chronic fatigue syndrome is excluded in patients whose symptoms meet criteria for a formal psychiatric disorder,

such as MDD or DD. Patients whose symptoms meet criteria for both a mood disorder and chronic fatigue syndrome should be maximally treated for the mood disorder with appropriate pharmacotherapy and cognitive-behavioral psychotherapy. The etiological relationship between mood disorder and chronic fatigue syndrome is unclear.

### Depression Due to Medications

If MDD is judged to be a direct physiologic effect of a medication, then substance induced mood disorder is diagnosed. Medications reported to cause depression involve several drugs from the associated groups listed in Table 46.1.

Among antihypertensive treatment, beta-adrenergic blockers have been studied regarding the risk of depression. No significant differences are found between individuals treated with beta-blockers and those treated with other antihypertensives regarding the propensity to develop depressive symptoms. Lethargy is the most common side effect reported. No significant depressive complications are reported with calcium channel blockers or angiotensin converting enzyme (ACE) inhibitors.

Hormonal treatments, such as corticosteroids and anabolic steroids, can elicit depression, mania, or psychosis. Oral contraceptives require monitoring regarding the possible precipitation of depressive symptoms. Because patients with seizure disorders and Parkinson's disease are at high risk for concomitant MDD, it is difficult to establish a link between anticonvulsant or antiParkinsonian treatment and the precipitation of depression. Nevertheless, patients require close monitoring and evaluation for evolution of depressive symptomatology.

**Table 46.1 Medications Associated with Depression**

Cardiovascular Drugs	Hormones	Psychotropics
Methyldopa	Oral contraceptives	Benzodiazepines
Reserpine	Corticotropin and glucocorticoids	Neuroleptics
Propranolol	Anabolic steroids	
Guanethidine		
Clonidine		
Thiazide diuretics		
Digitalis		
Anticancer Agents	Anti-inflammatory and Anti-infective Agents	Others
Cycloserine	Nonsteroidal antiinflammatory agents	Cocaine (withdrawal)
	Ethambutol	Amphetamines (withdrawal)
	Disulfiram	Levodopa
	Sulfonamides	Cimetidine
	Baclofen	Ranitidine
	Metoclopramide	

## Comorbidity Patterns: Other Clinical Psychiatric Disorders

The presence of a comorbid psychiatric disorder may alter the course of major mood disorder in a dramatic fashion and is identified as a primary risk factor for poor treatment response. More than 40% of patients with MDD have additional symptoms that meet criteria during their lifetime for one or more additional psychiatric disorders. In a sample, assessing both pure and comorbid MDD based upon findings from the NCS, the current prevalence of major depression was 4.9% (Blazer *et al.*, 1994). Of the sample with current MDD, 56.3% also had another psychiatric disorder. Among respondents to the NCS-R, the 12 month prevalence of disorders were considered to be serious in 22%, moderate in 37.3% and mild in 40.4%. Twenty-two percent of those with disorders carried two diagnoses, and 23% carried three more diagnoses. The most common comorbid conditions were with major depression and included:

- bipolar disorder (major depression with either hypomania or mania);
- double depression (major depression with dysthymia);
- anxious depression (major depression with generalized anxiety disorder).

## Alcohol/Drug Dependence

Results of family and twin studies in a population-based female sample are consistent with a modest correlation of the liability between alcohol dependence and MDD (Kendler *et al.*, 1993). It is common for individuals with alcohol dependence to evidence signs of depression or MDD, but alcoholism is not thought to be a common consequence of mood disorder. Between 10 and 30% of patients with alcoholism manifest depression (Petty, 1992), whereas alcoholism is thought to occur in under 5% of depressed patients (Depression Guideline Panel, 1993).

Depressed women are more likely to self-medicate their mood disorder with alcohol than are depressed men. The effect of comorbid alcoholism on the course of major mood disorder is unclear. Some evidence suggests that remission of depression occurs within the first month of sobriety. The effect of comorbid depression requires further attention in relation to the course of drug dependence. Drug dependence is often associated with major mood disorder and the presence of associated comorbid personality disorder.

## Anxiety Disorders

The cooccurrence of symptoms of anxiety and depression is very common. Kendler *et al.* (1986) found very high genetic correlations between MDD and generalized anxiety disorder in contrast to a modest overlap between phobic disorders and MDD. Anxiety symptoms commonly appear in depressive syndromes and MDD is frequently comorbid with anxiety disorders. From a longitudinal perspective, either symptom constellation can be a precursor to the development of the other disorder. The combination of anxiety and depression predicts greater severity and impairment than the presence of each syndrome in isolation. The association of severe panic and MDD is one of the predictors of suicidal risk. The clinician is advised to assess for symptoms of each disorder and to obtain a thorough family history. Patients with anxiety disorders often experience prior episodes of MDD or have relatives who suffer from mood disorder.

Ten to 20% of outpatients with MDD evidence comorbid panic disorder while 30 to 40% of depressed outpatients have had symptoms that met criteria for generalized anxiety disorder during the course of the mood disorder. In both cases, the anxiety disorder has preceded the major mood disorder about 50% of the time. An increased incidence of MDD is noted in patients with anxiety disorders who are followed over time.

The clinician is advised to evaluate three factors in order to determine treatment approaches when MDD cooccurs with panic disorder or social phobia: 1) the patient's family history; 2) the constellation of symptoms that were first evident in the current episode; and 3) the symptoms that cause the patient the most distress.

Recovery is less likely and symptomatology more severe in patients with comorbid MDD and panic disorder than in cases with a single diagnosis. Lifetime suicide rate is twice as high for patients with comorbid panic disorder and MDD than in panic disorder alone. It is imperative to assess for the presence of mood disorder and suicidality in patients who present with symptoms of anxiety.

## Obsessive–Compulsive Disorder

The occurrence of symptoms of depression is very common in patients with obsessive–compulsive disorder (OCD), although full symptom criteria may not be reached to warrant a formal diagnosis of MDD. Ten to 30% of patients with OCD have mood symptoms that meet full criteria for MDD. The relationship between OCD and schizophrenia is less clear. Patients with OCD are at increased risk to develop MDD but not schizophrenia. It is important to distinguish between obsessive–compulsive personality features which can accompany and are exacerbated during an episode of depression and OCD itself. Symptoms of depression often diminish with successful initial treatment of OCD, since biological treatments typically involve use of selective serotonergic antidepressant medications such as clomipramine, fluoxetine, or fluvoxamine.

## Post Traumatic Stress Disorder

Individuals with PTSD often experience cooccurring depressive disorders, anxiety disorders and substance use disorders. The range of reported rates of concurrent depressive disorder in patients with PTSD is 30 to 50%. Many of the symptoms of PTSD overlap with signs and symptoms of depression such that both PTSD and MDD can be considered to be the result of traumatic events. In addition, depressive disorder may be associated with worse outcome in individuals with cooccurring PTSD.

## Somatization Disorder

It is common for patients with MDD to experience somatic symptoms including pain, although the intensity and frequency of the somatic complaints and the range of body systems affected do not usually meet criteria for somatization disorder. Patients who have mood symptoms that meet criteria for MDD evidence more complaints of pain, experience more physical, interpersonal and occupational limitations, and perceive their overall health as worse than patients with chronic medical illness. The clinician should carefully evaluate for the presence of MDD in cases where the patient reports unexplained pain. Typically, pain complaints are relieved upon successful treatment of the MDD. However,

somatiform disorders, as outlined in DSM-IV, may be associated with demoralization and depression.

### Eating Disorders

There are little data available regarding prevalence of eating disorders in patients with MDD. However, 33 to 50% of patients with anorexia nervosa or bulimia nervosa experience a comorbid mood disorder. Between 50 and 75% of patients with an eating disorder have a history of a MDD over a lifetime. Initial treatment is aimed at the eating disorder. If depression continues after proper nourishment has been re-established in anorexia nervosa, treatment is directed at the primary mood disorder.

### Personality Disorders

High rates of personality disorders are found in depressed inpatients and outpatients. Most studies report a rate of cooccurrence between 30 and 40% in outpatients and 50 to 60% in inpatient samples. Sixty-three percent of our sample of acutely ill patients (mostly inpatients) with a MDD were assigned at least one Axis II diagnosis on the basis of a semistructured diagnostic instrument (Gruenberg *et al.*, 1993). Several studies have found that patients with comorbid MDD and personality disorder evidence an earlier age of onset for the first episode of depression, increased severity of depressive symptoms, more episodes, longer duration of episodes, poorer response to both pharmacotherapy and psychotherapy, and increased risk for self-injury.

A particular relationship is noted for comorbid MDD and borderline personality disorder (BPD). In a general psychiatric population, depressed patients show an estimated rate of 6% for cooccurring BPD. The link between BPD and MDD remains controversial. Anecdotally, there appear to be significant levels of depression accompanying PTSD in those women who have been sexually abused. Herman (1997) has made a cogent argument for conceptualizing these women as suffering from complex PTSD rather than BPD.

### Grief and Bereavement

Depressive symptoms associated with normal grieving usually begin within 2 to 3 weeks of the loss and resolve spontaneously over 6 to 8 weeks. If full symptom criteria for MDD persist for more than 2 months beyond the death of a loved one, then an episode of MDD can be diagnosed. Specific treatment for a major depressive episode such as short-term psychotherapy focusing on unresolved grief or pharmacotherapy is indicated.

### Etiology and Pathophysiology

Depressive disorders are common and recurrent, and associated with substantial psychosocial dysfunction as well as excess morbidity and mortality. Greater understanding of the underlying etiology and pathophysiology of MDD is the focus of genetic, neurobiological and psychosocial investigation.

### Integration of Genetic and Environmental Theories

Unipolar or nonbipolar MDD has been demonstrated to cluster in the first-degree relatives of patients with depression. The observation that MDD is familial, however, does not address whether the familial aggregation may be due to genetic or familial

environmental factors. All attempts to develop integrated etiologic models of depression have identified multiple psychosocial risk factors. In particular, female gender, limited social support, dependent, self-critical and neurotic personality traits, and stressful life events appear to influence the vulnerability to MDD. Whether specific life events are as important later in the course of MDD as in the precipitation of initial episodes is the subject of ongoing investigation. Post (1992) argued that negative, stressful life events are associated with the initial or second episode of recurrent MDD whereas neurobiological factors are most relevant with subsequent recurrent episodes. Post asserted that sensitization to stressors and episodes may become encoded at the level of gene expression, underscoring the role of neurobiological factors in the progression of the illness.

Since genetic factors are operative in the etiology of MDD and prior depressive episodes place an individual at risk for future depression, indirect genetic factors operate in the vulnerability to lifetime risk. In summary, clinical and genetic epidemiologic studies suggest that MDD is a multifactorial disorder influenced by several genetic and environmental risk factors. The effectiveness of the individual's social support network in association with successful treatment may protect the individual from the vulnerability to recurrent MDD.

### Neurobiological Theories

The complex interrelation and interdependence of neurochemical systems involving critical neurotransmitters, synaptic regulation, nerve cell mediation and modulation, neuropeptides and neuroendocrine systems are poorly understood. In the past four decades, explorations of these mechanisms have focused on simpler hypotheses derived from clinical observations of drug effects. The interaction of these multiple systems has been difficult to investigate in the laboratory.

Recent studies challenging the simpler paradigm of catecholamine deficit or excess in depression have focused upon neurotransmitter modulation of nerve cell regulation as well as effects of neurotransmitter systems on receptor sensitivity. Additional studies show that patients with depression as well as those who have died by suicide are reported to have lower levels of the serotonin transporter (SERT) than in control subjects (Owens and Nemeroff, 1998). As the pharmacology of the neurotransmitters and receptors is further explicated, receptor changes leading to effects on second messenger systems and the generation of new proteins affecting gene expression will become the focus of the neurobiology of MDD.

### Sleep Studies and Biological Rhythm Disturbances

Specific abnormalities in sleep and circadian rhythms are among the most consistent findings in biological psychiatry. Clinical observations of insomnia and hypersomnia are commonly noted as a central feature of depressive disorder. Polysomnography (PSG) demonstrates that the progression of sleep from nonrapid eye movement (nonREM) stages 1 to 4 to rapid eye movement (REM) sleep is disrupted in MDD. EEG recordings demonstrate a shorter than normal onset of REM sleep termed reduced or shortened REM latency. The frequency of eye movements during REM sleep is greater, termed increased REM density. During the sleep laboratory evaluation, increased awakening during sleep leads to the reduction in total sleep time in MDD. NonREM

abnormalities include prolonged sleep latency, increased wakefulness, decreased arousal threshold and early morning awakening. Giles and colleagues (1989) have suggested that sleep EEG parameters are more trait-like and that some sleep EEG alterations may precede the onset of clinical depression.

Biological rhythm abnormalities include advances in the timing of daily rhythms such as REM sleep, cortisol and body temperature. Endogenous processes within a day (approximately 25 hours) are **circadian rhythms**. Episodic recurrences of the illness over days, months, or years are called **infradian rhythms** (a period of more than a day). **Ultradian rhythms** are oscillations that occur more than once daily and occur at the cellular and neurohormonal level. Mechanisms which explain the alterations in oscillation of biological rhythms in depression are not well delineated. Clearly, homeostatic regulation of cellular, biochemical and psychological phenomenon is necessary to maintain euthymia. Seasonal variation in mood disorders represents the effect of change in light and temperature on the individual's biological vulnerability to depression. Treatments involving light manipulation have begun to address the impact of seasonal change on those individuals vulnerable to depression with seasonal pattern.

### Neurohormonal Theories

The contribution of endocrine system alterations in depression has been examined extensively in biological studies. Both hypothyroidism and hypercortisolism may result in depression.

### Hypothalamic–Pituitary–Thyroid Axis

Hypothalamic–pituitary–thyroid (HPT) axis abnormalities are commonly seen in patients with bipolar disorder. Thyroid hormone has been used in antidepressant augmentation as well as in the modulation of rapid cycling bipolar disorder. Neurotransmitters regulate hypothalamic functioning and initiate release of thyrotropin-releasing hormone (TRH) into the portal circulation. TRH is transported to the pituitary causing release of thyroid-stimulating hormone (TSH). TSH modulates synthesis and release of  $T_3$  and  $T_4$ .

Thyroid studies in depression are not conclusive. There are more reports of slightly increased peripheral  $T_4$  in major depression than low  $T_4$ . Some patients have mild or “sub-clinical” hypothyroidism as reflected in slight TSH abnormalities and associated antithyroid antibodies. The TRH stimulation test has provided suggestive findings: 1) blunted TSH response to TRH occurs in approximately 30% of depressed patients; 2) a possible bipolar/unipolar difference has been reported with bipolar depression showing an augmented TSH response while unipolar depression shows a blunted response; and 3) CSF TRH is found to be raised in some patients with depression, possibly responsible for the blunted response of TSH to TRH, and lower levels of circulating  $T_3$  and  $T_4$ . One implication of the suggested bipolar–unipolar distinction is that bipolar depressed patients may demonstrate a false hypothyroidism, when their TSH response is consistent with the underlying bipolar disorder. Effective treatment of the bipolar disorder may reverse the TSH abnormality.

### Hypothalamic–Pituitary–Adrenal Axis

The hypothalamic–pituitary–adrenal axis (HPA) has been the subject of intensive investigation as well. The observation of elevated cortisol secretion from the adrenal glands has been replicated

consistently in patients with major depression. Corticotropin-releasing factor (CRF) is the hypothalamic hormone that regulates pituitary secretion of corticotropin (ACTH). CRF activity is influenced by multiple neurotransmitters such as 5HT, NE, ACh and GABA. ACTH binds to cells in the adrenal cortex producing release of glucocorticoids, particularly cortisol. Cortisol inhibits secretion of ACTH at the anterior pituitary and CRF at the hypothalamus. Measurements of 24-hour urinary cortisol, cortisol in the CSF and cortisol following dexamethasone suppression suggested increased cortisol secretion in MDD. The dexamethasone suppression test (DST) performed by offering dexamethasone at 11PM followed by serum cortisol at 8AM, 4PM and 11PM is a neuroendocrine probe that demonstrated adrenocortical hyperactivity in depression. DST nonsuppression normalizes with recovery from depression. Persistent nonsuppression is associated with early relapse of MDD. Increased CRF secretion may explain the hypercortisolemia and HPA overactivity. Hypercortisolemia is one of the most consistent findings in biological studies of MDD.

### Intracellular Abnormalities

A number of intracellular changes, which involve alterations in cellular second messenger systems and ion channels, are postulated to occur in depression. They may involve changes in guanine triphosphate binding proteins, G-proteins on the receptor, cyclic adenosine monophosphate (cAMP) regulation, reduced protein kinase activity and brain derived neurotrophic factor (BDNF). Stress itself has been associated with lowered levels of BDNF, which leaves vulnerable to neurotoxic effects of stress. Antidepressants as well as ECT increase BDNF and BDNF has been found to increase functioning of serotonin.

### Psychosocial Theories

Psychoanalytic theory as postulated by both Freud and Abraham emphasized the connection between mourning and melancholia, wherein the melancholic patient experiences a loss of self-esteem with associated helplessness, prominent guilt and self-denigration. According to the theory, this results from internally directed anger which or aggression turned against the self, leading to a depressive experience. Self-psychologists have described the effects of loss and trauma on the development of a coherent sense of self. Bowlby's work on attachment elucidates the impact of very early loss and trauma with a resultant predisposition to depression among other things.

Behavioral theory holds that depression is an overgeneralized response to loss of social support. Indeed, the lack of social support appears to be one of the strongest factors in promoting vulnerability to depression. The experience of depression may also elicit negative responses from others which reinforces negatively held personal beliefs.

The cognitive-behavioral perspective emphasizes a set of dysfunctional attitudes, cognitions and images associated with depressive symptomatology. This theory is the most empirically examined psychosocial theory in relation to the management and treatment of the depressed patient, and emphasizes how cognitive distortions and negative self-image cause depression and are associated with maintenance of the disorder.

The cognitive perspective as well as contributions from the helplessness–hopelessness models formed an empirical basis for CBT. In CBT, education, behavioral assignments and cognitive retraining form the active components of the psychotherapy.

This cognitive therapy has been demonstrated to be an effective short-term psychotherapy for depression. Another current therapy called interpersonal therapy derives from a focus on difficulties in current interpersonal functioning. The relationship between psychological health and one's interpersonal environment has received substantial attention.

The current iteration of the interpersonal approach is reflected in the development of a specific treatment for depression termed interpersonal psychotherapy of depression (IPT). IPT involves a formal diagnostic assessment, inventory of important current and past relationships, and definition of the current problem area. In IPT, four areas of focus that could relate to depressive symptoms are: 1) grief, 2) interpersonal role disputes, 3) role transitions, and 4) interpersonal deficits.

The loss of "social zeitgebers" has been proposed as a link between biological and psychosocial formulations. The social zeitgebers theory suggests that social relationships, interpersonal continuity and work tasks entrain biological rhythms. Disruptions of social rhythms due to loss of relationships interfere with biological rhythms that maintain homeostasis. This disruption leads to changes in neurobiological processes including alterations in neurotransmitter functions, neuroendocrine regulation, and neurophysiologic control of sleep/wake cycle and other normal circadian oscillations.

## Diagnosis and Differential Diagnosis

The detection of depression in both primary care settings and mental health settings requires the presence of mood disturbance or loss of interest and pleasure in activities for 2 weeks or more accompanied by at least four other symptoms of depression. There are problems in differential diagnosis because depressive experiences vary from individual to individual. MDD is sometimes called unipolar depression or recurrent unipolar depression because the depressive episodes tend to recur in a lifetime. Dysthymic disorder (DD) is characterized by at least 2 years of depressed mood accompanied by two or three depressive symptoms which falls short of threshold criteria for a major depressive episode. Depressive disorder not otherwise specified (DDNOS) includes a set of conditions which do not meet criteria for MDD, DD, or adjustment disorder with depressed mood. These syndromes include premenstrual dysphoric disorder, minor depressive disorder, recurrent brief depressive disorder and postpsychotic depressive disorder occurring during the residual phase of schizophrenia. In DSM-IV, two other depressive disorders are diagnosed based upon etiology and include mood disorder due to a general medical condition and substance-induced mood disorder.

The core symptoms comprising a major depressive episode are illustrated in the DSM-IV criteria. Each symptom is critical to evaluate in a patient with depressive symptomatology since each represents one of the essential features of a major depressive episode. Their persistence for much of the day, nearly every day for at least 2 weeks, is the criterion for diagnosis. The clinical syndrome is associated with significant psychological distress or impairment in psychosocial or work functioning.

The clinical observation of mood reveals variations in presentation. An individual may have depressed symptomatology and experience typical sadness. Another individual may deny sadness and experience internal agitation and dysphoria. Another individual with depression may experience no feelings at all, and the depressed mood is inferred from the degree of psychological

pain that is exhibited. Some individuals experience irritability, frustration, somatic preoccupation and the sensation of being numb.

An equally important aspect of the depressive experience involves loss of interest or pleasure, when an individual feels no sense of enjoyment in activities which were previously considered pleasurable. There is associated reduction in all drives including energy and alteration in sleep, interest in food and interest in sexual activity.

A common experience of insomnia or hypersomnia is noted in individuals with persistent depression. Observations of psychomotor activity include profound psychomotor retardation leading to stupor in more severe cases or alternatively significant agitation leading to inability to sit still and profound pacing in agitated forms of depression.

The complaint of guilt or guilty preoccupation is a common aspect of the depressive syndrome. Delusional forms of guilt are a common presentation of depressive disorder with psychotic features.

The loss of ability to concentrate, to focus attention and to make decisions is a particularly distressing symptom for individuals. One may experience a loss of memory which simulates dementia. Loss of concentration is reflected in an inability to perform both complicated and more simple tasks. The loss of ability to perform in school may be a symptom of MDD in children, and memory difficulties in the older adult may be mistaken for a primary dementia. In some older adults, a depressive episode with memory difficulties occurs in the early phase of an evolving dementia.

The most common psychiatric syndrome associated with thoughts of death, suicidal ideation, or completed suicide is MDD. The experience of hopelessness is commonly associated with suicidal ideation. The preoccupation with suicide in MDD requires that the assessment always includes careful monitoring of suicidality.

## Subtyping of MDD

The current subtyping of MDD is based on severity, cross-sectional features and course features.

### Severity

The rating of severity is based on a clinical judgment of the number of criteria present, the severity of the symptomatology, and the degree of functional distress. The ratings of current severity are classified as mild, moderate, severe without psychotic features, severe with psychotic features, in partial remission, or in full remission. The definition of "mild" refers to an episode results in only mild impairment in occupational or psychosocial functioning or mild disability. "Moderate" implies a level of severity which is intermediate between mild and severe and is associated with moderate impairment in psychosocial functioning. The definition of "severe" describes an episode which meets several symptoms in excess of those required to make a diagnosis of major depressive episode and is associated with marked impairment in occupational or psychosocial functioning and definite disability characterized by inability to work or perform basic social functions. Severe with psychotic features indicates the presence of delusions or hallucinations which occur in the context of the major depressive episode. The categories of mood-congruent versus mood-incongruent psychotic features are made in the

context of a psychotic depressive disorder. When the content of delusions or hallucinations is consistent with depressive themes, a mood-congruent psychotic diagnosis is made. When the psychotic features are not related to depressive themes or include symptoms such as thought insertion, broadcast, or withdrawal, the modifier of mood-incongruent psychotic features is used. A recent review has suggested that mood-incongruent psychosis in MDD is associated with a poorer prognosis. For depression with psychotic features, whether they are mood-congruent or mood-incongruent, antipsychotic medication in combination with antidepressant medication or electroconvulsive therapy (ECT) is required to treat the disorder.

Partial remission indicates that the episode no longer meets full criteria for major depressive episode but that some symptoms are still present or the period of remission has been less than 2 months. In full remission, the individual has no significant symptoms of depression for a period of at least 2 months.

### Cross-sectional Features

The assessment of cross-sectional features involves the presence or absence of catatonic, melancholic, or atypical features during an episode of depression. The specifier with catatonic features is used when profound psychomotor retardation, prominent mutism, echolalia, echopraxia, or stupor dominate the clinical picture. The presentation of catatonia requires a differential diagnosis which includes schizophrenia, catatonic type, bipolar I disorder, catatonic disorder due to a general medical condition, medication-induced movement disorder leading to catatonic features, or neuroleptic malignant syndrome.

The specifier with melancholic features is applied when the depressive episode is characterized by profound loss of interest or pleasure in activities and lack of reactivity to external events as well as usual pleasurable stimuli. In addition, at least three of the following melancholic features must be present: depression is typically worse in the morning, early morning awakening, psychomotor change with marked retardation or agitation, significant weight loss, or profound and excessive guilt. MDD with melancholic features is particularly important to diagnose because of the prediction that it is more likely to respond to somatic treatment including electroconvulsive therapy. Individuals with melancholic features experience more recurrence of MDD. The findings of hypercortisolism following dexamethasone as well as reduced REM latency is associated with the melancholic subtype of MDD.

Finally, the category of MDD with atypical features was previously called “atypical depression”. This syndrome is characterized by prominent mood reactivity in which there is excessive responsiveness of mood to external events and at least two of the following associated features: increased appetite or weight gain, hypersomnia, leaden paralysis (a feeling of profound anergia or heavy feeling) and interpersonal hypersensitivity (rejection sensitivity). Depressive episodes with atypical features are also common in individuals with bipolar I or II disorder as well as seasonal affective disorder.

### Course Features

MDD is diagnosed with certain course features such as postpartum onset, seasonal pattern, recurrent, chronic, and with or without full interepisode recovery. Depression with onset in the postpartum period has been the subject of increasing attention

in psychiatric consultation to obstetrics and gynecology. The presence of a MDD may occur from 2 weeks to 12 months after delivery, beyond the usual duration of postpartum “blues” (3–7 days). Postpartum blues are brief episodes of labile mood and tearfulness which occur in 50 to 80% of women within 5 days of delivery. However, depression is seen in 10 to 20% of women after childbirth (Miller, 2002), which is higher than rates of depression found in matched controls. There is greater vulnerability in women with prior episodes of major mood disorder particularly bipolar disorder, and there is a high risk of recurrence with subsequent deliveries after an MDD with postpartum onset. The postpartum onset episodes can present either with or without psychosis. Postpartum psychotic episodes occur in 0.1 to 0.2% of deliveries. Depression in postpartum psychosis is associated with prominent guilt and may involve individuals with a prior history of bipolar I disorder. If an episode of postpartum psychosis occurs, there is a high risk of recurrence with subsequent deliveries. Heightened attention to identification of postpartum episodes is required because of potential risk of morbidity and mortality to mother and newborn child.

The specifier with seasonal pattern is diagnosed when episodes of MDD occur regularly in fall and winter seasons and subsequently remit during spring and summer. When the pattern of onset and remission occurs for the last 2 years, one diagnoses an MDD with seasonal pattern. Often, this pattern is characterized by atypical features including low energy, hypersomnia, weight gain and carbohydrate craving. Although the predominant pattern is fall–winter depression, a minority of individuals show the reverse seasonal pattern with spring–summer depression. Specific forms of light therapy with 2500 lux exposure has been shown to be effective in MDD with seasonal pattern. Because seasonal depression has clinical features which are similar to atypical features, the risk of a possible bipolar II disorder must be considered since atypical features are more common in depressive episodes occurring as part of bipolar II. These individuals when exposed to antidepressant medication or bright light therapy may evolve a switch into hypomanic or manic episode.

Clinical and scientific attention to the course of MDD focuses upon the depiction of longitudinal course. Life charting of MDD involves the use of several course specifiers. Each episode is denoted with or without full recovery. MDD manifests either a single or recurrent pattern of episodes. Remission of depression requires a 2-month interval in which the criteria are not met for a major depressive episode. The specifier chronic MDD involves the persistence of a major depressive episode continually, satisfying full MDD criteria for at least 2 years.

### Depression in Children and Adolescents

In prepubertal children, MDD occurs equally among boys and girls (Depression Guideline Panel, 1993). MDD in childhood is considered to have high recurrence rates with up to 70% recurrence in 5 years. After puberty, girls experience an increased rate of depression as compared with boys. There is increased risk of depressive disorder in children and adolescence when one or more of the parents are depressed. The earlier the age of onset of depression, the higher the familial loading. In addition, a number of childhood psychosocial risk factors have been identified to be associated with juvenile-onset MDD. These risk factors include: more perinatal insults, motor skill abnormalities, instability in caregivers and psychopathology in the first-degree relatives. Adolescent-onset depression often takes on a more chronic course

associated with dysthymic symptoms. In adolescence, MDD appears to be associated with greater fatigue, worthlessness and more prominent vegetative signs while DD has more prominent changes in mood, irritability, anger and hopelessness. The signs and symptoms used for diagnosis in children and adolescents are identical to those used for diagnosis in adults. The sequelae of depression in children and adolescents is often characterized by disruption in school performance, social withdrawal, increased behavioral disruption and substance abuse. Differential diagnosis among children and adolescents with MDD include behavioral disorders such as conduct disorder, attention deficit hyperactivity disorder and bipolar disorder.

Later-onset MDD in adolescents is also associated with decline in school performance, social withdrawal, or disruptive behavior. The critical differential diagnostic consideration in adolescents with MDD is the misdiagnosis of depression when the clinical presentation will evolve into a diagnosis of bipolar disorder. When depression occurs during adolescence, it often heralds a severe disorder with recurrent course and a family history of MDD is often noted. An additional psychosocial risk factor in later-onset depression in adolescence is childhood sexual abuse.

In a community sample of adolescents, ages 14 to 18 years, onset of MDD was associated with female gender and suicidal ideation. The mean age of onset for the first episode of MDD was 14.9 years. Episodes of MDD were relatively longer in adolescents who had onset before the age of 15.

### Major Depressive Disorder in the Older Adult

Older adults with depression often experience cognitive impairment as part of the clinical syndrome. Symptoms of depression may simulate dementia with concentration difficulties, memory loss and distractibility. Commonly, MDD and dementia cooccur. It is less frequent that findings of dementia are fully explained on the basis of depression (pseudodementia). The prevalence of MDD in older adults residing in nursing homes is estimated to be approximately 30%. MDD in the elderly often cooccurs in the presence of medical conditions which complicates the treatment for both the depression and the primary medical condition. Careful evaluation of medications may also reveal explanations for associated symptoms of depression. Older adults with first onset of depression must be carefully evaluated for cooccurring medical conditions. Among the common disorders to be considered are silent cerebral ischemic events, undiagnosed cancer, or complications of metabolic conditions such as adult-onset diabetes mellitus and thyroid dysfunction.

### Depression in Ethnic Groups

In working with individuals of different ethnic groups, the language which expresses depressive symptomatology varies. Non-western cultural expressions emphasize somatic complaints more prominently than psychological complaints. Depending on the particular ethnic group understanding the specific “language of depression” is important, because the prevalence estimates cross-culturally do not appear to differ significantly from those reported in the USA.

### Assessment

The assessment of MDD involves the specific identification of five of nine criterion symptoms which would constitute a diagnosis of

MDD. A careful general medical assessment to ascertain the presence of an etiologic general medical condition is required. After the assessment for general medical conditions, one examines the individual for the presence of alcohol or drug dependence. Then the clinician is required to assess retrospectively the occurrence of prior episodes of mood disorder, either depression or mania. It is necessary to examine for other comorbid psychiatric disorders as well. Depressive illnesses are very common and recurrent, but an individual with MDD may or may not recall prior episodes. It is therefore essential to interview a significant other in addition to the patient to identify prior manic, hypomanic, or prior depressive episodes. Family inquiry allows one to elicit the family history of addiction, anxiety, depressive disorder, mania, psychosis, trauma, or neurologic disorders in first-degree relatives.

To assess risk for suicide, one inquires about the presence of active suicidal ideation in relation to the current episode of depression and a history of prior suicide attempts. The occurrence of significant life events such as separation, divorce and death of significant others may precipitate the episode. It is also necessary to review onsets of other medical conditions which may precipitate a new episode of depression. When alcohol or other drug use cooccurs with such significant life events, the risk of suicidal behavior during an episode of depression increases. The presence of a recent suicide attempt may suggest the need for immediate hospitalization and treatment.

### General Medical Assessment

The individual who presents for outpatient or hospital treatment for a primary depressive disorder will require general medical examination including a physical examination and laboratory testing to rule out an associated medical condition. Clinical assessment, including the cognitive mental status examination, will direct the extent of the general medical examination.

Laboratory studies in the management of the individual with MDD includes complete blood count with differential, electrolytes, chemical screening for renal and liver function, as well as thyroid function studies. More detailed evaluation will depend upon the nature of the clinical presentation as well as neuropsychological examination. These studies may identify cerebral vulnerability factors that would complicate the treatment for MDD.

When clinical signs suggest cognitive disruption or cognitive impairment, the clinician may also consider administering neuropsychological tests or conducting more focused neurologic examination to explore cognitive, behavioral and neurologic correlates of brain function. Neuropsychological assessment may help to clarify the relative contribution of depression or another disease process to the patient’s clinical presentation. Further, neuropsychological assessment will provide a functional analysis of the patient’s cognitive and behavioral strengths and limitations. Neurological examination may reveal minor neurological abnormalities suggesting early neurodevelopmental vulnerability.

### Psychodiagnostic Assessment

Traditional psychological testing may complement structured diagnostic instruments developed to ascertain the presence or absence of depressive disorders according to DSM-IV criteria. Psychological testing such as the Rorschach Inkblot Test are sensitive to the degree of affective lability, intensity of suicidality and impulse control in individuals with depression. In addition, inventories are commonly used in outpatient and inpatient settings

to establish scores of clinical severity of depressive symptoms. Self-administered scales include the Beck Depression Inventory, the Zung Self-Rating Depression Scale and the Inventory for Depressive Symptomatology (self-report). Psychiatrist-administered scales used for assessment of depressive symptoms include the Hamilton Rating Scale for Depression, the Montgomery Asberg Depression Rating Scale and the Inventory for Depressive Symptomatology (psychiatrist rated). Structured diagnostic interviews that have been developed to confirm major psychiatric syndromes include the present state examination, the schedule for affective disorders and schizophrenia (SADS) and structured clinical interview for DSM-IV Axis I disorders (SCID-I). The use of these structured diagnostic interviews reliably predicts the presence of an MDD. It is essential to recognize that a cross-sectional assessment is only one component of the total assessment. Corroborative family data and longitudinal assessment and reassessment of mood disorder symptoms are crucial in following the natural history and course of MDD.

## Course and Natural History

### Clinical Course and Age of Onset

In order to document onset of depressive phases as well as periods of remission, psychiatrists must pay careful attention to clinical course. Improvements in assessment procedures, including structured interview guides for the assessment of depression as well as rating scales for depression, will promote better attention to course and natural history of MDD. Long-term studies of depression must incorporate information on recovery, recurrence and chronicity. The mean age of onset of major depression is 27 years of age, although an individual can experience the onset of MDD at any age.

### Natural History of Episodes

New symptoms of MDD often develop over several to several weeks. Early manifestations of an episode of MDD include anxiety, sleeplessness, worry and rumination prior to the experience of overt depression. Over a lifetime, the presence of one major depressive episode is associated with a 50% chance of a recurrent episode. A history of two episodes is associated with a 70 to 80% risk of a future episode. Three or more episodes are associated with extremely high rates of recurrence. Because the majority of cases of MDD recur, continuation treatment and ongoing education regarding warning signs of relapse or recurrence are essential in ongoing clinical care. In an MDD when single episode recurs, a change in diagnosis to MDD recurrent is necessitated.

In comparison to individuals who develop a single episode (many of whom return to premorbid functioning), individuals with recurrent episodes of depression are at greater risk to manifest bipolar disorder. Individuals who experience several recurrent episodes of depression may develop a hypomanic or manic episode requiring re-diagnosis to bipolar disorder. In children and adolescents, the transformation of a diagnosis of depression to a diagnosis of bipolar disorder is higher. Approximately 40% of adolescents who are depressed, evolve a bipolar course. Because bipolar disorder is initiated with a depressive episode in four of five cases, it is important to identify those patients who are most likely to develop a bipolar disorder. Therefore, the clinician is confronted with significant diagnostic and treatment challenges when called upon to evaluate a patient, particularly an adolescent, who presents with depression and has no previous history of mania. Several risk factors have been identified, which predict

when a first episode of MDD will evolve into bipolar disorder: 1) the first episode of depression emerges during adolescence; 2) the depression is severe and includes psychotic features; 3) psychomotor retardation and hypersomnia are present; 4) a family history of bipolar disorder exists, particularly across two to three generations; and 5) the patient experiences hypomania induced by antidepressant medication.

Recurrent MDD requires longitudinal observation because of its highly variable course. Generally, complete remission of an episode of MDD heralds a return to premorbid levels of social, occupational and interpersonal functioning. Therefore, the goal of treatment is a focus on achieving full remission of depressive symptoms and recovery. Untreated episodes of depression last 6 to 24 months. Symptom remission and a return to premorbid level of functioning characterize approximately 66% of depressed patients. By comparison, roughly 5 to 10% of patients continue to experience a full episode of depression for greater than 2 years and approximately 20 to 25% of patients experience partial recovery between episodes. Furthermore, 25% of patients manifest “double depression”, characterized by the development of MDD superimposed upon a mild, chronic depression (DD). Patients with double depression often demonstrate poor interepisode recovery. Four characteristics are seen in a partial remission of an episode: 1) increased likelihood of a subsequent episode; 2) partial interepisode recovery following subsequent episodes; 3) longer-term treatment may be required; and 4) treatment with a combination of pharmacotherapy and psychotherapy may be indicated.

Follow-up naturalistic studies have indicated that 40.3% of individuals with MDD carry the same diagnosis 1 year later, 2.6% evidence DD, 16.7% manifest incomplete recovery and 40.5% do not meet criteria for MDD. Keller and colleagues (1992) highlight the potential for chronicity in MDD. A 5-year follow-up study indicated that 50% of 431 patients showed recovery by 6 months but 12% of the sample continued to be depressed for the entire 5-year period. The authors noted that inadequate treatment may have contributed to chronicity.

## Definitions of Remission, Relapse, Recovery and Recurrence

The precise nature of severity and duration of phases during the natural course of MDD has not been empirically demonstrated in longitudinal, prospective studies. Definitions of remission, recovery, relapse and recurrence proposed by Frank and colleagues are illustrated in Table 46.2.

### Factors Affecting Recurrence and Outcome

Poor outcome and likelihood of recurrent episodes is associated with comorbid conditions such as personality disorder, active substance or alcohol abuse, organicity, or medical illness. Recurrence and outcome may be affected by the rapidity of clinical intervention. Inadequate treatment (e.g., insufficient dosing or duration of pharmacotherapy) contributes to poor outcome, including chronic MDD. Several authors have asserted that early treatment intervention in an episode of MDD is considered to be somewhat more effective than later intervention in an episode.

### Prognosis and Morbidity

MDD must be viewed as a serious medical illness. Although depression is treatable, the prognosis for an individual diagnosed with MDD involves important implications regarding morbidity, social functioning and mortality. Patients with MDD report

**Table 46.2** Proposed Definitions of Remission, Recovery, Relapse and Recurrence

Remission	A period in which the individual is asymptomatic. Does not meet syndromal criteria for MDD, and has no more than minimal symptoms; in clinical practice, this remission extends from 2 to 9 mo.
Recovery	A remission that lasts more than 9 mo without relapse after appropriate treatment.
Relapse	A return of symptoms meeting criteria for a full syndrome of an episode of MDD that occurs during a period of remission but before recovery.
Recurrence	A manifestation of a new episode of MDD that occurs during recovery.

health difficulties and actively use health services. Studies have indicated that as many as 23% of depressed patients report health difficulties severe enough to keep them bedridden. A community sample of patients with MDD demonstrated increased health care utilization in comparison to patients in the general medical setting (Regier *et al.*, 1988). The Medical Outcomes Study (Wells *et al.*, 1989) examined role functioning, social functioning and number of days in bed secondary to poor health, and compared the degree of impact of depression and other chronic medical conditions. Depression was associated with more impairment in occupational and interpersonal functioning, and more days in bed, in comparison to several common medical illnesses.

Patients with MDD were shown to be as functionally impaired as patients with serious, chronic medical conditions as well (Katon *et al.*, 1990). Patients with MDD evidence severely impaired occupational functioning, such as loss of work time. Further, long-term diminished activity has been shown to characterize depressed patients.

### Mortality

A significant relationship exists between MDD and mortality, characterized by suicide and accidents. Therefore, an accurate diagnosis of MDD, early appropriate intervention and specific assessment of suicidality is essential. Fifteen percent of patients with MDD who require hospitalization due to severe depression will die by committing suicide. Approximately 10% of patients with MDD who attempt suicide will eventually succeed in killing themselves. Roughly 50% of individuals who have successfully committed suicide carried a primary depressive diagnosis.

Factors associated with suicide 1 year after assessment included severe anhedonia, insomnia, concentration difficulties and comorbid panic attacks or substance abuse. Factors associated with suicide at 1 to 5 years after the assessment included prior suicide attempts, suicidal ideation and hopelessness.

Patients with MDD who were admitted to nursing homes were found to have a 59% greater likelihood of death within the

first year of admission in comparison with nondepressed admissions. The ECA study indicated that patients with MDD 55 years of age and older evidence a mortality rate over the next 15 months four times higher than nondepressed controls matched for age.

The occurrence of MDD in patients who previously have been hospitalized following MI is demonstrated as an independent risk factor for mortality at 6 months. The consequences of MDD were at the very least commensurate with that of left ventricular dysfunction and history of past MI.

### Goals of Treatment

The goals of treatment in MDD are full remission of symptoms of depression with restoration of optimal work and social functioning. During the course of treatment ongoing education of the individual and family regarding remission, relapse and recurrence is critical. This education alerts both those affected by the illness and their families to the early signs of relapse and can assist in prevention of recurrence. Improved social and work functioning following an episode of depression is an important associated goal of treatment. Many studies have demonstrated the benefit of depression-specific psychotherapy as an important aspect of maintaining remission and improving work and social functioning. The establishment of a collaborative working relationship among the patient, family and psychiatrist is an essential aspect of recovery. The data which demonstrate efficacy in psychiatric management and treatment infers that a collaborative relationship is present.

### Phases of Treatment

All psychiatric treatment whether pharmacotherapy or psychotherapy or the integration of pharmacotherapy and psychotherapy, first requires a well-established diagnostic formulation in order to achieve optimal response to treatment. As the diagnostic process is undertaken an ongoing therapeutic alliance must be established. In the treatment of MDD an understanding of the clinical history of each individual's distress is necessary. As the clinical history is elicited the appropriate target signs and symptoms of MDD are obtained and the patient is educated as to the nature of the symptom patterns which represent his or her unique form of depressive disorder.

The phases of treatment include:

1. An acute phase directed at reduction and elimination of depressive signs and symptoms, and active restoration of psychosocial and work functioning.
2. A continuation phase directed at prevention of relapse and reduction of recurrence through ongoing education, pharmacotherapy and depression-specific psychotherapy.
3. A maintenance phase of treatment directed at prevention of future episodes of depression based upon the patient's personal history of relapse and recurrence.

Acute phase treatment may involve all interventions that are directed toward decreasing signs and symptoms of depression and maintaining the individual's capacity to work and interact with others in a manner consistent with premorbid levels of social and work functioning. The acute phase treatments may include supportive psychotherapy focusing on resolution of current disputes. A form of supportive therapy may be combined with recommendations for pharmacotherapy. The standard pharmacotherapies which are available for treatment of depression have increased dramatically in the past two decades. In mild to moderate depressive disorder, more depression-specific forms of psychotherapy have been established including cognitive-behavioral psychotherapy, interpersonal psy-

chotherapy, or short-term dynamic psychotherapy. In these forms of psychotherapy, which have been studied to address mild to moderate nonbipolar depressive disorder, the focus of the psychotherapy is very clearly explicated to the patient before the initiation of the psychotherapy. For severe depressive disorder with melancholic or psychotic features, these specific forms of short-term psychotherapy may not be as effective as focused pharmacotherapy. Pharmacotherapy in these conditions is associated with more rapid treatment response than is psychotherapy. During the acute phase of treatment for depressive disorder the optimal treatment should result in resolution of depressive signs and symptoms anytime between week 8 and week 16 of treatment. If resolution of depressive signs and symptoms does not occur during the first 2 to 4 months then the initial diagnostic formulation must be reviewed and alternative treatment strategies must be introduced. Some of the factors associated with lack of complete treatment response include the presence of cooccurring personality disorders, concurrent alcohol or substance abuse, a poor therapeutic alliance leading to lack of adherence to treatment recommendations, and persistent or unfavorable side effects of treatment.

When acute phase treatment does lead to remission of signs and symptoms, then the next phase of treatment begins. This phase of treatment is termed continuation treatment and its goal is prevention of relapse. It is often necessary to maintain ongoing pharmacotherapy for 6 to 12 months after an acute episode of depression during this continuation phase, because there is substantial vulnerability to relapse if medication treatment is prematurely interrupted. During the continuation phase ongoing psychotherapy may be particularly important to address residual symptoms of depression, and to alert the individual to a depressive response to subsequent traumatic circumstances, as well as ongoing clinical interaction with significant others is required in order to address persisting interpersonal conflicts, and may promote even more complete recovery from the depressive episode. The continuation phase of treatment typically lasts 9 to 12 months to minimize the risk of recurrent episode. If this represents the initial episode of depression, then medication treatment may be carefully withdrawn at the end of the continuation phase. However, if this represents a history of recurrence of depression (particularly two or more episodes in the preceding 3 years), maintenance treatment may well be recommended. In addition, maintenance treatment is recommended if two prior episodes have occurred within one's lifetime.

Maintenance treatment of MDD is focused on prevention of future episodes of depression, after a recent recurrence of MDD and a prior history of two or more episodes of MDD. Often the maintenance phase of treatment involves ongoing treatment with antidepressants or alternatively mood-stabilizing treatment (particularly lithium carbonate), or a combination to sustain recovery from depression. When there is early onset (adolescent onset) of depressive symptoms with associated psychosocial impairment, then ongoing maintenance treatment along with rehabilitative psychotherapy may be most critical. During maintenance treatment, continuing education of the patient and family, identification of prodromal symptoms, and continuing efforts at work and psychosocial rehabilitation are indicated. Often the trials of maintenance pharmacotherapy in depression demonstrate the preventive benefit of maintenance medication. In the most often quoted study, recurrence rates of 20 to 25% were found in individuals maintained with full dose of imipramine, while the recurrence rate was 80 to 100% in those patients treated with placebo. The advantage of ongoing maintenance medicine has also been demonstrated at 5 to 10 years. With tricyclic antidepressants, maintenance medication is likely more effective at full dose rather

than lower doses. Limited data exists as to the dosing of SSRIs or other types of antidepressants in maintenance treatment.

## Site of Treatment

The site of treatment for MDD is based upon the severity of the acute episode and the psychiatrist's judgment of the individual's potential for suicide. Individuals with mild to moderate depression are often treated in primary care or psychiatry office settings. Acute phase pharmacotherapy involving antidepressant medication is often initiated by a primary care physician. However, the overall longitudinal care of MDD in primary care is the subject of increasing attention. Typically, individuals do not receive treatment for long enough periods and there is limited attention to the domains of social or work functioning. The referral to a psychiatrist may include a request for more expertise regarding medication as well as the need for depression-specific psychotherapy. In addition, there has been a lack of focused attention to the role of integrated psychotherapy and pharmacotherapy in primary care. Inpatient treatment for depression is recommended when there is an immediate risk for suicide or recent suicide attempt. In these settings safety of the individual is the primary concern and often more intensive treatments including electroconvulsive therapy may be initiated. When there are comorbid general medical conditions and psychiatric disorders, inpatient psychiatric hospitalization may be useful to stabilize both the general medical condition as well as the associated psychiatric disorder.

## General Approaches to Treatment

Initiation of treatment follows a careful psychiatric diagnostic interview. Assessment of the longitudinal clinical history must rule out bipolar disorder, comorbid PTSD, other anxiety disorders, and personality disorder. A completed mental status examination is used to rule out associated psychosis or marked cognitive disruption. When these procedures are conducted empathically, the beginning of a favorable therapeutic alliance is established. In all circumstances an effective therapeutic alliance facilitates recovery from MDD.

## Pharmacotherapy and Other Somatic Treatment

Treatment during the acute phase with medication is highly efficacious in reducing signs and symptoms of MDD. Antidepressant medication has the most specific effect on reduction of symptoms and is often associated with improved psychosocial functioning. When symptoms of depression are mild to moderate, a course of depression-specific psychotherapy without medicine may also be effective. If symptoms of depression are moderate to severe, acute phase treatment with medications is often indicated. A wide variety of antidepressant medications have been documented as effective in moderate to severe MDD.

The range of treatments available in the USA has included the tricyclic antidepressants, monoamine oxidase inhibitors (MAOIs), heterocyclic antidepressants and SSRIs. In addition, antidepressants with both serotonergic and noradrenergic activity or noradrenergic activity alone have become available. Clearly, clinical trials comparing the efficacy of newer treatments with standard tricyclic antidepressants have shown equal efficacy with improvement in overall tolerance to side effects with newer treatments.

Antidepressant medications which are currently available for acute treatment of MDD are listed in the associated table (Table 46.3).

**Table 46.3 Antidepressant Medications Category**

Category			Side Effects			
Trade Name	Compound	Usual Therapeutic Dose (mg)	Sedation	Hypotension (Decreased Blood Pressure)	Anticholinergic (i.e., Dry Mouth Constipation)	Cardiac (Slowed Heart Rate)
<i>Tricyclics</i>						
<i>Tertiary Amines</i>						
Anafranil	Clomipramine	150–300	High	High	High	Yes
Elavil	Amitriptyline	150–300	High	High	High	Yes
Sinequan	Doxepin	150–300	High	Moderate	Moderate	Yes
Surmontil	Trimipramine	150–300	High	Moderate	Moderate	Yes
Tofranil	Imipramine	150–300	Moderate	High	Moderate	Yes
Norpramine	Desipramine	100–300	Low	High	Low	Yes
Pamelor	Nortriptyline	50–150	Moderate	Low	Low	Yes
Vivactil	Protriptyline	20–60	Low	Low	High	Yes
<i>Monoamine</i>						
<i>Oxidase Inhibitors</i>						
Marplan	Isocarboxazid	30–60	Low	Moderate	Low	Low
Nardil	Phenelzine	45–90	Low	Moderate	Low	Low
Parnate	Tranylcypromine	30–90	Low	Moderate	Low	Low
<i>Atypical Agents</i>						
Ascendin	Amoxapine	200–300	Low	Moderate	Low	Yes
Desyrel	Trazodone	300–600	High	High	Minimal	Low
Ludiomil	Maprotiline	150–200	Moderate	Moderate	Low	Low
Wellbutrin	Bupropion	150–450	Minimal	Low	Minimal	Yes
<i>Selective Serotonin</i>						
<i>Reuptake Inhibitors</i>						
Paxil	Paroxetine	20–50	Low	Minimal	Minimal	Low
Prozac	Fluoxetine	20–100	Minimal	Minimal	Minimal	Low
Zoloft	Sertraline	50–300	Minimal	Minimal	Minimal	Low
Luvox	Fluvoxamine	150–400	Low	Low	Low	Low
Celexa	Citalopram	20–50	Minimal	None	None	Minimal
Lexapro	Escitalopram	10–30	Minimal	None	None	Minimal
<i>Serotonin/</i>						
<i>Norepinephrine</i>						
<i>Reuptake Inhibitors</i>						
Effexor	Venlafaxine	75–450	Low	None	None	Minimal
<i>Serotonin</i>						
<i>Transport</i>						
<i>Blocker and</i>						
<i>Antagonist</i>						
Serzone	Nefazadone	200–600	Minimal	Low	Minimal	Minimal
<i>Alpha-2-</i>						
<i>Adrenergic</i>						
<i>Antagonist</i>						
Remeron	Mirtazapine	30–60	Moderate	Low	Minimal	Minimal

Choice of treatment with a specific antidepressant treatment in a given clinical situation is based on prior treatment response to medication, consideration of potential side effects, history of response in first-degree relatives to medicines, and the associated presence of cooccurring psychiatric disorders that may lead to a more specific choice of antidepressant treatment. Table 46.4 illustrates an algorithm developed for pharmacotherapy of MDD which includes a staged trial of newer medications (because of their superior side-effect profiles) followed by treatments with older medicines available for the treatment of MDD. The ultimate goal of pharmacotherapy is complete remission of symptoms during a standard 6- to 12-week course of treatment.

### Selective Serotonin Reuptake Inhibitors

The most commonly prescribed antidepressant medicines in the past 10 years are SSRIs. They are selectively active at serotonergic neurochemical pathways and are effective in mild to moderate nonbipolar depression. They may also be particularly effective in MDD with atypical features as well as DD. Often these treatments are well tolerated and involve single daily dosing for MDD. Because of selective serotonergic activity, these treatments have also been demonstrated to be effective with cooccurring OCD, panic disorder, generalized anxiety disorder,

PTSD, premenstrual dysphoric disorder, bulimia nervosa, social anxiety disorder, as well as MDD. They tend to be reasonably well tolerated in individuals with comorbid medical conditions. There are particular medication-specific interactions based on inhibition of cytochrome P-450 liver enzyme systems which require attention if an individual is taking other medications for primary medical conditions or associated psychiatric conditions. The currently available SSRIs in the USA include fluoxetine, paroxetine, sertraline, fluvoxamine, citalopram and escitalopram.

### Other Newer Antidepressants

In addition to SSRIs, greater attention has been brought to medicines with dual noradrenergic and serotonergic pathways including venlafaxine which has become available in both immediate release (IR) and extended release formulations. In addition, an alpha-2-adrenergic agonist, mirtazapine has become available, as well as a serotonin transport blocker and antagonist nefazodone. Recent concerns about hepatic complications associated with nefazodone has required liver function monitoring. A predominantly noradrenergic and dopaminergic agonist, bupropion is also available in an immediate release and sustained release (SR) preparation. The newest dual acting antidepressant marketed in the USA is duloxetine.

**Table 46.4 Pharmacotherapy Algorithm in Major Depressive Disorder**

<b>Major Depressive Disorder, Single or Recurrent Episode, without Psychotic Features</b>
Begin effective monotherapy with bupropion SR, citalopram, escitalopram, fluoxetine, nefazodone, paroxetine, sertraline, or venlafaxine XR (augment with lithium carbonate 600–900 mg).
or
Begin effective monotherapy with alternative antidepressant from list above (augment with bupropion SR, mirtazapine, or tricyclic antidepressant, either nortriptyline or desipramine, recognizing important drug interactions).
If ineffective, consider tranylcypromine, augmented with lithium carbonate, if necessary, for anergic features.
or
Consider phenelzine, augmented with lithium carbonate, if necessary, for anxious, dependent and phobic features.
Augment with atypical antipsychotics for agitation, rumination, or suspicion.
or
Offer electroconvulsive therapy to remission (ECT).
<b>Major Depressive Disorder, Single or Recurrent Episode, with Psychotic Features</b>
Begin typical or atypical antipsychotic to adequate doses in order to interrupt delusional features, augmented with SSRI, venlafaxine XR, or tricyclic antidepressants, either nortriptyline or desipramine, recognizing important drug interactions.
or
Begin amoxapine as alternative.
or
Begin electroconvulsive therapy as alternative, in context of immediate suicide risk, physical deterioration, or prior response to electroconvulsive therapy.
<b>Major Depressive Disorder with Atypical Features</b>
Begin SSRI starting at low dose to minimize early side effects.
or
Begin MAOI, either phenelzine or tranylcypromine, to therapeutic doses.
<b>Major Depressive Disorder with Catatonic Features</b>
Begin lorazepam 1–3 mg/d, to interrupt catatonic symptoms; evaluate for presence of psychotic features or longitudinal history of bipolar disorder.
Add antipsychotic medication to therapeutic doses or lithium carbonate to therapeutic doses, if bipolar or schizoaffective disorder emerges from the longitudinal history.

## Tricyclic Antidepressants in Individuals with Severe MDD Including Melancholic Features

Tricyclic antidepressants have been best studied in individuals with MDD with melancholic features and with psychotic features. The combination of typical antipsychotic pharmacotherapy in association with tricyclic antidepressants has been recommended. The side-effect profile of tricyclic antidepressants has included moderate to severe sedation, anticholinergic effects including constipation and cardiac effects which has made these medicines less popular in typical primary care or psychiatric practice. Nevertheless, the secondary amines which are metabolites of imipramine and amitriptyline, specifically desipramine and nortriptyline, have continued to be useful agents in more refractory depression.

## Monoamine Oxidase Inhibitors

There continues to be a role for the use of MAOIs in patients with MDD with atypical features. These agents particularly may be useful in intervention in depressive episodes with atypical features, characterized by prominent mood reactivity, reverse neurovegetative symptom patterns (i.e., overeating and oversleeping) and marked interpersonal rejection sensitivity. MAOIs continue to have a significant role in treatment of comorbid panic disorder, social phobia and agoraphobia if individuals are not responsive to SSRIs. The ongoing prescription of phenelzine or tranylcypromine requires continued education of the patient regarding standard food interactions involving tyramine as well as specific drug–drug interactions involving sympathomimetic medications. These cautions regarding diet and drug interaction makes MAO inhibitors less attractive to primary care physicians and most psychiatrists. However, they continue to be effective treatments which may be useful in depression with atypical features as well as anergic bipolar depression.

## Therapeutic Blood Levels

Although therapeutic blood level monitoring in the treatment of MDD may have a role in future treatments, the only group of medicines where there has been reliable assessment of blood levels are the tricyclic antidepressants. Because tricyclic antidepressants have significant drug–drug interactions with certain SSRIs there continues to be a need for therapeutic blood monitoring particularly with nortriptyline and desipramine.

## General Pharmacotherapy Recommendations

Increasingly, a trial of one class of antidepressants may be associated with incomplete response leading to a question of augmenting a treatment with another medicine versus switching from one medicine to another within the same class or to a different class altogether. Augmentation strategies with other medications, including adding lithium carbonate and other antidepressants, particularly those with a different mechanism of action, atypical antipsychotics, thyroid and stimulants, have been the focus of a number of reviews of treatment resistance. A staging system for treatment resistant depression (TRD) has been proposed and ranges from failure to respond to a single agent (Stage 1) to failure of multiple treatments and electroconvulsive therapy (Stage 5) as shown in Table 46.5.

## Clinical Management

All of the antidepressant medications used in the treatment of MDD must be prescribed in the context of an overall clinical

**Table 46.5 Staging Criteria for Treatment Resistant Depression**

Stage	Description
1. Failure of at least one adequate trial of an antidepressant	
2. Stage 1 resistance plus failure of adequate trial of an antidepressant from a distinctly different class than in Stage 1	
3. Stage 2 resistance plus failure of an adequate trial of a tricyclic antidepressant (TCA)	
4. Stage 3 resistance plus failure of an adequate trial of a monoamine oxidase inhibitor (MAOI)	
5. Stage 4 resistance plus failure of a course of bilateral electroconvulsive therapy (ECT).	

psychiatric relationship characterized by supportive interaction with the patient and family and ongoing education about the nature of the disorder and its treatment. Clinical management optimally involves careful monitoring of symptoms using standardized instruments and careful attention to side effects of medication in order to promote treatment adherence. Outpatient visits, which may be scheduled weekly at the outset of treatment, and subsequently biweekly encouragement and sustain collaborative treatment relationships. These office consultations allow the psychiatrist to make dosage adjustments as indicated, monitor side effects and measure clinical response to treatment.

For the majority of individuals with MDD, a course of 6 to 8 weeks of acute treatment with weekly outpatient visits is indicated. Subsequent office visits may be scheduled every 2 to 4 weeks during the continuation phase of treatment. Appropriate adjustments of dose are determined by the psychiatrist as indicated by best clinical judgments of medication effect. The dose of an SSRI may be adjusted every 3 days on the basis of telephone contact and follow-up visits may be scheduled every 7 to 10 days. Similarly, the adjustment of dosing of tricyclic antidepressants and MAOIs must be attended to carefully in the first 2 to 3 weeks of treatment. Optimal dosing ranges of SSRIs, tricyclics and MAOIs are noted in Table 46.3. Because of the early anxiety, agitation and occasional insomnia associated with SSRIs, somewhat lower doses may be initiated early in the course before achieving the typical standard therapeutic dose.

Incomplete response, which entails the failure to respond to acute treatment with an antidepressant medication at 6 to 8 weeks, requires reassessment of diagnosis and determination of adequacy of dosing. Ongoing substance abuse, associated general medical condition or concurrent psychiatric disorder may partially explain a lack of complete response. If substance dependence is present, a full substance-free interval (preferably

4 weeks or longer) with appropriate detoxification and rehabilitation may be indicated. If a reassessment discloses an associated psychiatric disorder, then more specific treatment of that associated disorder, whether it be bipolar disorder or concurrent post traumatic disorder, is necessary. If the reassessment suggests an associated comorbid personality disorder, then appropriate and more specialized psychotherapy may be necessary in order to achieve a complete response to treatment. As indicated before, if the MDD has psychotic features, then antipsychotic pharmacotherapy to adequate doses must be initiated prior to initiating a course of standard tricyclic antidepressants or a combined serotonin norepinephrine uptake inhibitor such as venlafaxine. If MDD is associated with severe personality disorder (e.g., borderline personality disorder), then adjunctive psychotherapy and low dose antipsychotic medications may be necessary. If the patient has severe melancholic, delusional, or catatonic features, a course of electroconvulsive therapy may be necessary to achieve remission of symptoms.

There is also evidence that continuation of treatment beyond 6 to 12 weeks may convert some partial responders to responders if drug treatment is increased to full doses. This time allows for evaluation of the role of focused psychotherapy to address residual interpersonal disputes, loss or grief, or ongoing social deficits. The associated augmentation strategies to standard treatments include lithium carbonate augmentation, tricyclic antidepressant augmentation of SSRIs, thyroid hormone augmentation and bupropion augmentation of SSRIs.

### Electroconvulsive Therapy

Electroconvulsive therapy (ECT) remains an effective treatment in patients with severe MDD and those individuals with psychotic MDD. Many patients who have responded to electroconvulsive therapy do not respond to pharmacotherapy. There is increased need for understanding the role of maintenance electroconvulsive therapy in those individuals who respond to electroconvulsive therapy because ongoing pharmacotherapy does not always prevent recurrence of depression after ECT is successful. ECT can be particularly useful in interrupting acute suicidality for those patients who may require rapid resolution of symptoms. ECT may be indicated in older adults when lack of self-care and weight loss may represent a greater risk. The most common side effect associated with electroconvulsive therapy is amnesia for the period of treatment. There is no consistent evidence to suggest chronic cognitive or memory impairment as a result of ECT.

### Other Somatic Treatments

Light therapy investigators have continued to demonstrate benefit in individuals with seasonal MDD by providing greater than 2500 lux light therapy for 1 to 2 hours/day. Many of these patients experience recurrent winter depression in the context of a recurrent MDD or bipolar II disorder. Bright light exposure has been associated with favorable response within 4 to 7 days. As with electroconvulsive therapy, light therapy is best prescribed by specialists who have experience in its use and can appropriately evaluate the indication for light therapy and monitor carefully the response to treatment.

Ongoing investigation of alternative brain stimulation techniques have been the subject of recent investigation. The use of a powerful magnet to provide transcranial magnetic stimulation has been the subject of several open trials. It is not yet determined whether the repetitive transcranial magnetic stimulation

demonstrates its effectiveness through reduction of inhibitory neurotransmission or other mechanisms.

In addition, open clinical trials of vagus nerve stimulation (VNS) which has been found to be effective in epilepsy has been the subject of attention in refractory MDD. Several sites of investigation have begun to reveal positive effects at 9 months using VNS implantation. This procedure requires the implantation of a stimulating device in the chest with the capacity to stimulate the vagus nerve at regular intervals through the course of the day.

### Psychosocial Treatment

The past decade has also led to the development of more specific depression-based treatment for MDD. These treatments have included supportive psychiatric management techniques during pharmacotherapy, interpersonal psychotherapy, cognitive-behavioral therapy, brief dynamic psychotherapy, and marital and family therapy.

### Psychiatric Management and Supportive Psychotherapy

Psychiatric management and supportive psychotherapy is the standard in psychiatric office practice. The psychiatrist focuses on establishing a positive therapeutic relationship in the course of diagnosis and initiation of treatment of depression. The psychiatrist is attentive to all signs and symptoms of the disorder with particular attention to suicidality. The psychiatrist provides ongoing education, collaboration with the patient, and supportive feedback to the patient regarding ongoing response and prognosis. The supportive psychotherapeutic management of depression facilitates the ongoing pharmacologic response. Brief supportive psychotherapy in individuals with mild to moderate depression is indicated to improve medication compliance, to facilitate reduction of active depressive signs and symptoms, and to provide education regarding relapse and recurrence.

### Interpersonal Psychotherapy

Interpersonal psychotherapy in outpatients with nonbipolar MDD has been demonstrated to be effective in acute treatment trials. Interpersonal psychotherapy of depression addresses four areas of current interpersonal difficulties:

1. Interpersonal loss or grieving;
2. Role transitions;
3. Interpersonal disputes;
4. Social deficits.

This type of treatment, like other psychotherapies for depression, also involves education about the nature of MDD and the relationship between symptoms of depressive disorder and current interpersonal difficulties. Prior studies demonstrated efficacy of interpersonal psychotherapy for outpatients with depression. Interpersonal psychotherapy, cognitive-behavioral psychotherapy and medication treatment were comparable on several outcome measures and superior to placebo. Medication treatment was associated with the most rapid response and was superior to both interpersonal psychotherapy and cognitive-behavioral therapy in more severely depressed patients. Continuation studies with interpersonal psychotherapy offered monthly, as well as during maintenance treatment, have demonstrated response in prevention of recurrence, and was

superior to placebo treatment. Those patients who received ongoing interpersonal psychotherapy and medication had the longest intervals without recurrence of depressive symptoms.

### Cognitive–Behavioral Therapy

Cognitive–behavioral therapy for depression is a form of treatment aimed at symptom reduction through the identification and correction of cognitive distortions. These involve negative views of the self, one's current world and the future. Several controlled studies have demonstrated the efficacy of cognitive therapy in resolution of MDD in adults. Cognitive–behavioral therapy as well as interpersonal psychotherapy are somewhat less effective than medication treatment in moderate to severe MDD although some have suggested a relatively equal response to cognitive–behavioral therapy and medication in more severely depressed outpatients.

### Brief Dynamic Psychotherapy

Brief dynamic psychotherapy addresses current conflicts as manifestations of difficulty in early attachment and disruption of early object relationships. Brief dynamic psychotherapy was not specifically designed for treatment of MDD and is currently the subject of ongoing studies as well as controlled clinical trials in comparison with medication treatment. The results of these trials will allow us to address the appropriate role of brief dynamic psychotherapy in outpatients with mild to moderate depression. In addition, it will be important to understand whether dynamic psychotherapy may address demoralization or response to traumatic circumstances.

### Marital and Family Therapy

It has been difficult to assess the specific efficacy of marital or family therapy in individuals with MDD based on current studies to date. There is substantial evidence that marital distress is a major event associated with the development of a depressive episode. Marital discord will often persist after the remission of depression and subsequent relapses are frequently associated with disruptions of marital relationships. There has been no controlled clinical trial of marital therapy in relation to other treatments for promoting the resolution of depressive signs and symptoms. Both acute and continuation phase treatment of MDD will require ongoing attention to marital and family issues to prevent recurrence of depression.

### Factors Influencing Treatment Response

There are a number of factors which influence ultimate treatment response in MDD including patient characteristics, diagnostic issues, comorbidity, treatment-related complications including side effects and demographic factors. Reevaluation of diagnosis, comorbidity and the physician–patient relationship itself is often critical.

### Suicide Risk

Patients with MDD are often at increased risk for suicide. Suicidal risk assessment is especially indicated as patients begin to recover from depression with increased energy and simultaneous continued despair. Persistent suicidal ideation coupled with increased energy can often lead to impulsive suicidal acts. The careful attention to the physician–patient relationship can mediate suicidal urges through availability and accessibility. Outpatients and inpatients with MDD and melancholic features will often require antidepressant therapy addressing multiple neurotransmitter systems, or ECT as well.

### Psychotic Features

MDD with psychotic features requires careful assessment to rule out comorbid psychiatric conditions. The combined treatment with antipsychotic as well as antidepressant medication is indicated. In addition, electroconvulsive therapy is an effective intervention in psychotic depression and may be considered as a first line alternative.

### Catatonic Features

MDD with catatonic features can be associated with significant morbidity due to the individual's refusal to eat or drink. Active treatment with a benzodiazepine such as lorazepam 1 to 3 mg daily may offer short-term treatment response. Subsequent treatment with lithium alone or in association with antidepressants may be indicated given the possible link between catatonic features and bipolar vulnerability. If psychosis is associated with catatonia, then atypical antipsychotic medication or a course of electroconvulsive therapy may be indicated as well.

### Atypical Features

Atypical features are associated with significant comorbid anxiety disorders, reverse neurovegetative symptoms such as hypersomnia, increased appetite and weight gain, as well as fatigue and leaden paralysis. SSRIs are likely to be effective in individuals with MDD with atypical features as well as MAOIs. Conversely, tricyclic antidepressants, in particular, are unlikely to be effective in such individuals.

### Severity

Individuals with mild to moderate depression may be effectively treated with psychotherapy, pharmacotherapy, or the combination. Individuals with severe MDD often require somatic intervention with antidepressant medication or electroconvulsive therapy.

### Recurrence

Because MDD is a recurrent disorder, current treatment guidelines (Hirschfeld, 1994) suggest maintenance antidepressant treatment at full therapeutic doses if there is a history of more than two prior episodes of MDD.

### History of Hypomania or Mania

Any of the antidepressant treatments including medication, electroconvulsive therapy, light therapy, or newer somatic interventions may induce hypomania or mania in individuals who are vulnerable to bipolar disorder. Individuals who may have a family history of bipolar disorder should be carefully evaluated for treatment with lithium carbonate or other anticonvulsant mood stabilizers before antidepressant treatment because they are at particular risk for antidepressant-induced mania. Attention to this history of prior hypomania or mania as well as family history may promote treatment response if such individuals have mood stabilizing treatment offered initially.

### Comorbid Psychiatric Disorders with Major Depressive Disorder

#### Alcohol or Substance Dependence

The comorbidity of MDD and alcohol or other substance dependence requires careful attention to both diagnoses. The first priority in treatment is abstinence from alcohol or substance use. Cooccurring addiction will complicate depressive disorders and

increases risk for suicide. If detoxification from alcohol or other substance abuse is required, this should be undertaken before initiation of any somatic antidepressant therapy. Individuals who have a family history of depression or bipolar disorder are likely to require early initiation of appropriate mood disorder treatment following detoxification.

### Obsessive–Compulsive Disorder

In individuals with OCD, lifetime risk of MDD approaches 70%. The use of higher dose SSRI treatment is often indicated to treat both conditions. Alternatively, the tricyclic antidepressant, clomipramine (Anafranil), may be effective for those individuals with both OCD and MDD who do not respond to SSRIs.

### Panic Disorder

Lifetime risk of MDD approaches 50% in individuals with panic disorder. Because many of the SSRI and other antidepressants are effective treatments to treat panic as well as depression, these treatments have gained increasing popularity. One may continue to prescribe short-term courses of benzodiazepines, including lorazepam or clonazepam to alleviate acute symptoms of panic as low doses of antidepressant treatments are introduced into the treatment for comorbid panic and MDD. In addition, MAOIs continue to be effective treatments for both panic and MDD.

### Generalized Anxiety Disorder

Lifetime risk of MDD in individuals with generalized anxiety disorder (GAD) approaches 40%. New studies demonstrating efficacy of venlafaxine as well as paroxetine make these effective interventions in situations in which an individual has both MDD and GAD.

### Post traumatic Stress Disorder

An essential feature of PTSD is the vulnerability to the development of MDD. Recent studies (Friedman, 1998) demonstrate effectiveness in treating the core symptoms of PTSD as well as MDD. In addition, specific psychotherapy which addresses the core aspects of PTSD may be appropriate in individuals with comorbid PTSD and MDD in order to minimize the vulnerability to depression because of persistent PTSD symptomatology.

### Cognitive Impairment

When cognitive impairment is due to depressive disorder (as in “pseudodementia”), active treatment of depression may minimize associated cognitive difficulties. Many seniors evolve mild cognitive impairment and depression as early signs of dementia. Nevertheless, when MDD is mild it requires specific antidepressant treatment, or when severe or psychotic, electroconvulsive therapy.

### Dysthymic Disorder

The exacerbation of a persistent or chronic DD into a more severe depressive episode is termed “double depression”. Many treatments for MDD are also useful in DD. It is likely that SSRIs, newer antidepressants as well as tricyclic antidepressants are effective for both DD and MDD. Specific forms of psychotherapy which are cognitive–behavioral have been investigated as effective in addressing poor inter-episode recovery from MDD associated with DD.

### Personality Disorder

Increasing evidence of the cooccurrence of MDD with personality disorder with rates up to 40 to 50% in outpatient clinics

suggests incomplete response to antidepressants alone. Specific psychotherapy treatments which focus on maladaptive personality traits may facilitate the ongoing response to antidepressant pharmacotherapy.

## General Medical Conditions Cooccurring with Major Depressive Disorder

### Asthma

Ongoing attention to pharmacotherapy of individuals with asthma relates to the use of bronchodilators and steroid inhalers for asthma. These may complicate associated anxiety and depression and must be addressed carefully in consideration of appropriate antidepressant therapy. Generally, SSRIs and newer antidepressants appear to be well tolerated with typical asthma treatments.

### Cardiac History

SSRIs, newer mixed noradrenergic and serotonergic reuptake inhibitors, bupropion and ECT are likely to be safe treatments for patients with cardiac disease (Glassman *et al.*, 2002).

### Epilepsy

In individuals with epilepsy and MDD, adjunctive antidepressant medications, particularly SSRIs and bupropion are well tolerated in combination with most anticonvulsant treatments.

### Glaucoma

Previously, tricyclic antidepressants with anticholinergic properties were known to precipitate acute angle closure glaucoma in vulnerable patients. The effect on intraocular pressure is benign with newer antidepressant treatments.

### Hypertension

Many older antihypertensive treatments including reserpine and alpha methyl dopa were reported to precipitate depression. Fatigue, lethargy and possible depression were associated with beta-adrenergic blockers. Newer antihypertensive drugs including angiotensin converting enzyme inhibitors (ACEI) and calcium channel blockers have fewer side effects and are tolerated well in combination with standard antidepressant treatments.

### Parkinson’s Disease

There is prominent cooccurrence of MDD with Parkinson’s disease. The prescription of low dose SSRIs, bupropion and mixed noradrenergic serotonergic reuptake inhibitors may be helpful in the management of comorbid MDD and Parkinson’s disease without risk of worsening the underlying movement disorder or promoting psychosis.

## Demographic and Sociocultural Factors in Treatment

### Children

It is increasingly important to identify children at risk for MDD. There have been insufficient controlled studies of pharmacotherapy or psychotherapy in children with MDD. However, early studies of SSRIs appear promising in terms of overall treatment efficacy in children with MDD.

## Adolescents

Adolescent-onset depression with psychotic features may be an early predictor of bipolar course. Adolescent-onset depression, therefore, must be carefully diagnosed, ruling out a bipolar history in the family and assessing evidence for mixed hypomanic or manic states in the prepubertal or pubertal period. The appropriate prescription of lithium carbonate in those individuals with bipolar vulnerability must precede antidepressant pharmacotherapy. Alternatively, early studies suggest the role for standard SSRIs in adolescents with nonbipolar depression.

## Older Adults

MDD in older adults is often characterized by more prominent somatic signs and cognitive impairment. It is important to diagnose and treat depression to minimize associated morbidity and mortality. Standard SSRI pharmacotherapy is likely to be associated with demonstrated efficacy as is depression-specific psychotherapy assuming the level of depression is mild to moderate.

## Gender

Because of substantial hormonal changes associated with the onset of menses, pregnancy and delivery, and menopause, hormonal effects must be part of the standard assessment of depression. Woman may be at somewhat higher risk for depression at these critical intervals of hormonal change. Standard antidepressant pharmacotherapy as well as depression-specific psychotherapy appear to be equally effective in both men and women. Both men and women require careful attention to sexual side effects of antidepressant pharmacotherapy in the course of the longitudinal management.

## Refractory Major Depressive Disorder

A staging system for treatment-resistant depression (TRD) has been proposed and ranges from failure to respond to a single agent (Stage 1) to failure of multiple treatments and electroconvulsive therapy (Stage 5; Thase and Rush, 1995), and is presented in Table 46.5. The term refractory depression has been proposed to describe patients who have Stage 5 treatment-resistant depression.

Refractory MDD or Stage 5 in Table 46.5 is estimated to occur in up to 20% of patients. A larger percentage of patients with MDD, up to 30%, may show only partial improvement. The concept of treatment-resistant depression or refractory depression describes this lack of response to a number of clinical trials using optimal dosing and duration of antidepressant medication. One must typically offer the patient a rational series of treatment trials using optimal dosing and duration of each antidepressant. Many individuals consider a patient refractory if a course of three, four, or five treatments is offered without substantial clinical response. The standard approach to the management of refractory depression includes increasing the antidepressant dose and monitoring for a full 8 to 12 week course augmenting the treatment with several augmentation strategies using an adequate combination of antidepressant drug treatment and psychotherapy and switching to alternative somatic treatments including ECT when indicated.

Refractory MDD is ameliorated in the context of a caring and collaborative treatment relationship based on a favorable ther-

apeutic alliance. Patients sometimes will undermine treatment through their own persistent use of substances such as alcohol or lack of adherence to specific pharmacotherapy recommendations. In this context the attention to the therapeutic alliance is particularly critical. In assessing an individual with refractory symptoms, pharmacologic factors including pharmacokinetic considerations, drug–drug interactions and extreme sensitivity to antidepressant drugs must be considered.

Despite many alternative strategies, substantial morbidity and occasional mortality are associated with refractory MDD. In addition, careful attention to psychosocial factors associated with refractoriness is critical. These psychosocial factors include early childhood adversity and abuse, early family dysfunction, increased neuroticism and marked disruption in the development of a stable sense of self.

## Dysthymic Disorder

### Definition

Dysthymic disorder is defined by the presence of chronic depressive symptoms most of the day, more days than not, for at least 2 years. While chronic depressive conditions were traditionally conceptualized as characterological and amenable to psychotherapy and resistant to pharmacotherapy, recent pharmacologic trials of antidepressants as well as depression-specific psychotherapy have demonstrated effectiveness in the overall treatment of DD. Both focused interpersonal and variations of cognitive–behavioral psychotherapy have demonstrated response in dysthymia. Individuals with DD have a substantial risk for the development of MDD. This highlights the importance of early assessment and treatment to minimize subsequent long-term complications.

If signs and symptoms of DD follow a MDD, then a diagnosis of MDD, in partial remission, is made. A diagnosis of DD can be made if the individual develops full remission of MDD for 6 months and subsequently develops signs and symptoms of DD which then last a minimum of 2 years. In contrast, the diagnosis of chronic MDD is made when an episode of MDD meets full criteria for MDD continuously for at least 2 years. If DD has been present for at least 2 years in adults (or 1 year in children and adolescents) and is subsequently followed by a superimposed MDD, then both DD and MDD are diagnosed, which is often referred to as “double depression”. The following specifiers apply to DD as noted in DSM-IV:

1. Early onset – if the onset of dysthymic symptoms occurs before age 21.
2. Late onset – if the onset of dysthymic symptoms occurs at age 21 or older, and with atypical features.

Atypical features refer to a pattern of symptoms which include mood reactivity and two of the additional atypical symptoms (i.e., weight gain or increased appetite, hypersomnia, leaden paralysis, or interpersonal rejection sensitivity). Early-onset DD is usually associated with subsequent episodes of MDD. DD with atypical features may herald a bipolar I or II course.

Ongoing studies have not completely clarified the distinction between DD and depressive personality disorder. Depressive temperaments may predispose an individual to a condition within the spectrum of Axis I mood disorders. However, it may not be

**DSM-IV-TR Criteria 300.4****Dysthymic Disorder**

- A. Depressed mood for most of the day, for more days than not, as indicated either by subjective account or by observation by others, for at least 2 years. **Note:** In children and adolescents, mood can be irritable and duration must be at least 1 year.
- B. Presence, while depressed, of two (or more) of the following:
- (1) poor appetite or overeating
  - (2) insomnia or hypersomnia
  - (3) low energy or fatigue
  - (4) low self-esteem
  - (5) poor concentration or difficulty making decisions
  - (6) feelings of hopelessness
- C. During the 2-year period (1 year for children or adolescents) of the disturbance, the person has never been without the symptoms in criteria A and B for more than 2 months at a time.
- D. No major depressive episode has been present during the first 2 years of the disturbance (1 year for children and adolescents); i.e., the disturbance is not better accounted for by chronic major depressive disorder or major depressive disorder, in partial remission.
- Note:** There may have been a previous major depressive episode provided there was a full remission (no significant signs or symptoms for 2 months) before development of the dysthymic disorder. In addition, after the initial 2 years (1 year in children or adolescents) of dysthymic disorder, there may be superimposed episodes of major depressive disorder, in which case both diagnoses may be given when the criteria are met for a major depressive episode.
- E. There has never been a manic episode, a mixed episode, or a hypomanic episode, and criteria have never been met for cyclothymic disorder.
- F. The disturbance does not occur exclusively during the course of a chronic psychotic disorder, such as schizophrenia or delusional disorder.
- G. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hypothyroidism).
- H. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

*Specify if:*

**Early onset:** if onset is before age 21 years

**Late onset:** if onset is age 21 years or older *Specify* (for most recent 2 years of dysthymic disorder):

**With atypical features**

specifically associated with MDD. This depressive temperament may also be associated with vulnerability to bipolar disorder.

**Epidemiology**

A lifetime prevalence of 4.1% for women and 2.2% for men was reported for DD (Weissman *et al.*, 1988). In adults, DD is more common in women than in men. In children DD occurs equally in both sexes. Across both women and men, DD has a 2.5% 12-month prevalence (Kessler *et al.*, 1994, 2005).

**Comorbidity Patterns**

Individuals with early-onset DD are at substantial risk for development of other psychiatric conditions including alcohol or substance dependence, MDD and personality disorders. Up to 15% of patients with DD may also have a substance use pattern that meets criteria for comorbid alcohol or substance dependence diagnosis. The most common associated personality disorders include mixed, dependent and borderline. Childhood and adolescent-onset DD is associated with a substantial risk for later occurrence of both MDD and bipolar disorder.

**Etiology and Pathophysiology****Biological Findings**

Sleep abnormalities demonstrate reduced REM latency, increased REM density, reduced slow wave sleep and impaired sleep continuity in 25 to 50% of individuals with DD. There are minimal data on cortisol or thyroid abnormalities in individuals with DD. Other neurobiological studies have not yielded consistent results.

**Diagnosis and Differential Diagnosis**

The diagnosis of DD cannot be made, if depressive symptoms occur during the course of a nonaffective psychosis such as schizophrenia, schizoaffective disorder, or delusional disorder. Diagnosis of depressive disorder NOS is made if there are symptoms which meet criteria for MDD during the residual phase of a psychotic disorder. If DD is determined to be etiologically related to a chronic medical condition, then one diagnoses secondary mood disorder due to a general medical condition. If substance dependence is judged to be the etiologic factor, then a substance-induced mood disorder is diagnosed. Individuals with DD often have cooccurring personality disorders and in these situations separate diagnoses on Axis I and II are made.

**Course and Natural History**

Dysthymic disorder often begins in late childhood or early adolescence and by definition takes a chronic course. The risk for development of MDD among children who have DD is significant because childhood onset of DD is an early marker for recurrent mood disorder, both recurrent MDD and bipolar disorder.

The course of DD suggests impairment in functional status including social and occupational, and physical functioning. Patients who have both DD and MDD have more severe functional impairment. Untreated DD contributes to significant occupational and financial burden. There is substantial reduction in activity, more days spent in bed, more complaints of poor general medical health, and more disability days than reported in the general population.

The treatment goals in DD are similar to those in MDD. They include full remission of symptoms and full psychosocial recovery.

## Depressive Disorder not Otherwise Specified

Depressive disorder NOS refers to a variety of conditions listed in DSM-IV that are distinguished from MDD, DD, adjustment disorder with depressed mood, or adjustment disorder with mixed anxiety and depressed mood. These conditions involve a large number of depressed individuals who do not meet formal criteria for MDD or DD. In the ECA study, 11% of subjects had DD NOS. In a primary care outpatient sample, the prevalence of DD NOS was 8.4 to 9.7%. DD NOS is associated with impairment in overall functioning and general health. Among the conditions listed as occurring within this category are premenstrual dysphoric disorder, minor depressive disorder, recurrent brief depressive disorder, postpsychotic depressive disorder of schizophrenia and depressive episode superimposed on delusional disorder or other psychotic disorder.

### Premenstrual Dysphoric Disorder

Premenstrual DD is characterized by depressed mood, marked anxiety, affective lability and decreased interest in activities, experienced during the last week of the luteal phase which remits during the follicular phase of the menstrual cycle. This pattern occurs for most months of the year. The severity of symptoms is comparable to MDD, but the duration is briefer by definition. The symptoms disappear with the onset of menses. Current criteria emphasize the disturbance in mood as well as impairment in social functioning associated with premenstrual DD. Current assessments require that the typical cyclical patterns be confirmed by at least 2 months of prospective daily ratings. Premenstrual DD often worsens with increasing age, but then diminishes at menopause. Premenstrual DD appears to respond to standard SSRI treatments including fluoxetine as well as sertraline and dual acting agents but may not respond to other types of antidepressants, such as bupropion. This responsiveness to SSRIs suggests a premenstrual serotonergic hypoactivity which may account for the premenstrual dysphoric symptomatology.

### Minor Depressive Disorder

Minor depressive disorder is characterized by episodes lasting 2 weeks and characterized by at least two but fewer than five depressive symptoms. Minor depressive disorder is also associated with less psychosocial impairment than MDD. The prevalence of minor depressive disorder reported in primary care settings ranges from 3.4 to 4.7%. A number of general medical conditions have been associated with minor depressive disorder including stroke, cancer and diabetes. Maier and colleagues report increased symptoms of minor depressive disorder in families in which a proband with MDD is present. In the differential diagnosis of minor depressive disorder, one must consider adjustment disorder with depressed mood and other experiences of sadness that may be part of grieving. Because of frequent cooccurrence with general medical condition, one must rule out a secondary mood disorder due to a general medical condition.

Minor depressive disorder tends to begin in late adolescence and probably affects men and women equally. Minor depressive disorder is often associated with greater impairment of routine activities in older adults. Consultation psychiatrists should pay careful attention to depressive symptoms in association with medical illness in order to establish the impact of depressive disorder on the overall course and recovery from general medical conditions (Cassem, 1990).

## Recurrent Brief Depressive Disorder

Recurrent brief depressive disorder refers to brief episodes of recurrent depressive symptoms that last for at least 2 days but less than 2 weeks and meet full criteria (except duration) for MDD. These episodes typically occur monthly for 12 months, but are not specifically related to menstrual cycles. These depressive episodes typically cause clinically significant distress and impairment in social and occupational functioning. In some individuals, RBDD is associated with a high degree of suicidality.

Associated clinical features may include comorbid substance dependence or anxiety disorders. By definition, recurrent brief depressive episodes are not associated with menstrual cycles and are equally common among men as women.

Up to 12 to 20% of first-degree relatives of patients with recurrent brief depressive disorder have MDD. Ongoing research focusing on familial aggregation and associated comorbid conditions is important. It will be particularly important to address its association with personality characteristics and the overlap between personality disorder and the syndrome of RBDD.

## Mixed Anxiety–Depressive Disorder

The syndrome of mixed anxiety–depressive disorder is commonly diagnosed in outpatient medical practices internationally and it is included as a disorder in ICD-10. It is typically associated with dysphoric mood lasting at least 1 month and at least four associated clinical symptoms which are derived from both symptoms associated with MDD, DD, panic disorder and generalized anxiety disorder. These symptom characteristics include: difficulty concentrating or mind going blank; sleep disturbance characterized by difficulty falling or staying asleep or restless; unsatisfying sleep; fatigue or low energy; irritability; worry; being easily moved to tears; hypervigilance; anticipating the worst; hopelessness and pessimism about the future; and low self-esteem or feelings of worthlessness. The symptoms cause significant impairment in social and occupational functioning or other aspects of functioning. These symptoms must not be due to the direct physiologic effects of a substance or a general medical condition. Finally, the symptoms are present in the absence of criteria being met for MDD, DD, panic disorder, or generalized anxiety disorder. The presence of these common mixed anxious and depressive symptoms is estimated to range from 1 to 2% in primary care settings.

## Post-psychotic Depressive Disorder of Schizophrenia

The diagnosis of postpsychotic depressive disorder of schizophrenia is intended to cover depressive episodes occurring during the residual phase of schizophrenia. In the residual phase there may be associated negative symptoms which can be difficult to differentiate from mood symptoms. The diagnosis should be made only if the full criteria are met for a major depressive episode and if the symptoms are not due to substance abuse, akinesia, or other antipsychotic medication effects.

Features associated with the development of a postpsychotic depressive episode include limited social support, the impact of prior hospitalization, or the trauma of having a major mental illness. It is estimated that up to 25% of individuals with schizophrenia experience postpsychotic depressive disorder. There is no significant age of onset difference between men and women. Individuals who have a family history of MDD may be at higher risk for postpsychotic depression. Treatment studies have demonstrated the efficacy of standard antidepressive medication in the postpsychotic depressive disorder of schizophrenia.

# Mood Disorders: Bipolar (Manic–Depressive) Disorders

Until recently, the disorders in this chapter were referred to as “Bipolar Disorders”, yet this book includes the older term “manic–depressive disorder”. An increasing amount of data indicates that mania and hypomania do not typically take the classic, euphoric, optimistic form that appears to be the polar opposite of depression. Rather, hyperactivation appears to be the core symptom of mania and hypomania while mood itself is quite variable; dysphoria and depression rather than euphoric mood are the rule rather than the exception; and patients rate their quality of life during mania or hypomania as worse than or no better than normal, rather than being enhanced as commonly supposed. Thus the term **manic–depressive** is more accurate and less misleading than **bipolar**, which implies that the two characteristic mood states are somehow polar opposites.

## Episodes as the Basis for Diagnosis of Manic–Depressive Disorder

The DSM-based definition of manic–depressive disorder is built on the identification of individual mood **episodes** (Table 47.1). DSM-IV criteria for individual mood episodes are summarized below for manic, mixed and hypomanic episodes. Criteria for these episodes are reviewed in greater detail in the subsequent section on diagnosis. It is important to understand that the diagnosis of manic–depressive disorder derives from the occurrence of individual episodes over time. Persons who experience a manic, hypomanic, or mixed episode, virtually all of whom also have a history of one or more major depressive episodes, are diagnosed with manic–depressive disorder. Those who experience major depressive and manic episodes are diagnosed with **bipolar I** disorder, and those with major depressive and hypomanic (milder manic) episodes are diagnosed with **bipolar II** disorder.

Not surprisingly, most data regarding manic–depressive disorder come from the study of the more severe end of the spectrum, primarily type I disorder. Throughout this chapter, data on manic–depressive disorder derive from studies of type I disorder unless otherwise noted. DSM-IV-TR is the first version of the DSM series to include a specific category for bipolar II disorder. Previously, persons with depressive and hypomanic episodes were grouped under the broad “bipolar disorder not otherwise specified”, which included a variety of unusual presentations.

Study of the course over time of type II disorder indicated that persons with hypomania tended to have recurrent hypomanic episodes and did not convert into type I by developing mania. In addition, persons with type II disorder may have more episodes over

time than persons with type I indicating that the course of type II differs from that of type I. However, biological differences between these manic–depressive types have not been reliably demonstrated. However, it should not be construed that manic–depressive disorder type II is in all respects milder than type I, although hypomania is by definition less severe than mania. Specifically, the social and occupational function and quality of life for persons with type II disorder are similar to those for persons with type I disorder.

Persons who experience subsyndromal manic–depressive mood fluctuations over an extended period without major mood episodes are diagnosed with **cyclothymic disorder**. Much less is known about this milder disorder because afflicted persons present for medical attention less frequently than those with full-blown manic–depressive disorder. Cyclothymic disorder has been considered at various times a temperament, a personality disorder and a disorder at the milder end of the manic–depressive. DSM-IV-TR Criteria 301.13

## Etiology and Pathophysiology

It is clear from current data that no single paradigm can explain the occurrence, and variability in course and severity of manic–depressive disorder. Rather, a more integrative approach to understanding the causes of manic–depressive disorder is needed, one which recognizes the contributions of varying degrees of importance from several sources.

Further, in trying to understand the source of symptoms at a particular time in a particular person with manic–depressive disorder we must keep in mind that there may be multiple sources that lead to the symptoms that we are trying to treat. It is not likely that biological theories will explain all the pathology seen in manic–depressive disorder. Similarly, the effectiveness of medications such as lithium renders purely psychosocial theories untenable. An integrative **biopsychosocial** mindset will likely be the most successful approach to treatment, as Engel articulated for all illnesses, both medical and psychiatric.

## Genetic Hypotheses

Available evidence indicates that familial factors are important determinants of who will develop manic–depressive disorder. Numerous studies have shown that relatives of manic–depressive **probands** (identified cases) have higher rates of manic–depressive disorder than controls or unipolar probands. Overall, rates of manic–depressive disorder in first-degree relatives (parents, siblings, children) of probands with manic–depressive

**Table 47.1 Summary of Mood Episodes and Mood Disorders**

Episode	Disorder
Major depressive episode	Major depressive disorder, single episode
Major depressive episode + major depressive episode	Major depressive disorder, recurrent
Major depressive episode + manic/mixed episode	Manic–depressive disorder, type I
Manic/mixed episode	Manic–depressive disorder, type I
Major depressive episode + hypomanic episode	Manic–depressive disorder, type II
Chronic subsyndromal depression	Dysthymic disorder
Chronic fluctuations between subsyndromal depression and hypomania	Cyclothymic disorder

**DSM-IV-TR Criteria****Manic Episode**

- A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood, lasting at least 1 week (or any duration if hospitalization is necessary).
- B. During the period of mood disturbance, three (or more) of the following symptoms have persisted (four if the mood is only irritable) and have been present to a significant degree:
- (1) inflated self-esteem or grandiosity
  - (2) decreased need for sleep (e.g., feels rested after only 3 hours of sleep)
  - (3) more talkative than usual or pressure to keep talking
  - (4) flight of ideas or subjective experience that thoughts are racing
  - (5) distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli)
  - (6) increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation
  - (7) excessive involvement in pleasurable activities that have a high potential for painful consequences (e.g., engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments)
- C. The symptoms do not meet criteria for a mixed episode.
- D. The mood disturbance is sufficiently severe to cause marked impairment in occupational functioning or in usual social activities or relationships with others, or to necessitate hospitalization to prevent harm to self or others, or there are psychotic features.
- E. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication, or other treatment) or a general medical condition (e.g., hyperthyroidism).

**Note:** Manic-like episodes that are clearly caused by somatic antidepressant treatment (e.g., medication, electroconvulsive therapy, light therapy) should not count toward a diagnosis of manic–depressive I disorder.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

**DSM-IV-TR Criteria****Mixed Episode**

- A. The criteria are met both for a manic episode and for a major depressive episode (except for duration) nearly every day during at least a 1-week period.
- B. The mood disturbance is sufficiently severe to cause marked impairment in occupational functioning or in usual social activities or relationships with others, or to necessitate hospitalization to prevent harm to self or others, or there are psychotic features.
- C. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication, or other treatment) or a general medical condition (e.g., hyperthyroidism).

**Note:** Mixed-like episodes that are clearly caused by somatic antidepressant treatment (e.g., medication, electroconvulsive therapy, light therapy) should not count toward a diagnosis of manic–depressive I disorder.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

disorder are elevated 5 to 10 times over rates found in the general population. In the latter group, the rates are 0.5 to 1.5%. while in the former group rates are 5 to 15%. Interestingly, rates of unipolar depression in first-degree relatives are about twofold elevated over those in the general population. Because of the rate of depression in the general population (5–20%), this means that a twofold increase is a rate of about 20%. Important for genetic counseling, this in turn means that the probability that a manic–depressive proband will have a unipolar child is greater than the probability that they will have a manic–depressive child (5–15% versus 20%); note that it is most likely that they will have neither (100 minus 25–35%).

Most genetic research has been done on manic–depressive type I disorder. However, manic–depressive type II also appears to have a familial component. Manic–depressive type II probands have more manic–depressive type I disorder and more manic–depressive type II disorder than unipolar depressives and less type I disorder than type I probands. Familial occurrence

### DSM-IV-TR Criteria

#### Hypomanic Episode

- A. A distinct period of persistently elevated, expansive, or irritable mood, lasting throughout at least 4 days, that is clearly different from the usual nondepressed mood.
- B. During the period of mood disturbance, three (or more) of the following symptoms have persisted (four if the mood is only irritable) and have been present to a significant degree:
  - (1) inflated self-esteem or grandiosity
  - (2) decreased need for sleep (e.g., feels rested after only 3 hours of sleep)
  - (3) more talkative than usual or pressure to keep talking
  - (4) flight of ideas or subjective experience that thoughts are racing
  - (5) distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli)
  - (6) increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation
  - (7) excessive involvement in pleasurable activities that have a high potential for painful consequences (e.g., the person engages in unrestrained buying sprees, sexual indiscretions, or foolish business investments)
- C. The episode is associated with an unequivocal change in functioning that is uncharacteristic of the person when not symptomatic.
- D. The disturbance in mood and the change in functioning are observable by others.
- E. The episode is not severe enough to cause marked impairment in social or occupational functioning, or to necessitate hospitalization, and there are no psychotic features.
- F. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication, or other treatment) or a general medical condition (e.g., hyperthyroidism).

**Note:** Hypomanic-like episodes that are clearly caused by somatic antidepressant treatment (e.g., medication, electroconvulsive therapy, light therapy) should not count toward a diagnosis of manic–depressive II disorder.

does not differentiate between inborn and environmental factors. Familial aggregation could be due to sharing genetic material, nongenetic congenital factors (e.g., similar inherited or acquired intrauterine factors, or exposure to similar perinatal risk factors), or physiologic or psychological environmental factors.

Data from other types of studies indicate that at least part of this risk is due to biological, and likely genetic factors. Twin studies indicate that **monozygotic** have higher concordance rates for manic–depressive disorder than do **dizygotic** twins 60 to 80% for monozygotic twins versus 20 to 30% for dizygotic twins. Linkage studies have suggested that in certain families manic–depressive disorder may be linked to specific genes. On

### DSM-IV-TR Criteria 301.13

#### Cyclothymic Disorder

- A. For at least 2 years, the presence of numerous periods with hypomanic symptoms and numerous periods with depressive symptoms that do not meet criteria for a major depressive episode.
- Note:** In children and adolescents, the duration must be at least 1 year.
- B. During the above 2-year period (1 year in children and adolescents), the person has not been without the symptoms in criterion A for more than 2 months at a time.
  - C. No major depressive episode, manic episode, or mixed episode has been present during the first 2 years of the disturbance.
  - D. The symptoms in criterion A are not better accounted for by schizoaffective disorder and are not superimposed on schizophrenia, schizophreniform disorder, delusional disorder, or psychotic disorder not otherwise specified.
  - E. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hyperthyroidism).
  - F. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

the other hand, studies of monozygotic twins also indicate that only 40 to 70% are concordant for manic–depressive disorder. Thus, although there is clearly a genetic component to this illness, genetics is not destiny.

Several **genetic loci** have been proposed but independent confirmations have been lacking. Overall, the number of families in which a single gene has been associated with manic–depressive disorder is small. Further, no single locus has been replicated in multiple studies. It is likely that genes may confer susceptibility to the disorder without actually determining that the disorder occurs. That is, to have the disorder one must have both the gene and another factor.

A related approach to investigating genetic contributions to manic–depressive disorder is to look for differences in genes that code for components of systems thought to be involved in the pathophysiology of the disorder. Chief among such candidate genes have been those responsible for dopamine and serotonin receptors, transporters and metabolic enzymes. The recent study by Mundo and coworkers (2001) showed that individuals who developed manic symptoms when treated with serotonin-active antidepressants had higher rates of the gene coding for a particular form of the serotonin transporter, compared with those similarly treated who did not develop manic symptoms. In addition, several studies have indicated that the gene coding for the norepinephrine-metabolizing enzyme catechol-*O*-methyl transferase (COMT) may be associated with the rapid cycling form of manic–depressive disorder.

In addition, recent evidence raises the possibility that the expression of a psychiatric illness that is coded genetically may not be due simply to the presence or absence of specific genes, but rather to modifying pieces of DNA in close proximity to important genes. Specifically, small sections of DNA, three base-pairs in length (called **trinucleotide repeats**), appear to be overrepresented in genetic disorders with prominent psychiatric symptoms.

### Neurotransmitter Hypotheses

Many theories have something of value to contribute regarding the pathologic basis of manic–depressive disorder. Nonetheless we do not yet have data to indicate whether the disorder is basically a disorder of a particular neurotransmitter, a particular neuroanatomic locus, or a particular physiologic system. Integration of these hypotheses awaits development of new methodologies for clinical neurobiologic investigations.

### Second-messenger System Hypotheses

When neurotransmitters bind to postsynaptic neuronal receptors, a series of intracellular events are initiated that are mediated by chemical systems linked to those receptors. So-called G-proteins link the receptors to second-messenger systems, which in turn are linked to protein kinases that control the synthesis and operation of cellular components.

The cyclic AMP and phosphatidyl inositol systems are the most extensively studied of these second-messenger systems. Recent data have generated substantial interest in the phosphatidyl inositol system as a possible mediator of the clinical effects of lithium in manic–depressive disorder, particularly since this second-messenger system is linked to subtypes of adrenergic, serotonergic, dopaminergic and cholinergic neurotransmitter systems. Persons with manic–depressive disorder have alterations in platelet phosphatidyl inositol levels and responsiveness of neutrophil phosphoinositol accumulation.

### Neuroendocrine Hypotheses

Typical neuroendocrine studies investigate peripheral or cerebrospinal fluid abnormalities of a particular system in persons with mood disorders and in controls and propose that either the neuroendocrine system itself or the neurotransmitter system that controls the hormone is in some way linked to the pathophysiology of the mood disorder of interest. Taken together, the literature does not identify particular endocrine findings as characteristic of manic–depressive disorder.

The thyroid axis may be of particular relevance to the pathophysiology of mood disorders since it serves not only as a dependent variable that is studied as a function of mood (as most neuroendocrine systems have been), but because the thyroid axis has also been studied as an independent variable of some impact. Several studies have shown that thyroid hormone administration may actually ameliorate mood disorders in certain paradigms. Further, in the rapid cycling variant of manic–depressive disorder, evidence indicates that supplementation with high doses of the thyroid hormone thyroxine ( $T_4$ ) may induce remission in persons who are refractory to standard. The mechanism for these effects has been the subject of much speculation. Various models posit that the brain is functionally hypothyroid either due to changes in hormone synthesis, transport, or metabolism, or due to increased demand; alternatively, other models propose that the

brain has an excess of a thyroid-related substance, which administration of exogenous thyroid hormone diminishes.

### Cell Degeneration and Neuroprotective Effects of Medications

One of the most exciting areas of recent research focuses on the possibility that lithium and perhaps certain anticonvulsants such as valproate may actually exert a **neuroprotective** effect in manic–depressive disorder. Evidence indicates that these agents may protect nerve cells by stimulating production of protective proteins or by stimulating nerve growth. Interestingly, there is some clinical evidence from MRI that lithium treatment may actually increase total brain gray matter, although this will of course require replication. Thus, it is possible that cellular degeneration, albeit not as virulent as in Alzheimer's, may play a role in manic–depressive disorder.

### Biological Rhythms

Two types of data indicate that biological rhythms may play a role in the pathogenesis of manic–depressive disorder. First, there are a large number of observational studies that have demonstrated seasonal peaks in the onset of affective episodes or hospitalizations for mood disorders. For manic–depressive disorder, the predominant seasons appear to be spring and fall, although other patterns may occur with some consistency across years. Seasonal affective disorder in which persons become depressed and remit at specific, regular times of year, has been codified in DSM-IV by applying the course modifier “seasonal pattern” to recurrent mood disorders. Although the relationship of seasonal affective disorder, particularly the winter depression variant, to manic–depressive disorder is not yet clear, there does appear to be some overlap. For instance, in most studies a large percentage of persons with seasonal affective disorder have manic–depressive disorder. In addition, the clinical picture of winter depression is similar to the hypersomnolent, anergic, hyperphagic depression common in manic–depressive disorder. Further, treatment with bright light has been shown to be efficacious in winter depression, and also appears to be an effective antidepressant in nonseasonal manic–depressives treated in the winter.

The second type of data which may provide a mechanism for seasonal patterns is that persons with manic–depressive disorder often exhibit abnormalities of circadian or daily rhythms. Many rhythmic parameters have been studied in persons with manic–depressive and other mood disorders, with various abnormalities found regarding the **amplitude** (height of the rhythm) and **phase** (timing of the rhythm). Among the most promising findings is that light sensitivity to suppression of the rhythmic hormone melatonin may be altered in persons with manic–depressive disorder and their relatives. Sleep has also been implicated in the pathogenesis of manic–depressive disorders. However, it should be noted that it is not clear whether it is the rhythmic aspects of sleep or its nonrhythmic, restorative components which are most relevant. One of the most striking findings in mania is the lack of need for sleep and there is evidence that sleep deprivation may be both antidepressant and promanic.

An autonomous pattern of affective episodes in manic–depressive disorder may develop from increasing sensitization of an individual to stressors. This process was proposed to be similar to kindling in animals and humans, in which subthreshold

convulsant stimuli can decrease the threshold for seizures and eventually lead to spontaneous seizures. There are several attractive aspects to this hypothesis. It is supported by the increased frequency of episodes over the course of manic–depressive disorder, and the response of many persons with manic–depressive disorder to treatment with the anticonvulsants carbamazepine and valproate. However, the clinical data in support of this heuristically powerful conceptual paradigm are at this point quite limited. Thus it is not clear whether the increase in episode frequency sometimes seen is due to accumulating damage from prior episodes, or is simply the unfolding over time of what was destined from the beginning to be a malignant case of the illness.

### Stress and Manic–Depressive Disorder

The possible association of stressful life events and the onset of depression has generated substantial interest among researchers from various theoretical backgrounds. Most of the literature regarding analysis of the relationship between stressful life events and manic–depressive disorder has focused on the precipitation of episodes in established manic–depressive disorder rather than the onset of the disorder *de novo*. There are several studies that demonstrate a relationship between stressful life events and the onset of affective episodes in already established manic–depressive disorder. However, several studies failed to find meaningful associations. It is likely that adverse life events are associated with mood episodes, particularly those episodes that are sufficiently severe to warrant hospitalization. In this respect such life events need to be attended to for clinical purposes. However, from a theoretical point of view it is not clear that such events actually play a pathogenic role.

### Conclusions: The Biopsychosocial Approach

Numerous family genetic studies indicate that there is a hereditary biological component to manic–depressive disorder, yet the fact that only 40 to 70% of monozygotic twins are concordant for manic–depressive disorder indicates that genetics is not destiny. Most neurotransmitter systems and most neuroendocrine axes studied to date have shown some abnormalities in manic–depressive disorder, yet it is not clear to what degree these are individual in the pathogenesis of symptoms, and to what degree these findings reflect “downstream”, or secondary changes. Each of the complex physiologic and psychosocial hypotheses are attractive heuristically, yet they have in most cases little supporting data and are notoriously difficult to test. Clinicians and educators of individuals and families who suffer with manic–depressive disorder are best advised to take a nonreductionistic and biopsychosocial view of this illness.

### Assessment and Differential Diagnosis

Mood episodes are discrete periods of altered feeling, thought and behavior. Typically they have a distinct onset and offset, beginning over days or weeks and eventually ending gradually after several weeks or months. Manic–depressive disorder is defined by the occurrence of depressive plus manic, hypomanic, or mixed episodes, or the occurrence of only manic or mixed episodes. The diagnostic decision tree for manic–depressive disorder is given in Figure 47.1.

It is important to note that the phenomenologic differentiation between hypomania and mania is not as cut-and-dried. Of the three characteristics by which one is “promoted” from hypomania to mania, only the presence of psychosis is firmly grounded in the characteristics of the individual. The other two characteristics, marked social or occupational role impairment or hospitalization, clearly have components that are primarily external to the individual. If, for instance, one individual has relatively mild manic symptoms but is living with a family who is unable to tolerate the behavior, she/he is more likely to be hospitalized. Similarly, the comorbid presence of a severe disorder is more likely to result in hospitalization and a “promotion” from type II to type I disorder. Contrarily, limited insurance benefits, or a more tolerant family increase the probability that a manic syndrome of a given severity will be managed without hospitalization and thus be diagnosed as “hypomania” rather than “mania”.

### A “Bipolar” Disorder?

Classically, mania has been considered to be the opposite of depression: manic individuals were said to be cheery, optimistic and self-confident, hence the name bipolar disorder. However, in most descriptive studies, substantial proportions of hypomanic and manic patients actually exhibit substantial dysphoric symptoms. Mixed episodes, defined as the simultaneous occurrence of full-blown manic and depressive episodes, are the most prominent example of dysphoria during mania.

### Additional Features: Psychosis and Rapid Cycling

Psychosis can occur in either pole of the disorder. If psychotic symptoms are limited to the major mood episode, the individual is considered to have manic–depressive disorder with psychotic features. On the other hand, if psychotic symptoms endure significantly into periods of normal mood, the diagnosis of schizoaffective disorder is made. For formal research diagnostic criteria and DSM definitions, 2 weeks of psychotic symptoms during normal mood is sufficient to convert a diagnosis of manic–depressive or major depressive disorder into schizoaffective disorder, because it is thought that such persons have a clinical course midway

#### DSM-IV-TR Criteria

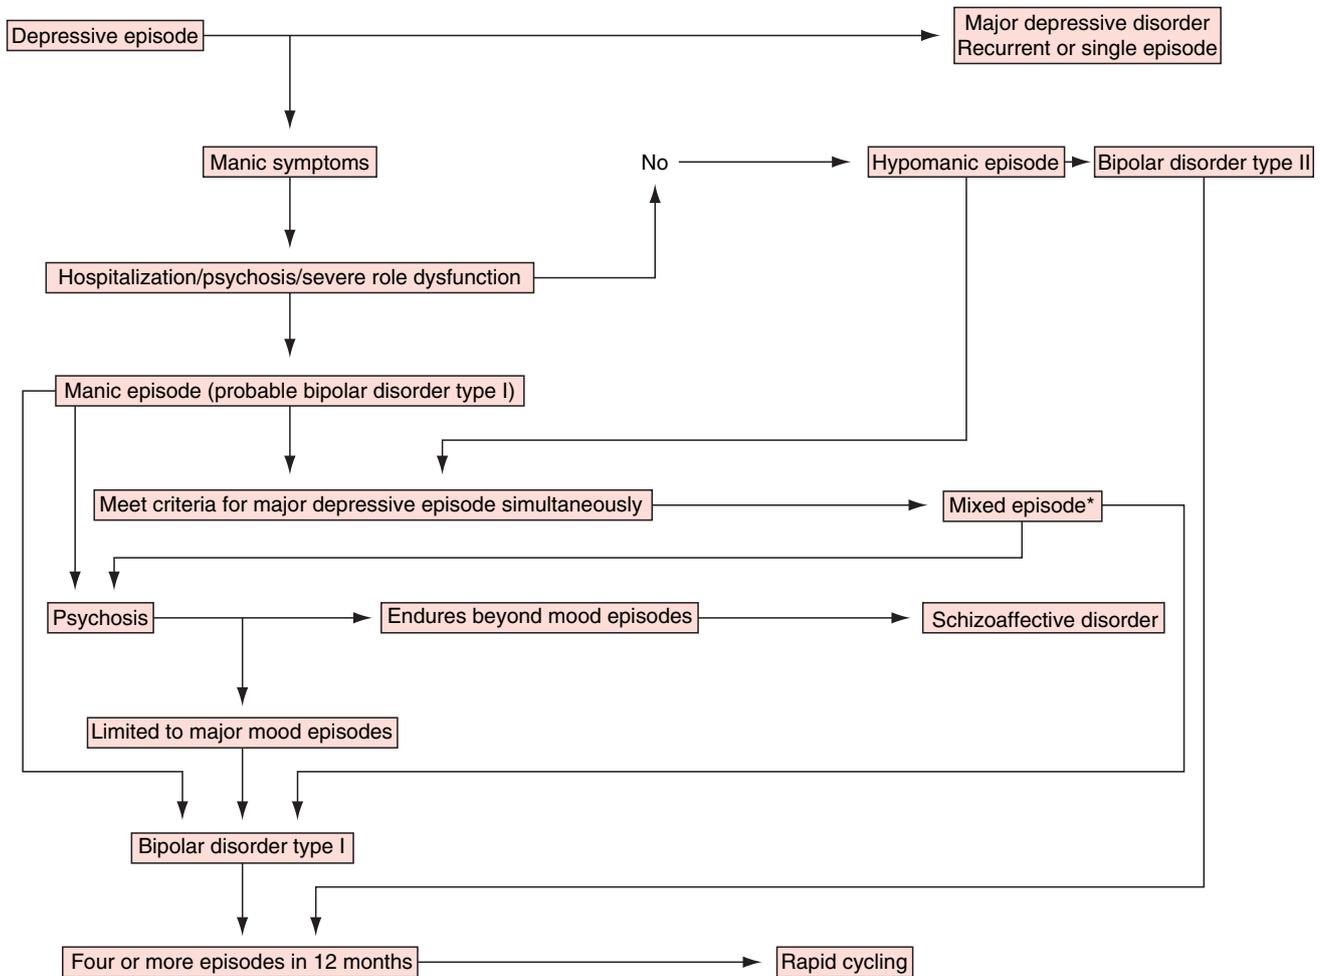

##### Rapid-Cycling Specifier

*Specify if:*

**With rapid cycling** (can be applied to manic–depressive I disorder or manic–depressive II disorder). At least four episodes of a mood disturbance in the previous 12 months that meet criteria for a major depressive, manic, mixed, or hypomanic episode.

**Note:** Episodes are demarcated by either partial or full remission for at least 2 months or a switch to an episode of opposite polarity (e.g., major depressive episode to manic episode).

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

**Figure 47.1** Diagnostic decision tree for manic–depressive disorder. The building blocks for a diagnosis of manic–depressive disorder are individual episodes and their characteristics, as summarized in Table 47.1. This decision tree helps the psychiatrist through the steps that lead to diagnosis of manic–depressive disorder and identification of its subtypes. \*Does not apply to hypomanic episode as per DSM-IV. (Source: Bauer M, Whybrow P, Gyulai L, et al. [1994a] Testing definitions of dysphoric mania and hypomania: Prevalence, clinical characteristics, and inter-episode stability. *J Affect Disord* 32, 201–211; McElroy S, Keck P, Pope H, et al. [1992] Clinical and research implications of the diagnosis of dysphoric or mixed mania or hypomania. *Am J Psychiatr* 149, 1633–1644.)

between individuals with mood disorders or schizophrenia. However, this cutoff point is fairly arbitrary, and its validity is not well established. For example, it may be that psychotic symptoms actually represent a separate, comorbid disorder, or they may be integral features of severe manic–depressive disorder that simply take longer to resolve. Identification of pathophysiological and genetic bases of psychosis and of manic–depressive disorder will certainly help to resolve these issues.

Rapid cycling is defined by the occurrence of four or more mood episodes within 12 months. It should be noted that, despite the name, the episodes are not necessarily or even commonly truly cyclical; the diagnosis is based simply on episode counting. This subcategory is of significance because it predicts a relatively poorer outcome and worse response to lithium and other drugs. Although rapid cycling has been considered by some to be an “end stage” of the disorder, empirical evidence indicates that it may have its onset at any time during the disorder and may come and go during the course of illness. Several specific risk factors may be associated with rapid cycling, each of which may give clues to its pathophysiology. These include female gender, antidepressant use and prior or current hypothyroidism.

## History, Physical Examination and Laboratory Studies

Although the diagnosis of manic–depressive disorder is made on the basis of phenomenology, there are several reasons to conduct a thorough medical history and physical examination. First, there are several general medical or substance-related causes of manic depression that, if treated, may lead to the resolution of the mood episode. Similarly, mania may be the first sign of a general medical illness that will be progressive and serious in its own right. Secondly, medical evaluation is necessary before starting medications used in the treatment of manic–depressive disorder. Finally, for many patients with psychiatric illnesses, particularly chronic or severe illnesses, their first contact with medical care as an adult is during the psychiatric interview, often under inpatient or even involuntary conditions. Because psychiatric illness is clearly not **protective** against medical illnesses, and since even common general medical illnesses may never have been screened for in the past, a thorough medical history and physical examination are necessary parts of the basic care of patients.

The overall approach to evaluating persons with manic–depressive disorder for medical problems may be generalized as

follows: persons with psychiatric disorders, including manic–depressive disorder, should have regular screening for disease detection and health maintenance purposes as recommended for the general population. However, it should also be kept in mind that individuals with manic–depressive disorder, by virtue of having an often severe and disabling behavioral disorder, are less likely than the general population to have had adequate medical screening and treatment. Thus, special care must be made to ensure that health problems are not overlooked and that appropriate treatment or referral is effected. Unfortunately, it is the exception rather than the rule to have well-integrated medical and mental health systems so that the mental health provider can assume that some effort will need to be expended to ensure adequate care is delivered for individuals with manic–depressive disorder.

Which general medical illnesses may cause symptoms of manic–depressive disorder? Most medical illnesses that affect brain function have been described in case reports or small case series to cause one or another psychiatric syndrome. Several general medical illnesses have been associated with the development of manic–depressive disorder (Table 47.2) although none can be considered specific risk factors. Administration of medications has been observed frequently in clinical practice to be associated with the onset of mania, particularly in patients with preexisting depression. Such medications are listed in Table 47.3.

Some controversies have been hotly debated, particularly regarding the role of antidepressants in causing mania and rapid cycling. Of particular importance to psychiatric practice, all efficacious antidepressant treatments have been suspected to cause the induction of mania, with the exception of lithium and the possible exception of psychotherapy. This caveat for antidepressants also includes nonpharmacological antidepressants such as light and electroconvulsive therapy (ECT). The latter effect is paradoxical, as ECT is also used successfully to treat mania.

### Age, Gender, and Cultural Issues in Diagnosis and Assessment

It is important to note that manic–depressive disorder is a worldwide problem and is among the top 10 of all diseases in terms of global burden worldwide, and fifth in terms of self-reported disability. There are no major differences in the manifestations of manic–depressive disorder across gender, age, or culture. However, women appear to be at higher risk for rapid cycling dysphoria during mania and comorbid disorders. Note, however, that affective psychoses may be relatively un-

**Table 47.2 Medical Disorders Commonly Associated with Mania** Neurologic Disorders Endocrine

der-diagnosed and schizophrenia over-diagnosed, in African-Americans compared with Caucasians. Among children and adolescents, the diagnosis of manic–depressive disorder is often complicated by less consistent mood and behavior baseline than occur in adults. Little evidence is available regarding course and outcome in children. Available data indicate that, as with adults, mixed or cycling episodes predict more recurrences; unlike in adults, manic and mixed presentations may be associated with relatively shorter episodes compared with depressive presentations.

### Epidemiology

#### Epidemiological Studies of Manic–Depressive Disorder

Estimates of the lifetime risk for manic–depressive I disorder from epidemiological studies have ranged from 0.2 to 0.9%. The Epidemiological Catchment Area (ECA) study found a lifetime prevalence rate of 1.2% for combined type I and type II variants. These rates are approximately tenfold greater than the prevalence rate for schizophrenia and about one-fifth that for major depressive disorder. Little is known regarding the prevalence of cyclothymic disorder. The National Comorbidity Survey Replication (NCD-R) found a considerably higher lifetime prevalence of bipolar I-II disorders of 3.9% (Kessler *et al.*, 2005). The lifetime prevalence for all mood disorders was 20.8%. Unlike major depressive disorder, manic–depressive disorder has an approximately equal gender distribution. Few consistent data are available regarding differences in prevalence across ethnic, cultural, or rural–urban settings. However, one of the more intriguing puzzles is the tendency of manic–depressive disorder to occur in higher socioeconomic strata than schizophrenia, which tends to aggregate in lower socioeconomic strata. Although many theories have been advanced to explain this phenomenon, no certain mechanism has been identified. However, several issues are clear. First, the finding is most likely not exclusively due to diagnostic bias (i.e., overdiagnosing persons of lower socioeconomic

class with schizophrenia more frequently than manic–depressive disorder and the converse in persons of higher socioeconomic class). Secondly, the upward socioeconomic “drift” is not due to highly impaired patients “dragged” upward by higher functioning family members who are normal or who have adaptive sub-syndromal manic–depressive spectrum characteristics; rather, patients themselves, at least those with type II disorder, are in many cases highly successful and occupy higher socioeconomic levels. Thirdly, the findings are not limited to the USA but have been replicated in European samples.

Of particular interest in regard to the epidemiology of manic–depressive disorder is that the incidence of manic–depressive disorder (and depressive disorders) appears to have increased since the 1940s. Reasons for this are not clear, although environmental factors, either physiological or psychosocial, may be responsible. For instance, exposure to increasingly severe social stressors, or the breakdown of cultural supports that may buffer stresses, may contribute; increases in exposure to putative environmental toxins might also be considered. In addition, in those families afflicted with manic–depressive disorder across generations, those in later generations tend to have earlier onset. This may be due to changes in genetic loading across generations or to environmental factors either within the family or in the wider environment. Regardless of the cause, the increasing incidence and earlier onset of manic–depressive disorder indicate that this illness is not likely to decrease in importance as a clinical and public health issue.

### Comorbidity with Other Psychiatric Disorders

Alcohol and drug abuse and dependence represent the most consistently described and most clinically important psychiatric comorbidities with manic–depressive disorder. Whereas rates of alcohol abuse combined with alcohol dependence are from 3 to 13% in the general population, lifetime rates for alcohol dependence from ECA data indicate that they are greater than 30% in persons with manic–depressive I disorder (Regier *et al.*, 1990). Further, ECA lifetime rates for drug dependence in individuals with manic–depressive I disorder are greater than 25% and rates for any substance abuse or dependence are above 60%. Comparable rates for alcohol, drug, or any substance abuse or dependence in major depressive disorder in ECA data are, respectively, 12%, 11% and 27%. Thus, manic–depressive disorder represents an enriched sample for substance use disorders, with substantially greater rates than for the general population or even those with unipolar depression. The reasons for the co-occurrence of manic–depressive disorder and substance dependence are not clear. In addition to self-medicating for depression, mania and intensifying the manic experience with stimulants, it is possible that some common genetic predisposition for mood instability is associated with both manic–depressive mood phenomenology and increased craving for substances, and the predominant phenotypic expression is then determined by other genetic or environmental factors. According to this hypothesis, some persons possessing the gene develop manic–depressive disorder, some develop substance dependence and some develop both. Regardless of the mechanism, comorbid substance dependence represents an important clinical challenge for clinicians treating persons with manic–depressive disorder.

Lifetime anxiety disorders have been described in as many as 44% of individuals with manic–depressive disorder. Other psychiatric comorbidities have been described in modest

proportions of manic–depressive patients. Interestingly, data indicate that comorbidity may be higher in women with manic–depressive disorder than in men which may contribute to the tendency for the female gender to be associated with more complex forms of manic–depressive disorder such as rapid and dysphoric mania.

### Clinical Outcome, Functional Outcome and Illness Costs

#### Clinical Outcome Studies

Manic–depressive disorder has its onset in most persons in adolescence and young adulthood, between the ages of 15 and 30. However, prepubertal mania and first-onset disease in the ninth decade of life are not unheard of. Once developed, multiple episodes are the rule. A review of the literature indicates that the majority of patients have four or more episodes in a lifetime. Among rapid-cycling patients, the basis for the diagnosis is four or more episodes in a year with an average of more than 50 lifetime episodes. There is no typical pattern to episode recurrence, with some patients having isolated manic, hypomanic, or depressive episodes, others switching from one pole to the other in linked episodes, and still others switching continually from one pole to the other in quasi-cyclical fashion. However, even among rapid-cycling patients, episodes are rarely periodic. Rather, the pattern is more accurately described by chaotic dynamics.

Episode length typically ranges from 4 to 13 months, with depressive episodes typically longer than manic or hypomanic episodes. Women appear to have more depressive relapses than manic ones, whereas men have a more even distribution. Also women predominate among rapid-cycling patients, representing 70 to 90% in most studies.

The early optimistic view of outcome, which derived primarily from experience in controlled clinical trials, contrasts with the overall guarded prognosis described by most longitudinal studies in the last three decades, which have been less controlled but more inclusive than formal clinical trials.

  - A. Improve clinical outcome
  - B. Improve functional outcome
  - C. Improve host factors
    - i. Illness management skills
    - ii. Medical and psychiatric comorbidities

\*Indications for increased intensity of care: danger to self or others; complicating medical or psychiatric comorbidities; aggressive medication titration; social factors that compromise treatment.

Approximately 20 to 40% of patients with manic–depressive disorder do not respond well to lithium, and that proportion may increase to as much as 80% for certain subgroups such as patients who experience rapid-cycling pattern (Dunner and Fieve, 1974; Maj *et al.*, 1989) or mixed manic and depressive episodes (Keller *et al.*, 1986). When assessed 1.5 years after index hospitalization, between 7 and 32% of manic–depressive patients remain chronically ill, depending on the polarity of index episode (Keller *et al.*, 1986). Only 26% of one sample had good outcome after hospitalization for mania, whereas 40% had moderate and 34% had poor outcome (Harrow *et al.*, 1990). The probability of remaining ill at 1, 2, 3 and 4 years after hospitalization for mania was, respectively, 51%, 44%, 33% and 28% (Tohen *et al.*, 1990). Sixty percent of an ambulatory sample of manic–depressive patients had fair to poor outcome based on a global outcome score after 1-year follow-up (O’Connell *et al.*, 1991).

Relatively little is known regarding clinical outcome in manic–depressive type II patients, although they appear to be at least as impaired in terms of relapse as manic–depressive type I patients. For instance, 70% of manic–depressive II patients followed up for 5 years experienced multiple relapses, whereas only 11% were episode free (Coryell *et al.*, 1989).

Subsyndromal affective symptoms may remain in up to 13 to 34% (Harrow *et al.*, 1990), and substantial interepisode morbidity may remain despite adequate treatment with lithium. It is not clear whether such interepisode pathology represents incompletely resolved major affective episodes, medication side effects, demoralization due to functional impairment, or a combination of these. It should be noted here that side effects are more than a trivial issue, as they may lead to medication discontinuation in 18 to 53%, a figure that is greater in lower socioeconomic classes.

### Functional Outcome Studies

Substantial levels of functional impairment are also characteristic of manic–depressive disorder, even when major clinical indices have improved. Tohen and coworkers (1990) found 28% of subjects unemployed after index hospitalization for mania. Bauwens and associates (1991) found that levels of functional disability correlated both with number of prior episodes and with residual interepisode psychopathology. Five-year follow-up data from the NIMH Collaborative Program on the Psychobiology of Depression (Coryell *et al.*, 1989) provide evidence that levels of impairment in manic–depressive type I and type II disorders are similar. This included similarly fair to very poor work (in 30 and 42% of patients with types I and II, respectively), marital (30 and 23%), social (45 and 45%) and recreational (45 and 48%) function; sense of satisfaction or contentment (57 and 62%); and overall social adjustment (68 and 62%). More recent analysis of that data set has revealed enduring deficits in educational and occupational status at 5 years of follow-up in a mixed group of manic–depressive and unipolar patients, even in those who were recovered for 2 years (Coryell *et al.*, 1993). This led the authors to comment succinctly: “Follow-up studies have usually defined recovery as the absence of symptoms. The present findings show that this convention may result in an overly benign portrayal of outcome” (Coryell *et al.*, 1993, pp. 726).

Much less is known about which characteristics predict functional deficits in manic–depressive disorder, an issue of some importance in identifying high-risk groups for particular attention. A recent review (Bauer and Whybrow, 2001) indi-

cates, surprisingly, that baseline demographic and functional outcome do not predict future functional outcome. However ongoing depressive symptoms, even to a mild degree, are strongly associated with ongoing functional deficits. The direction of causability is not clear, however. It is plausible that depressive symptoms render individuals less able to function in work and personal roles. It is equally plausible that unemployment, divorce, social isolation and the like can cause or exacerbate depressive symptoms. In fact, both are likely. In any event, careful attention to functional deficits, depressive symptoms and their interplay is important to optimizing care and hopefully outcome.

### Personal and Societal Costs of Manic–Depressive Disorder

Although there are as yet few available data regarding direct and indirect illness costs for manic–depressive disorder, the direct treatment costs of manic–depressive disorder are substantial. Among the major mental disorders, the rate of hospitalization for manic–depressive disorder is exceeded only by that for schizophrenia. It is also clear that substantial loss of productivity, in addition to personal suffering, may occur in manic–depressive disorder. In mental illness in general, functional impairment was responsible for 55% of the costs of non-addictive mental illness in the USA in 1986 (Rice *et al.*, 1990). It is striking that the functional impairment may be responsible for as much as 75% of the costs of affective illness. Specifically in manic–depressive disorder, evidence indicates that costs from lost productivity are substantial as well. For instance, 19% of persons with manic–depressive disorder attempt suicide at some time in their lives (Klerman *et al.*, 1992), thus placing almost one-fifth of persons with manic–depressive disorder at high risk of loss of life through this one cause alone. Without adequate treatment, a person with manic–depressive disorder from age 25 years can expect to lose 14 years of effective major activity (e.g., work, school, family role function) and 9 years of life. The indirect costs of this disorder are also high, because 15% of persons with manic–depressive disorder are unemployed for at least five consecutive years and more than 25% of those younger than age 65 years receive disability payments (Klerman, 1992). Therefore, it stands to reason that treatments targeted at reducing functional impairment, as well as clinical outcome, can have a substantial impact on the burden of mental illness costs to society and quality of life for the individual and her or his family.

### Rating Scales

For clinical usage, clinicians rating scales in general use for depression can also be used for depressive episodes in manic–depressive disorder. Most share in the shortcoming of tending to underrate hypersomnia, hyperphagia and weight gain, “atypical” features that are common in manic–depressive disorder. Among mania scales, the Young Mania Rating Scale (Young *et al.*, 1978) is well validated on outpatients as well as inpatients, and for hypomanic as well as manic episodes. Self-report scales have the advantage of being brief (typically 5 minutes) and amenable to frequent, even daily, usage without undue burden. However, there have been questions about their reliability and validity, particularly in severely ill manic patients, although one instrument, the Internal State Scale (Bauer *et al.*, 1991) has demonstrated reasonable psychometric properties across several replications.

## Treatment\*

### General Considerations

Traditionally, treatment for manic–depressive disorder has been categorized as acute versus prophylaxis, or maintenance; that is, treatment geared toward resolution of a specific episode versus continued treatment to prevent further symptoms. Treatment can also be considered along several other lines. In general, more structured treatment settings, such as full or partial hospitalization, are indicated if patients are likely to endanger self or others, if manic–depressive disorder is complicated by other medical or psychiatric illnesses that make ambulatory management particularly dangerous, or if more aggressive management is desired than is easily available on an ambulatory basis (e.g., intensive psychosocial intervention or rapid dosage titration of psychotropic agents). In addition, social factors play an important role in the decision to hospitalize in the real world of clinical psychiatry. Such reasons may include lack of social support to ensure medication compliance during acute illness, social stresses aggravating symptoms and making treatment compliance difficult (e.g., manipulative or hostile living situation), or lack of transportation to accommodate frequent ambulatory appointments during acute illness. Unfortunately, it is sometimes the case, although less frequent in this era of managed care, that a person's insurance plan covers inpatient but not ambulatory mental health treatment, forcing expensive inpatient care when less costly, time-limited, intensive ambulatory care would suffice.

Finally, treatment can be categorized according to its goals. Treatment can be focused on improving clinical outcome (episodes and symptoms) or functional outcome (social and occupational function and health-related quality of life). Although this categorization appears straightforward, clinical practice reveals many subtleties. For instance, it is erroneous to assume that clinical outcome is the domain of pharmacotherapy and that functional outcome is the domain of psychotherapy. In actuality, most psychotherapies by design focus on improving symptoms. Likewise, pharmacotherapeutic stabilization of symptoms clearly contributes to improved role function. Further, treatments that improve one domain may cause decrements in another. For instance, effective maintenance treatment with lithium may come at the cost of hand tremor, which interfere with work function and causes embarrassment in social situations. Compassionate psychoeducation and alliance building are integral goals of each form of treatment. In analogy to infectious disease treatment, attention to such host factors can often make the difference between success and failure of treatment.

### The “Efficacy–Effectiveness Gap”

Great optimism justifiably accompanied the introduction of lithium in the 1960s, with the drug projected to save society millions of dollars in direct and indirect treatment costs. However, there are reasons to be concerned that lithium has made much less of an impact than originally projected, and there is clear evidence that manic–depressive disorder remains a major health concern, even with the addition of anticonvulsants to our armamentarium. For example, readmission rates for manic–depressive disorder may be as high as 90% during 2-year follow-up, with no difference between lithium-treated and nontreated patients (Markar and Mandar, 1989). Overall, the impact of lithium “under ordinary clinical conditions” appears to be much less than would be expected from results of randomized clinical trials.

How can these data be reconciled with early estimates projecting dramatic decreases in treatment costs due to the introduction of lithium? Presumably, the medications themselves do not differ between controlled clinical trials and general clinical practice. If anything, the diffusion over time of the new pharmacological technology into general clinical practice might be expected to lead to further gains in illness management beyond those initially seen. The use of several anticonvulsants such as carbamazepine, valproic acid and lamotrigine in the treatment of manic–depressive disorder holds promise for further improvement in outcome. For instance, these drugs may have **efficacy** in controlled clinical trials, but concerns regarding the **effectiveness** of lithium in clinical practice also apply to the use of these anticonvulsants.

What, then, are the sources of this **efficacy–effectiveness gap** in the treatment of manic–depressive disorder? It is likely that the gap is in part due to the exclusion of “complicated” manic–depressive patients from clinical trials (e.g., those with substance abuse, personality disorders, or medical problems, and those unwilling to risk exposure to placebo. Although such exclusions are appropriate for establishing the efficacy of potential treatments, the exclusivity of structured clinical trials limits their relevance in the general clinical setting. Another likely contributor to the efficacy–effectiveness gap is variation in provider attributes such as attitudes and capabilities. For instance, it is well established that even at academic medical centers, the intensity of medication treatment for mood disorders is much less than that which experts consider optimal. It is possible, then, that supporting providers with specific data regarding treatment options will aid in decreasing the efficacy–effectiveness gap. With this in mind, several organizations have developed clinical practice guideline to assist providers. Finally, the organization and orientation of care giving systems may not be optimally supportive.

## Somatotherapy

### Efficacious Agents for Various Phases of Manic–Depressive Disorder

Over the past 10 years medications have proliferated for the treatment of various phases of the disorder. The clinician must pick through an array of scientific data and marketing claims in order to choose the appropriate treatment. Two conceptual approaches help in this task. First, available scientific data can be reviewed and evaluated according to the techniques of “evidence-based medicine”.

The second conceptual approach that we have found useful is to propose an explicit definition for the term “mood stabilizer” and evaluate the role of various medications against this definition. The US Food and Drug Administration (FDA) does not formally define the term, but it stands to reason that an agent would be optimally useful for treatment of manic–depressive disorder if it had efficacy in four roles: 1) treatment of acute manic symptoms; 2) treatment of acute depressive symptoms; 3) prophylaxis of manic symptoms; and 4) prophylaxis of depressive symptoms. Table 47.5 summarizes the findings of this approach.

There are additional Class A controlled trials (nonplacebo-controlled) that support efficacy for multiple older, typical neuroleptics as well as the benzodiazepines, lorazepam and clonazepam.

In contrast to evidence regarding acute mania, evidence is scarce concerning efficacy of specific agents for acute

depressive episodes. Most treatment is undertaken primarily by extension from treatment experience in unipolar depression. In reviewing studies of agents for the prophylaxis of manic or depressive symptoms, most studies report recurrence rates without distinguishing between manic and depressive symptoms. For instance, some studies reported such statistics as time-to-first-episode without specifying whether the first episode was manic or depressed. Other studies reported summary statistics for affective symptoms without separating manic or depressive symptoms. Far and away, the most placebo-controlled support for any prophylactic agent comes from studies of lithium including studies of relapse prevention for depression, with support from controlled trials that are not placebo-controlled for carbamazepine and lamotrigine. The one prophylaxis study of valproate (Bowden *et al.*, 2000) showed no difference from placebo (lithium was also found to be no different from placebo in this study, although the study was under-powered to make definitive conclusions about this comparison).

It may be surprising that, given the paucity of data on treatment of acute depression and prophylaxis of manic–depressive disorder, frequently many other medications are used chronically in this illness, sometimes as first-time agents, for instance, valproate or carbamazepine. Although neuroleptics have acute anti-manic evidence, despite the fact that there is little evidence for prophylactic efficacy, they are often used chronically. This is because these agents are typically started during the course of an acute manic episode and clinicians are reluctant to stop them and switch to a different agent such as lithium. In addition, many individuals have failed or have been intolerant of treatment with lithium and they are therefore treated using the “next best thing”. This is not necessarily suboptimal treatment. However, it is important that the clinician recognize that data on long-term prophylactic efficacy is quite scanty for these agents, as it is for many other agents used in psychiatric practice.

Several additional issues in prophylaxis of manic–depressive disorder deserve comment. First, when is lifetime, or at least long-term, prophylaxis warranted? After one manic episode? One hypomanic episode? One depressive episode with a strong family history of manic–depressive disorder? There is insufficient empirical evidence with which to make strong recommendations. In clinical practice without clear guidelines, such decisions need to take into account the capability of the patient and family in

reporting symptoms, rapidity of onset of episodes, episode severity and associated morbidity. Clearly, the risks of a wait-and-see strategy would be different in a person who had a psychotic manic episode than in a person who had mild hypomania.

Secondly, can lithium ever be discontinued? Again, there are no solid data on which to base this decision. However, if lithium discontinuation is contemplated, there is evidence that rapid discontinuation (in less than 2 weeks) is more likely to result in relapse than slow taper (2–4 weeks), with relapse rates higher in type I than in type II patients. In type I patients, relapse rates for rapid discontinuation versus slow taper were, respectively, 96 and 73%, whereas in type II patients they were 91 and 33% (Faedda *et al.*, 1993).

Thirdly, a set sequence of treatment for refractory manic–depressive disorder has yet to be established. In particular, persons with rapid cycling represent a treatment dilemma. Although antidepressants may induce rapid cycling, they often leave the person in a protracted, severe depression. Switching from one antimanic agent to another often results in resumption of cycling. Complex treatment strategies may be required, such as anticonvulsants plus lithium, combinations of anticonvulsants, or adjuvant treatment with high doses of the thyroid hormone thyroxine.

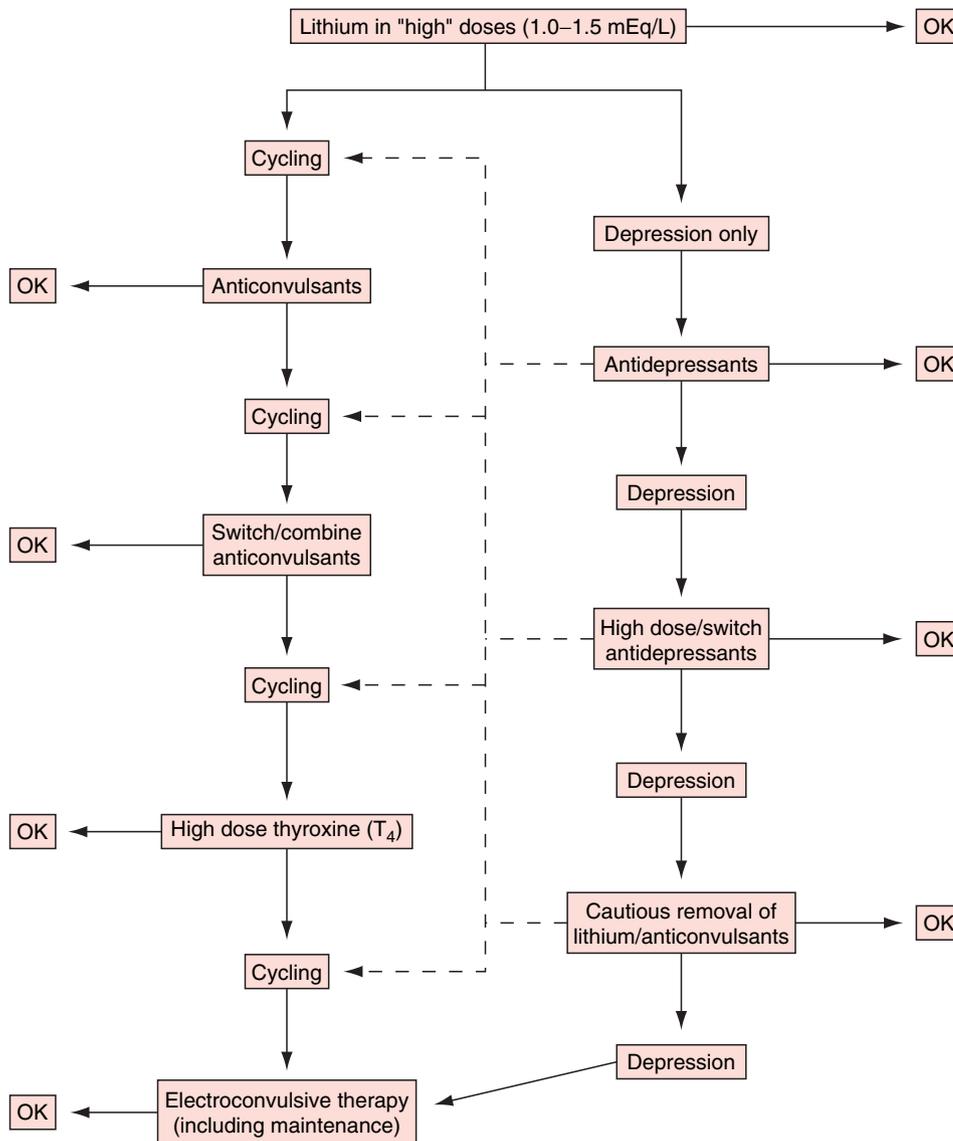

### A Simple Treatment Algorithm for Manic–Depressive Disorder

A treatment algorithm for refractory manic–depressive disorder, including strategies to deal with rapid cycling is found in Figure 47.2. It is derived from clinical practice guidelines from the US Veterans Administration and, by design, primarily specifies drug classes rather than individual agents. The entry point for this algorithm is the occurrence of any major mood episode (depression, hypomania, mania, or mixed episode) in an unmedicated patient. Patients with recurrence on medications may enter the algorithm at the appropriate point along the flow diagram. For simplicity of presentation, only depressive and cycling outcomes are illustrated. This is because depressive episodes are more common than manic or hypomanic episodes, and all but the most refractory of the latter episodes are relatively easily treated by the addition (or resumption) of lithium or anticonvulsants or the use of neuroleptics, as summarized above.

### Balancing Beneficial and Unwanted Effects of Medications

All psychotropic medications have side effects. Some are actually desirable (e.g., sedation with some antidepressants in persons with prominent insomnia), and specific medications are often chosen on the basis of desired side effects. However, side effects usually represent factors that decrease a patient’s quality of life and compromise compliance. Reviews of side effects of antidepressants and neuroleptics can be found in the chapters on depression and schizophrenia, respectively. It should be recalled in regard to antidepressants, however, that all can cause rapid cycling and mixed states in persons with manic–depressive disorder. These effects are not uncommonly encountered in clinical practice and should be watched for, even in persons taking mood-stabilizing agents.

A brief overview of the most frequent or important side effects of lithium, carbamazepine and valproic acid can be found in Table 47.6a–c. Note that some side effects may be encountered at any serum level of the drug, even within the therapeutic range. Some side effects may be dose-related even within that range and

**Figure 47.2** Treatment algorithm for manic–depressive disorder. (Source: Reprinted by permission of Taylor & Francis, from Bauer MS [1994] Rapid cycling, in *Anticonvulsants in Mood Disorders* [eds], Joffe RT and Calabrese JR. Marcel Dekker, New York, pp. 1–26.) Note: Refractory mania is relatively rare. This general algorithm addresses the more common clinical scenarios of depression and rapid cycling. \*For a complete discussion of this topic, see Bauer and McBride (2002); of how to use various psychopharmacologic agents, see Bauer (2003).

Hepatic		Increased LFTs	Increased LFTs	

may respond to dosage reduction. Others are more idiosyncratic and may need other management, as detailed in a subsequent section. Note that not all laboratory findings represent pathological processes that are associated with or presage morbidity for the patient; that is, not all are clinically significant.

Note also that the concept of the “therapeutic level” is not straightforward. The lower limit is usually established by the lowest level necessary for therapeutic effect, whereas the upper limit is set by the lowest level associated with regular, significant toxicity. This range is never established with complete precision. For some medications such as lithium, the therapeutic window is actually quite narrow, with toxic effects developing with some regularity after the upper limit of the therapeutic range

is surpassed and with serious toxicity developing at only modestly higher serum levels. As a further complication, for many persons the minimum level of lithium for good response may be substantially above the 0.5 to 0.8 mEq/L that is usually set as the lower therapeutic limit, but this is reached only at the cost of increased incidence of side effects. On the other hand, experience with valproic acid, the upper limit of the therapeutic range for mood stabilization may actually be 125 mg/dL rather than the listed range of 100 mg/dL usually accepted for antiepileptic effect, and this level may be reached without undue side effects. Thus, established therapeutic levels should be used as important guidelines, and therapeutic levels should only be exceeded with careful monitoring. However, one must not be falsely reassured

that reaching the lower level of a therapeutic range is equally effective for all patients, while taking with a grain of salt the upper limits of the therapeutic range in drugs with a wider therapeutic window.

Another important issue to consider is drug–drug interactions, which may lead to side effects. Such interactions are often associated with increases in serum levels of the drug of interest. For example, addition of thiazide diuretics, or nonsteroidal antiinflammatory agents, the latter available over the counter, is a common reason for increase in lithium level and development of toxicity. However, at other times the drug–drug interactions may not be reflected in an increased serum level if the main interaction is displacement of protein-bound drug. Because free drug concentrations are usually 1 to 10% of total serum drug, a displacement of even 50% of bound drug may be associated with negligible if any changes in total serum level. However, since both therapeutic and toxic effects are due to free, not bound, drug, unwanted side effects may develop despite total drug levels measured in the therapeutic range.

### Guiding Principles of Managing Side Effects

Although some side effects may be desirable, in many cases they are impediments to treatment, frequently of sufficient importance to lead to noncompliance. Clinicians might reframe the noncompliance issue more appropriately as “insufficient provider–patient cost–benefit analysis”. Stressing compliance when a person suffers from significant side effects is usually much less effective than working to set appropriate expectations of the patient and to find a regimen of minimal toxicity. Managing side effects is as much psychotherapeutic as medical.

There are several strategies available to improve patients’ tolerance of medications. First, dose reduction may be achieved without compromising efficacy in some patients. Some side effects, such as lithium-induced nausea, usually respond well to this, whereas others, such as lithium-induced memory loss, improve less reliably. Secondly, simple changes in preparation may be helpful, such as using enteric-coated lithium. Uncoated valproic acid causes nausea so frequently that only the coated forms are routinely used; however, the pediatric “sprinkle” preparation may be of some benefit in persons with nausea even with enteric-coated valproic acid. Thirdly, changing the administration schedule may ameliorate side effects. Commonsense strategies such as taking nausea-inducing medications after a meal should not be overlooked. Single daily dosing of lithium, carbamazepine, or valproic acid may decrease daytime sedation without compromising efficacy. For more obscure reasons, single daily dosing of lithium appears to decrease polyuria quite effectively.

Fourthly, addition of medications to counteract side effects can sometimes be the only way to continue treatment. Addition of beta-blockers can reduce lithium- or valproic acid-induced tremors. Judicious use of thiazide diuretics, often in conjunction with potassium-sparing diuretics or potassium supplements, can reduce lithium-induced polyuria. Finally, change to another drug may be the only alternative. This is clearly indicated in the case of serious allergic reactions. Polypharmacy should be avoided wherever possible.

### Psychotherapies

It is important to note that psychotherapy has been studied almost exclusively in the context of ongoing medication management, rather than as a substitute for, or alternative to, medication treatment. Rather, psychotherapy has been utilized as an adjuvant

treatment to optimize outcome in the illness. Psychotherapy has been viewed as having one or more of several roles in the management of the disorder.

Recall that both somatic therapies and psychotherapies to date have been predominantly oriented toward improving clinical outcome. Under this conceptualization psychotherapy has been thought directly to address symptoms, such as cognitive therapy for depressive symptoms. Less frequently has psychotherapy been developed with an explicit component geared toward addressing the functional deficits in manic–depressive disorder. However, functional outcome has often been measured in formal trials of various types of psychotherapy. A third conceptualization has been to use psychotherapy as a predominantly educative method to assist patients in participating more effectively in treatment. In this latter regard, treatment is geared toward improving “host factors”, that is, those factors not directly due to the disease but that have an impact on its course or treatment, through education, support and problem solving. Such host factors include illness management skills, which may be improved through psychoeducation and attention to building the therapeutic alliance. Basics of education are summarized in Table 47.7.

An evidence-based review similar to that for somatotherapy has recently been carried out for psychotherapeutic interventions. Bauer and McBride (2002) identified five main types of psychotherapy that have been studied in manic–depressive disorder: couples–partners, group interpersonal or psychoeducative, cognitive–behavioral, family, and interpersonal and social-rhythms. Couples–partners, cognitive–behavioral and family methods all have some Class A data supporting a role in improving clinical outcome or functional outcome or the intermediate outcome variable of improving illness management skills. An additional finding in this review is the degree of convergent validity across interventions regarding agenda for disease management information and skills to be imparted. Specifically, imparting education, focusing on early warning symptoms and triggers of episodes, and developing detailed and patient-specific action plans are found across most of the other interventions as well. For instance, this core agenda is also an important part of such diverse approaches as the cognitive–behavioral interventions of Palmer and Williams (1995) and Lam and coworkers (2000); the psychoeducational interventions of Bauer and coworkers (1998), Perry and coworkers (1999) and Weiss and coworkers (2000); the interpersonal and social rhythms therapy (IPSRT) intervention of Frank and coworkers (1999); and the family intervention of Miklowitz and coworkers (1999). Thus, given the positive results most of these interventions with explicit disease management components (i.e., patient education, collaborative management strategies with the patient, inclusion of as wide a social support system as is available) have produced, it is likely that this basic approach will be critical. It will perhaps be more critical even than the specific type of intervention in which these disease management components are embedded.

## Special Features Influencing Treatment

### Treatment of Comorbid Disorders

As noted earlier, several reversible “organic” factors may cause mood episodes, either *de novo* or in the course of already established manic–depressive disorder. For instance, removal of pro-manic drugs, both illicit and prescribed, is advisable in the treatment of substance-induced manic episodes. Treatment of

**Table 47.7 Basics of Education to Improve Disease Management Skill 1.**

1. Principles	
A.	Gear education to educational, cultural, motivational factors of individuals and their families.
B.	Include both knowledge about the disorder in general and exploration of the individual's specific form of illness and how it affects their own life.
C.	Pay close attention to opportunities for destigmatization and demystification.
D.	Emphasize the role of the person in treatment and his/her family as comanagers of the illness, including judging costs and benefits of specific treatment options according to the individual's priorities
2. Components of Psychoeducation	
A.	The disorder
a.	Biological basis

ii.	Avoidance/management of triggers for episodes
iii.	Activation of adaptive coping behaviors and avoidance of maladaptive responses

general medical conditions, such as hypothyroidism, that may complicate course or treatment is also important.

Several conceptual approaches, not always explicit, underlie the choice of approach to managing comorbid disorders. Psychiatrists may assume that the comorbid disorder is caused by manic–depressive disorder and consequently that treatment of the manic–depressive disorder will lead to resolution of the comorbidity. For instance, panic attacks might be considered a consequence of mood episodes, or alcohol use a means of self-medication of depressive symptoms or a function of increased appetitive drive due to mania. On the other hand, psychiatrists may assume that the mood instability of manic–depressive disorder is due to the comorbid illness. For instance, mood episodes may be thought to be due to alcohol or drug intoxication or withdrawal or to intrapsychic or psychophysiological effects of prior trauma. There are few data available to support either approach. Even the temporal sequence of onsets (e.g., manic–depressive disorder preceding substance abuse or vice versa) provides little information and in fact may be misleading in planning treatment.

The literature on alcohol dependence comorbidity, which is perhaps the most extensively studied of the comorbidities, provides no data with which to plan treatment strategy.

It stands to reason, however, that some type of **parallel** (simultaneous) treatment is preferable to **sequential** treatment (treating one disorder until resolution and then attending to the other), as the prognosis of manic–depressive disorder is worse when complicated by substance use and the course of alcoholism is worse when complicated by mood disorders. It is also likely that the highly confrontative approaches of some traditional substance dependence treatment programs will not likely serve the needs of often highly impaired depressed or manic persons.

### **Treatment of Manic–Depressive Disorder Across the Life-cycle**

Although the somatotherapeutic and psychotherapeutic mainstays of treatment endure across the life-cycle, several phases of life present particular challenges. There is mounting data on treatment of manic–depressive disorder in childhood. Treatments are

chosen by extension from the adult literature, with the one caveat that there have been rare cases of liver failure in conjunction with valproic acid use in children younger than 10 years of age who have been exposed to multiple anticonvulsants (Dreifuss, 1989).

In pregnancy, there is some early evidence that lithium may be teratogenic, associated with increased rates of cardiac abnormalities although more recent data indicate that this risk may be overestimated. Valproic acid and perhaps have been associated with neural tube defects leaving the neuroleptics, antidepressants and ECT as the preferable management strategies during pregnancy, particularly during the first trimester. It should be kept in mind, however, that treatment decisions are based on **risk**, not **certainty**. Risk of fetal malformation, parental attitude toward raising children with birth defects, severity of illness and ease of management with alternative therapies all need to be considered in conjunction with the woman and her partner.

Aging also presents certain treatment concerns. Tricyclic antidepressants may be associated with clinically significant cardiac conduction abnormalities, hypotension, sedation, glaucoma and urinary retention, particularly in the presence of prostatic hypertrophy. These are of even greater concern in the elderly. The risk of sedation due to neuroleptics and benzodiazepines and of hypotension due to low-potency neuroleptics can also particularly complicate treatment of elderly persons with manic–depressive disorder. Such side effects can cause far-reaching and serious complications, such as hip fracture which is not infrequently the initial event in a cascade of complications that can be terminal.

By contrast, lithium, carbamazepine and valproic acid are relatively well tolerated in the elderly once attention is given to the slower clearance of drugs in general in this population group. The risk of clinically significant renal toxicity with appropriately dosed lithium is not great. Although glomerular filtration rate decreases with age in persons treated with lithium, the rate of decline does not appear to be accelerated by lithium treatment. Nonetheless, careful monitoring of renal function is needed in the elderly. In addition, increasing age is clearly a risk factor for hypothyroidism as is lithium use. Thus, elderly persons taking lithium should be followed up carefully for decrements in thyroid function, although hypothyroidism is not an indication for lithium discontinuation but rather simply for thyroid hormone supplementation.

### Comparison of DSM-IV/ICD-10 Diagnostic Criteria

The ICD-10 item set for a manic episode contains nine items in contrast to the seven items in the DSM-IV-TR criteria set, the two additional items being marked sexual energy or indiscretions and loss of normal social inhibitions. However, the number of items required by ICD-10 Diagnostic Criteria for Research remains the same as the number in DSM-IV-TR (i.e., three items if mood is euphoric, four items if mood is irritable) which is likely to result in a more inclusive diagnosis of a manic episode in ICD-10. Furthermore, the duration of mixed episodes differ, with DSM-IV-TR requiring a duration of 1 week (as is the case for a manic episode), whereas the ICD-10 Diagnostic Criteria for Research require a duration of at least 2 weeks.

The criteria sets for hypomanic episode differ as well. The ICD-10 Diagnostic Criteria for Research contain several additional items (increased sexual energy and increased sociability) and does not include the DSM-IV-TR items inflated self-esteem and flight of ideas. Furthermore, ICD-10 does not require that the change in mood be observed by others.

Regarding the definition of bipolar I disorder, in addition to differences in the diagnostic criteria for a manic and major depressive episode, the ICD-10 definition of “Bipolar Affective Disorder” (i.e., any combination of hypomanic, manic, mixed and depressive episodes) does not distinguish between bipolar I and bipolar II disorder (i.e., cases of DSM-IV-TR Bipolar II Disorder are diagnosed as Bipolar Affective Disorder in ICD-10). However, ICD-10 Diagnostic Criteria for Research does include diagnostic criteria for bipolar II in its appendix that is identical to the criteria set in DSM-IV-TR.

For cyclothymic disorder, the ICD-10 Diagnostic Criteria for Research provides list of symptoms that must be associated with the periods of depressed mood and hypomania which differ from the ICD-10 item sets for dysthymic disorder and hypomania. In contrast, the DSM-IV-TR definition of cyclothymic disorder.

# Mood Disorders: Premenstrual Dysphoric Disorder

## Definition

Premenstrual syndrome (PMS) is a combination of emotional, behavioral and physical symptoms that occur in the premenstrual or luteal phase of the menstrual cycle. The term “premenstrual tension” appeared in the medical literature 70 years ago but widely accepted diagnostic criteria for PMS do not exist. Approximately 80% of women report at least mild premenstrual symptoms, 20 to 50% report moderate to severe premenstrual symptoms, and approximately 5% of women report severe symptoms for several days with impairment of role and social functioning. The 5% of women with the severest form of PMS generally have symptoms that meet the diagnostic criteria for premenstrual dysphoric disorder (PMDD).

The diagnostic criteria for PMDD are listed in the appendix of DSM-IV (American Psychiatric Association, 1994). A clinician can indicate that a woman has symptoms that meet the diagnostic criteria for PMDD by using the DSM-IV diagnosis 311, depressive disorder not otherwise specified. To meet the PMDD criteria, at least five out of 11 possible symptoms must be present in the premenstrual phase; these symptoms should be absent shortly following the onset of menses; and at least one of the five symptoms must be depressed mood, anxiety, lability, or irritability. The PMDD criteria require that role functioning be impaired as a result of the premenstrual symptoms. The functional impairment reported by women with PMDD is similar in severity to the impairment reported in major depressive disorder and dysthymic disorder (Pearlstein *et al.*, 2000). Unlike the functional impairment reported in depressive disorders, women with severe PMS and PMDD report more disruption in their relationships and parenting roles than in their work roles.

The PMDD criteria require that a woman prospectively rate her emotional, behavioral and physical symptoms over two menstrual cycles to confirm the diagnosis. Charting two menstrual cycles is advantageous, since some women have variability of symptom severity from cycle to cycle due to factors such as seasonal worsening, or a woman might have the unusual presence of follicular phase psychological symptoms due to a transient stressor. Recent studies tend to utilize visual analog scales, or Likert scale daily rating forms such as the Daily Record of Severity of Problems (Endicott and Harrison, 1990), with a scoring method that compares the average of symptom scores during the premenstrual days to the average of symptom scores postmenses.

A woman presenting with PMS should ideally bring to her clinician two cycles of an established daily rating form, or

alternatively ratings of her most problematic symptoms, rated with anchor points ranging from “not present” to “severe”. The clinician should review the daily ratings to confirm that the symptoms are in fact confined largely to the premenstrual phase, with the relative absence of symptoms in the follicular phase, and the clinician should also assess premenstrual functional impairment (Figure 48.1). Ratings that demonstrate follicular symptoms with increased symptom severity in the premenstrual phase suggest “premenstrual exacerbation” of an underlying disorder rather than PMDD. The DSM-IV-TR PMDD criteria state

## DSM-IV-TR Criteria

### Diagnostic Criteria for PMDD

#### Research Criteria for Premenstrual Dysphoric Disorder

- A. In most menstrual cycles during the past year, five (or more) of the following symptoms were present for most of the time during the last week of the luteal phase, began to remit within a few days after the onset of the follicular phase, and were absent in the week postmenses, with at least one of the symptoms being either (1), (2), (3), or (4):
- (1) markedly depressed mood, feelings of hopelessness, or self-deprecating thoughts
  - (2) marked anxiety, tension, feelings of being “keyed up,” or “on edge”
  - (3) marked affective lability (e.g., feeling suddenly sad or tearful or increased sensitivity to rejection)
  - (4) persistent and marked anger or irritability or increased interpersonal conflicts
  - (5) decreased interest in usual activities (e.g., work, school, friends, hobbies)
  - (6) subjective sense of difficulty in concentrating
  - (7) lethargy, easy fatigability, or marked lack of energy
  - (8) marked change in appetite, overeating, or specific food cravings
  - (9) hypersomnia or insomnia
  - (10) a subjective sense of being overwhelmed or out of control
  - (11) other physical symptoms, such as breast tenderness or swelling, headaches, joint or muscle pain, a sensation of “bloating,” weight gain

- B. The disturbance markedly interferes with work or school or with usual social activities and relationships (e.g., avoidance of social activities, decreased productivity and efficiency at work or school).
- C. The disturbance is not merely an exacerbation of the symptoms of another disorder such as major depressive disorder, panic disorder, dysthymic disorder, or a personality disorder (although it may be superimposed on any of these disorders).
- D. Criteria A, B, and C must be confirmed by prospective daily ratings during at least two consecutive symptomatic cycles. (The diagnosis may be made provisionally prior to this confirmation).

that the premenstrual symptoms should not be an exacerbation of an underlying disorder, but that PMDD could be superimposed on another disorder, like panic disorder. No formal guidelines exist for how to apply this criterion clinically.

### Differential Diagnosis

Depression and anxiety disorders are the most common Axis I psychiatric disorders that may be concurrent and exacerbated

premenstrually, with less clear evidence for bipolar disorder, eating disorders and substance abuse. Since most PMDD symptoms are affective or anxiety-related, “pure PMS” or PMDD is generally not diagnosed when an underlying depression or anxiety disorder is present; these women would be considered to have premenstrual exacerbation of their underlying depression or anxiety disorder. Personality disorders are not elevated in prevalence in women with PMDD, but women with PMDD and a personality disorder may demonstrate premenstrual phase amplification of personality dysfunction. Schizophrenia may be an example of a disorder that does not have premenstrual exacerbation of psychotic symptoms but may have the superimposition of affective and anxiety symptoms of PMDD. The prevalence of premenstrually exacerbated disorders is unknown, but women with these conditions present frequently to their primary care clinician or gynecologist. Since most recent treatment studies have been conducted on women with PMS and PMDD without follicular symptomatology, this literature is not particularly informative on how to treat women with premenstrually exacerbated disorders. The general guideline is to treat the underlying disorder first and see if subsequent daily ratings suggest persistence of premenstrual symptoms that might meet criteria for PMDD.

Several medical conditions should also be considered when evaluating a woman with premenstrual complaints. Symptoms of endometriosis, polycystic ovary disease, thyroid disorders, disorders of the adrenal system, hyperprolactinemia and panhypopituitarism may mimic symptoms of PMS. Several medical disorders may demonstrate a premenstrual increase in

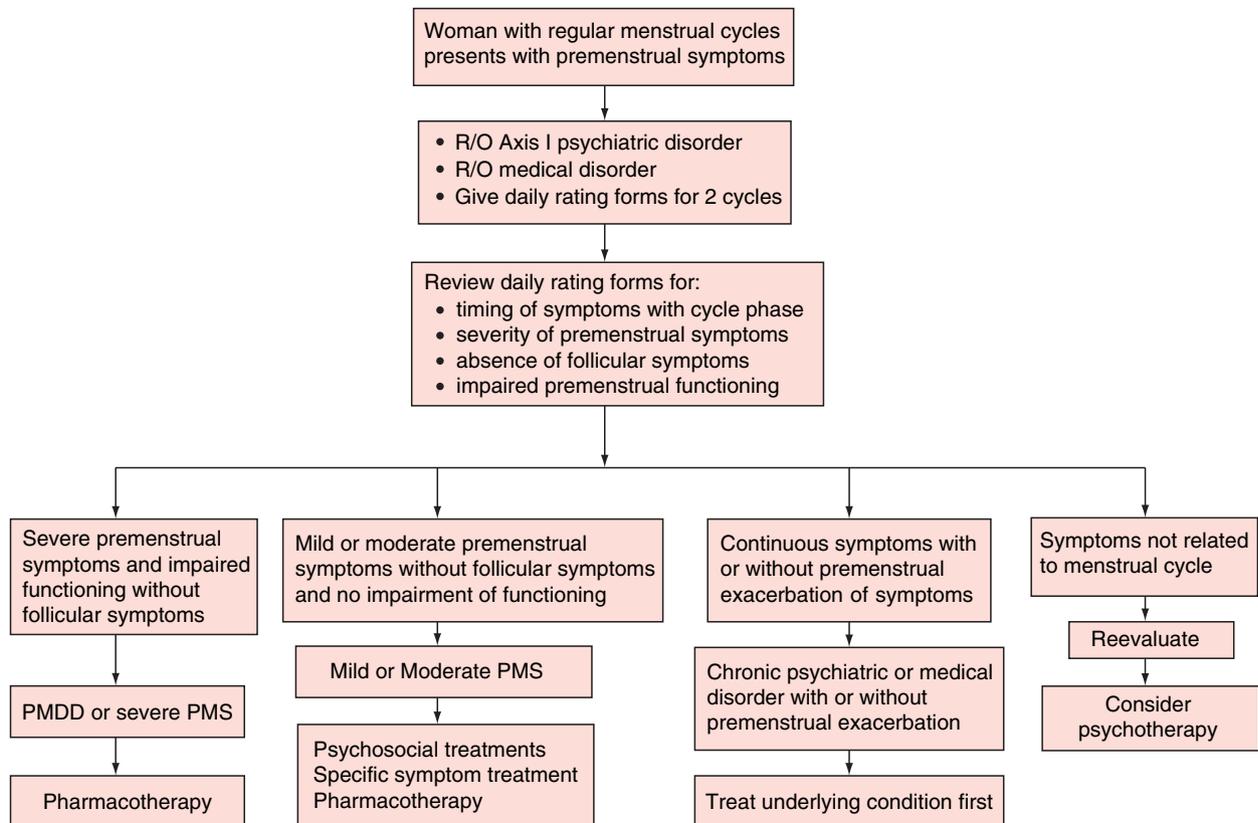

Figure 48.1 Diagnosis and initial treatment algorithm of premenstrual symptoms.

symptoms without accompanying emotional symptoms, such as migraines, asthma, epilepsy, irritable bowel syndrome, diabetes, allergies and autoimmune disorders. It is presumed that the menstrual cycle fluctuations of gonadal hormones influence some of the symptoms of these medical conditions.

## Epidemiology

Irritability has been identified as the most common premenstrual symptom in USA and European samples. Studies examining age, menstrual cycle characteristics, cognitive attributions, socioeconomic variables, lifestyle variables and number of children have not yielded consistent conclusions. Studies have suggested some genetic liability for PMS, but the overlap with genetic liability for major depression or personality characteristics has received mixed. A polymorphism in the serotonin transporter promoter gene has been suggested in women who have both PMDD and seasonal affective disorder (Praschak-Rieder *et al.*, 2002). Elevated lifetime prevalence of major depressive disorder in women with PMDD has been reported in several studies as well as an elevated lifetime prevalence of postpartum. Even though premenstrual symptoms are described in women from menarche to menopause, it is unclear if symptoms remain stable or increase in severity with age. PMS has been described in several countries and cultures and some have a preponderance of somatic rather than emotional symptoms.

## Etiology

Since abnormalities in the hypothalamic-pituitary-gonadal axis (HPG) have not been identified, it is thought that premenstrual symptoms may occur due to a differential sensitivity to mood-perturbing effects of gonadal steroid fluctuations in women with PMS and PMDD. It is probable that the etiology of the “differential sensitivity” is multifactorial. The specific neurotransmitter, neuroendocrine and neurosteroid abnormalities in women with PMS and PMDD are not known, but serotonin, norepinephrine, gamma-aminobutyric acid (GABA), allopregnanolone (an anxiolytic metabolite of progesterone that acts at the GABA<sub>A</sub> receptor) and factors involved in calcium homeostasis are all possibly involved.

A large number of studies have reported abnormalities in the serotonin system in women with PMS and PMDD. Several studies have also suggested that women with PMDD have decreased luteal phase levels of GABA, abnormal allopregnanolone levels, and decreased sensitivity of the GABA<sub>A</sub> receptor as shown by flumazenil challenge, and the sedative and saccadic eye velocity responses to benzodiazepines. It is possible that the rapid efficacy of selective serotonin reuptake inhibitors (SSRIs) in PMDD may be due in part to their ability to increase allopregnanolone levels in the brain, thus enhancing GABA transmission as well as serotonin transmission.

Several factors that influence calcium and bone homeostasis fluctuate with the menstrual cycle and it is possible that some of these factors are abnormal in women with PMS and PMDD. Thys-Jacobs and colleagues (1995) reported that women with PMS had reduced periovulatory calcium levels and elevated parathyroid hormone levels compared with controls, perhaps secondary to elevated preovulatory estrogen levels, and these authors proposed that women with PMS may have a cyclical, transient secondary hyperparathyroidism. It has been reported that when calcium homeostasis is corrected in

primary hyperparathyroidism, cerebrospinal fluid monoamine metabolites normalize and affective symptoms are reduced. It is possible that the administration of supplemental calcium normalizes the peri-ovulatory fluctuations in calcium and parathyroid hormone, thus regulating calcium effects on neurotransmitter synthesis and release leading to symptom relief in women with PMS.

## Treatment

### Antidepressant Treatment

The treatment studies of SSRIs and venlafaxine in PMDD have suggested a similar efficacy rate to treatment studies of SSRIs in major depressive disorder, with 60 to 70% of women responding to SSRIs compared with approximately 30% of women responding to placebo. In general, the effective doses for all SSRIs are similar to the doses recommended for the treatment of major depressive disorder (Figure 48.2) The efficacy of the continuous versus intermittent dosing is equivalent.

A large RCT has reported that fluoxetine 20 mg/day during the luteal phase only was superior to placebo in reducing premenstrual emotional and physical symptoms in 252 women with PMDD (Cohen *et al.*, 2002). There have not been reports of discontinuation symptoms from these doses of SSRIs when abruptly stopped from the first day of menses. There are no published studies to date of the efficacy of “symptom onset” dosing of SSRIs, that is, administering SSRIs the postovulatory day that premenstrual symptoms appear until menses. The efficacy of intermittent dosing, as well as the findings from most SSRI trials that efficacy is achieved by the first treatment cycle, has suggested a more rapid and different mechanism of action of SSRIs in PMDD compared with its effect in major depressive disorder, which typically takes 2 to 6 weeks. As discussed above, it has been hypothesized that the rapid improvement of premenstrual symptoms by SSRIs may be due to an increase in allopregnanolone levels. The selective superiority of serotonergic antidepressants for PMDD is compatible with the postulated serotonin dysfunction in PMDD.

Most SSRI trials have been 6 months or less in duration, so efficacy-based long-term treatment recommendations do not exist. Clinically, many women note the recurrence of premenstrual symptoms after SSRI discontinuation and many clinicians treat women over a long period of time. As reviewed, a few open studies report maintenance of SSRI efficacy over a couple of years (Yonkers, 1997). Studies are needed to identify whether or not some women develop tolerance to the SSRI and need a higher dose over time and whether or not some women stay in remission for a period of time following SSRI discontinuation.

### Ovulation Suppression Treatments

Gonadotropin releasing hormone (GnRH) agonists suppress ovulation by downregulating GnRH receptors in the hypothalamus, leading to decreased follicle-stimulating hormone and luteinizing hormone release from the pituitary, resulting in decreased estrogen and progesterone levels. GnRH agonists are administered parenterally (e.g., subcutaneous monthly injections of goserelin, intramuscular monthly injections of leuprolide, daily intranasal buserelin) (see Figure 48.2). GnRH agonists lead to improvement in most emotional and physical premenstrual symptoms, with possible decreased efficacy for premenstrual dysphoria and severe premenstrual symptoms

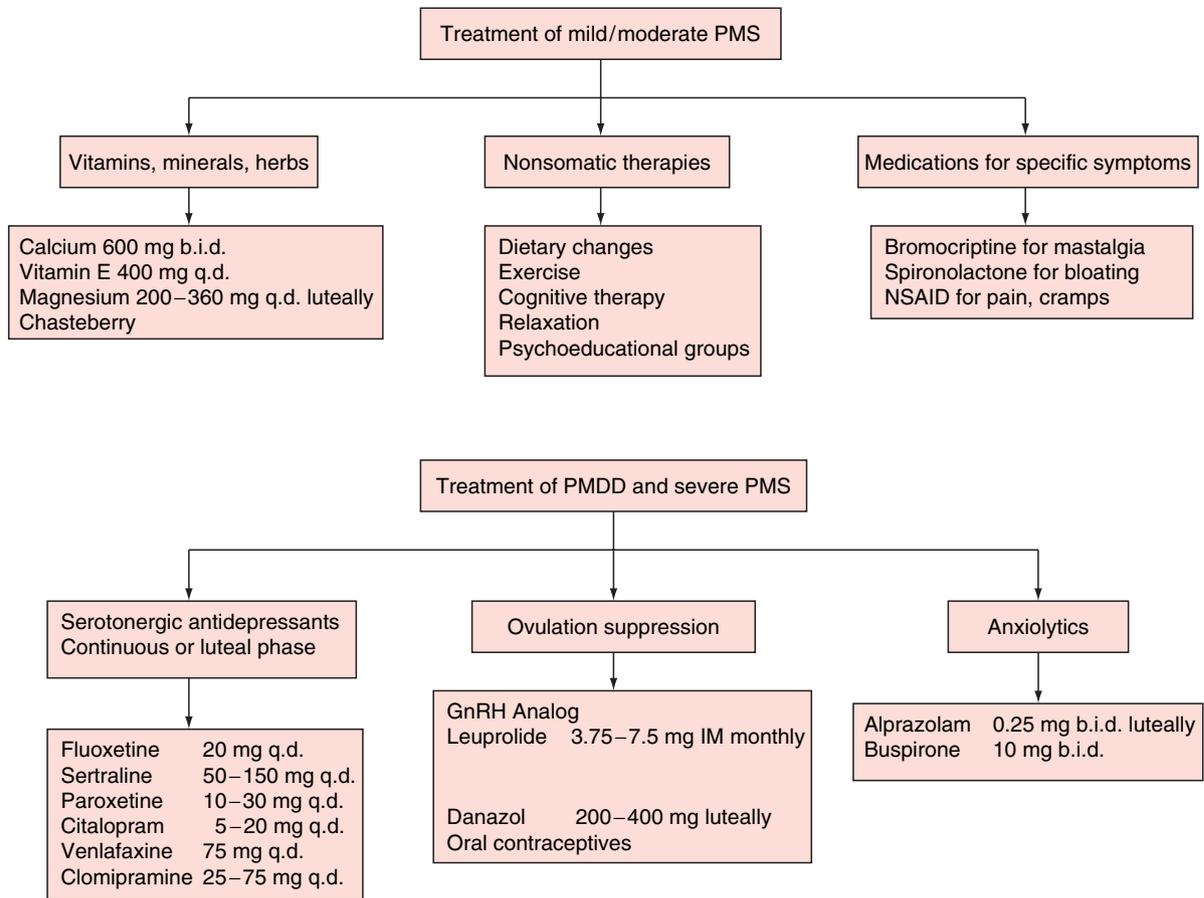

Figure 48.2 Treatment algorithm of premenstrual symptoms.

or for the exacerbation of chronic depression. After relief of PMS is achieved with a GnRH agonist, “add-back” hormone strategies have been investigated due to the undesirable medical consequences of the hypoestrogenic state resulting from prolonged anovulation. The addition of estrogen and progesterone to goserelin and leuprolide led to the reappearance of mood and anxiety symptoms. Since women with severe PMS and PMDD have an abnormal response to normal hormonal fluctuations, it is not surprising that women had the induction of mood and anxiety symptoms from the addition of gonadal steroids, reducing the benefit of the replacement strategy.

### Oral Contraceptives

Even though oral contraceptives (OCs) are a commonly prescribed treatment for PMS, there is minimal literature endorsing its efficacy. Anecdotally, women report that oral contraceptives may benefit, worsen, or not affect their premenstrual symptoms. The induction of dysphoria may be related to the type and dose of the progestin component, the androgenic properties of the progesterone, or to the estrogen/progestin ratio (Kahn and Halbreich, 2001). A more recent RCT compared an oral contraceptive to placebo in 82 women with PMDD (Freeman *et al.*, 2001). Even though the OC containing ethinyl estradiol 30 µg and drospirenone 3 mg improved most premenstrual symptoms, due in large part to a placebo response rate of 40%, the OC was significantly more efficacious than placebo only in decreasing food cravings, increased appetite and acne. Oral contraceptives have been reported not to alter the response to SSRIs in women with PMDD.

### Progesterone

The early assumption that PMS was due to a progesterone deficiency, which has never been substantiated, led to luteal phase progesterone being one of the earliest treatments of PMS in the literature. A recent systematic review of published double-blind placebo-controlled randomized studies of luteal phase progesterone (given as vaginal suppositories or oral micronized tablets) and progestogens reported that there was no clinically meaningful difference between all progesterone forms and placebo, although there was a small statistically significant superiority of progesterone over placebo (Wyatt *et al.*, 2001).

### Other Medications

Alprazolam (administered during the luteal phase) has been reported to be superior to placebo in most studies, and although it has a lower efficacy rate than SSRIs, it is effective for premenstrual emotional symptoms. Alprazolam should be tapered over the first few days of menses each cycle. Buspirone at 25 mg/day during the luteal weeks has some efficacy. Spironolactone has been reported to decrease premenstrual emotional and physical symptoms. Bromocriptine has been reported to decrease premenstrual breast.

### Herbal Treatments and Dietary Supplementation

Most RCTs have shown little efficacy from herbal treatments and therefore at this time no herbal treatment can be recommended. With respect to dietary supplementation, calcium is reported to

have a nearly 50% efficacy rate for reducing the emotional and physical symptoms of the PMDD diagnostic criteria, except for fatigue and insomnia, compared with 30% for placebo. However, women with concurrent psychiatric illness were not clearly excluded, and other treatments except for analgesics were allowed. The efficacy of calcium was somewhat less in women who were also taking oral contraceptives (Thys-Jacobs *et al.*, 1998). The results of this study were notable, and calcium deserves further study. Like herbal preparation, there is a paucity of data to support the efficacy of vitamin supplementation.

### Lifestyle Modifications and Psychosocial Treatments

Many lifestyle modifications and psychosocial treatments have been suggested for PMS. Lifestyle modifications are often suggested through self-help materials or in an individual or group psychoeducation format. A recent study reported that a weekly peer support and professional guidance group for four sessions was superior to waitlist control in terms of reducing premenstrual symptoms. The treatment consisted of diet and exercise regimens, self-monitoring and other cognitive techniques and environment modification (Taylor, 1999). Studies have not been conducted on individual lifestyle or psychosocial treatments to identify which components are most efficacious.

Dietary recommendations include decreased caffeine, frequent snacks or meals, reduction of refined sugar and artificial sweeteners, and increase in complex carbohydrates. Premenstrual increased appetite and carbohydrate craving increases the availability of tryptophan in the brain, leading to increased serotonin synthesis. There is little data at this time supporting dietary interventions.

Exercise is likewise a frequently recommended treatment for PMS that has yet to be tested in a sample of women with prospectively-confirmed PMS or PMDD. As reviewed, negative effect and other premenstrual symptoms improve with regular exercise in women in general. Cognitive therapy (CT) is reported to be a promising treatment for PMS. There are limited studies in the use of light therapy, massage therapy, reflexology, chiropractic manipulation, acupuncture and biofeedback.

### Conclusion

Women with severe PMS and PMDD comprise a substantial proportion of menstruating women. These women have several symptomatic days each month that lead to disrupted relationships and decreased quality of life. Women presenting with premenstrual complaints need prospectively to rate their symptoms for two menstrual cycles to rule out the presence of a concurrent psychiatric or medical disorder. Once the diagnosis of severe PMS or PMDD is confirmed, SSRI medication is considered the first line treatment. SSRI medication may be administered daily or intermittently (from ovulation to menses) to be effective. Nutritional approaches, exercise and cognitive therapy may be appropriate as first treatments in mild cases, otherwise they should accompany medication treatment. Second line treatment options include changing to a second SSRI, gonadal

hormone therapy (such as GnRH analogs or oral contraceptives), or adding adjunctive anxiolytics, calcium, or other medications targeted to specific symptoms (American College of Obstetrics and Gynecology, 2000; Altshuler *et al.*, 2001). Future studies are still needed for women with severe PMS and PMDD, such as to identify predictors for which women may benefit from hormonal strategies, to determine the optimal duration for medication treatment, and to determine whether or not some women may maintain remission following successful medication treatment.

### Comparison of DSM-IV/ICD-10 Diagnostic Criteria

Premenstrual Dysphoric Disorder is not included in ICD-10. A related condition “premenstrual tension syndrome” is included in Chapter 14 for diseases of the genitourinary system.

# Anxiety Disorders: Panic Disorder With and Without Agoraphobia

## Definitions and Diagnostic Criteria

According to the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR) (American Psychiatric Association, 2000), panic disorder is defined by recurrent and unexpected panic attacks. At least one of these attacks must be followed by one month or more of:

1. persistent concern about having more attacks;
2. worry about the implications or consequences of the attack; or
3. changes to typical behavioral patterns (e.g., avoidance of work or school activities) as a result of the attack.

In addition, the panic attacks must not stem solely from the direct effects of illicit substance use, medication, or a general medical condition (e.g., hyperthyroidism, vestibular dysfunction) and are not better explained by another mental disorder (e.g., such as social phobia for attacks that occur only in social situations). A diagnosis of panic disorder with agoraphobia is warranted when the criteria for panic disorder are satisfied and accompanied by agoraphobia.

Although panic attacks are a cardinal feature of panic disorder and in combination with agoraphobia (i.e., anxiety about being in a place or a situation that is not easily escaped or where help is not easily accessible if panic occurs) are essential to a diagnosis of panic disorder with agoraphobia, the criteria sets for panic attacks and for agoraphobia are listed separately as standalone noncodable conditions that are referred to by the diagnostic criteria for panic disorder and agoraphobia without history of panic disorder. Notwithstanding, accurate diagnosis is difficult without a proficient understanding of these features. Tables 49.1 and 49.2 show the DSM-IV-TR criteria for panic attack and agoraphobia, respectively. While the criteria for agoraphobia are generally straightforward, panic attacks can be difficult to understand.

A number of investigations indicate that people report having what they consider to be a panic attack during or in association with actual physical threat (i.e., a true alarm situation). It is, however, important to distinguish between a fear reaction in response to actual threat and a panic attack. In an attempt to do so, the DSM-IV-TR has clarified that panic attacks occur “in the absence of real danger”. Such attacks involve a paroxysmal occurrence of intense fear or discomfort accompanied by a minimum of four of the 13 symptoms shown in Table 49.1. The DSM-IV-TR recognizes three characteristic types of panic attacks, including those that are **unexpected** (i.e., not associated with an identifiable internal or external trigger and appear to occur “out of the blue”), **situationally bound**

**Table 49.1** Definition and Criteria for Panic Attack

A panic attack is a discrete period of intense fear or discomfort in the absence of real danger that develops abruptly, reaches a peak within 10 min, and is accompanied by four (or more) of the following symptoms:

- (1) palpitations, pounding heart, or accelerated heart rate
- (2) sweating
- (3) trembling or shaking
- (4) sensations of shortness of breath or smothering
- (5) feeling of choking
- (6) chest pain or discomfort
- (7) nausea or abdominal distress
- (8) feeling dizzy, unsteady, light-headed, or faint
- (9) derealization (feelings of unreality) or depersonalization (being detached from oneself)
- (10) fear of losing control or going crazy
- (11) fear of dying
- (12) paresthesias (numbness or tingling sensations)
- (13) chills or hot flushes

(i.e., almost invariably occur when exposed to a situational trigger or when anticipating it) and **situationally predisposed** (i.e., usually, but not necessarily, occur when exposed to a situational trigger or when anticipating it). The term **limited symptom attacks** is used to refer to panic-like episodes comprising fewer than four symptoms.

Although unexpected panic attacks are required for a diagnosis of panic disorder, not all panic attacks that occur in panic disorder are unexpected. The occurrence of unexpected attacks can wax and wane and over the developmental course of the disorder they tend to become situationally bound or predisposed. Moreover, unexpected panic attacks as well as those that are situationally bound or predisposed can occur in the context of other psychiatric disorders, including all of the other anxiety disorders, e.g., a person with social phobia might have an occasional unexpected panic attack without the other feature required to diagnose panic disorder; a dog phobic might panic whenever a large dog is encountered) and some general medical conditions. A clear understanding of the

**Table 49.2** Criteria for Agoraphobia

- A. Agoraphobia is characterized by anxiety about being in places or situations from which escape might be difficult (or embarrassing) or in which help may not be available in the event of having an unexpected or situationally predisposed panic attack or panic-like symptoms. Agoraphobic fears typically involve characteristic clusters of situations, such as being outside the home alone, being in a crowd, standing in a line, being on a bridge, or traveling in a motor vehicle.
- B. The situations are avoided or are endured with marked distress or worry about having a panic attack or panic-like symptoms. Confronting situations is aided by the presence of a companion.
- C. The anxiety or avoidance is not better accounted for by another mental disorder.

Adapted from American Psychiatric Association (2000) *Diagnostic and Statistical Manual of Mental Disorders*, 4th edn., Text Rev. American Psychiatric Association, Washington DC.

distinction between types of panic attacks outlined in the DSM-IV-TR provides a foundation for diagnosis and differential diagnosis. However, consideration of other characteristics of panic – including duration of attacks, frequency of attacks, number and intensity of symptoms, nature of catastrophic thinking and mechanism responsible for termination of an attack – can be important in identifying exacerbating and controlling factors.

### Historical Overview

Descriptions of cases resembling agoraphobia date back thousands of years, appearing in the writings of Hippocrates and others. The term **agoraphobia** was, however, coined less than 150 years ago to describe patients who seemingly experienced unexpected and situational panic attacks accompanied by anticipatory anxiety and functional incapacitation when walking the streets of their neighborhoods. Freud (1894/1949), whose description of anxiety attacks holds many similarities (but also some notable differences) to contemporary descriptions of panic disorder, was the first to explicate this association. In describing agoraphobia, he specifically mentioned the role of panic, anticipatory anxiety and escape concerns as central to the condition.

The origin of the panic disorder construct as a separate diagnostic entity was influenced by the work of a number of researchers but none so much as Donald Klein in the late 1950s and early 1960s. Klein observed that contrary to expectation a subgroup of patients with anxiety neurosis did not improve on chlorpromazine and in some cases became worse. When he gave this subgroup imipramine, a new compound derived from modifications to chlorpromazine, marked improvements were observed. Prior to taking imipramine these patients unlike those who were responsive to chlorpromazine had been experiencing rapid rushes of terror, racing hearts and other physical sensations, which prompted them to rush to the nurses station with reports that they were about to die. On the basis of this differential drug response, Klein concluded that imipramine was effective against these seemingly spontaneous episodes of panic and, importantly, that these attacks were distinct from other forms of anxiety. He also suggested that agoraphobia was a consequence of spontaneous panic attacks.

### Prevalence and Course

The one-year prevalence for any panic attack, whether unexpected or situationally cued, is approximately 28%. Lifetime prevalence rates for unexpected panic attacks and agoraphobia are approximately 4 and 9%, respectively. The National Comorbidity Survey Replication (NCS-R) found lifetime prevalence rates of 4.7% for panic disorder and 1.4% for agoraphobia without panic (Kessler *et al.*, 2005). Investigations of unexpected panic attacks in college student samples using self-report methodology have revealed similar rates, ranging from approximately 5 to 11%.

The National Comorbidity Study (Eaton *et al.*, 1994) has reported the lifetime prevalence of panic disorder (with or without agoraphobia) in the general population to be 3.5%. However, despite uncertainty as to the reason, this rate is somewhat of an anomaly in the literature. Most epidemiological studies, including those based on Epidemiologic Catchment Area and other data sources, have consistently shown lifetime rates between 1 and 2%. The National Comorbidity Survey Replication (NCS-R) found lifetime prevalence rates of 4.7% for panic disorder and 1.4% for agoraphobia without panic (Kessler *et al.*, 2005). In

### DSM-IV-TR Criteria

#### Summary of DSM-IV-TR diagnostic criteria for 300.01 Panic Disorder Without Agoraphobia and 300.21 Panic Disorder With Agoraphobia

- A. Both (1) and (2):
- (1) recurrent unexpected panic attacks
  - (2) at least one of the attacks has been followed by one month (or more) of one (or more) of the following:
    - (a) persistent concern about having additional attacks
    - (b) worry about the implications of the attack or its consequences (e.g., losing control, having a heart attack, “going crazy”)
    - (c) a significant change in behavior related to the attacks
- B. This criterion differs for Panic Disorder With and Without Agoraphobia as follows:
- For 300.21 Panic Disorder With Agoraphobia: the presence of Agoraphobia**
- For 300.01 Panic Disorder Without Agoraphobia: absence of Agoraphobia**
- C. The panic attacks are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hyperthyroidism).
- D. The panic attacks are not better accounted for by another mental disorder, such as social phobia (e.g., occurring on exposure to feared social situations), specific phobia (e.g., on exposure to a specific phobic situation), obsessive–compulsive disorder (e.g., on exposure to dirt in someone with an obsession about contamination), posttraumatic stress disorder (e.g., in response to stimuli associated with a severe stressor), or separation anxiety disorder (e.g., in response to being away from home or close relatives).

treatment seeking individuals, the prevalence of panic disorder is considerably higher. Approximately 10% of patients in mental health clinics and between 10 and 60% in various medical specialty clinics (e.g., cardiology, respiratory, vestibular) have panic disorder. Panic disorder with agoraphobia is more common than panic disorder without agoraphobia in clinical samples.

Age of onset for panic disorder is distributed bimodally, typically developing between 15 and 19 or 25 and 30 years. The clinical features of panic disorder such as number and severity of symptoms are much the same across the sexes. However, women are diagnosed with panic disorder more than twice as often as men. Recent research indicates that women are more likely to have panic disorder with agoraphobia and that they are more likely to have recurrence of symptoms after remission of their panic attacks than are men (Yonkers *et al.*, 1998). Men, on the other hand, are more likely to have panic disorder without agoraphobia (Yonkers *et al.*, 1998) and are more likely to self-medicate with alcohol than are women. The literature remains unclear as to why these sex differences exist but alludes to the possible role of biological and/or socialization factors.

Panic disorder symptoms may wax and wane but, if left untreated, the typical course is chronic. Data from a sample of patients assessed and treated through the Harvard/Brown Anxiety Disorders Research Program and followed prospectively over a 5-year period indicated remission rates in both men and women to be 39% (Yonkers *et al.*, 1998). In general among those receiving tertiary treatment, approximately 30% of patients have symptoms that are in remission, 40 to 50% are improved but still have significant symptoms, and 20 to 30% are unimproved or worse at 6 to 10 years follow-up.

### Costs of Panic Disorder

Panic disorder with or without agoraphobia is associated with impaired occupational and social functioning and poor overall quality of life. People with panic disorder, compared with people in the general population, report poorer physical health. Panic disorder is a leading reason for seeking emergency department consultations and a leading cause for seeking mental health services, surpassing both schizophrenia and mood disorders. Panic disorder exceeds the economic costs associated with many other anxiety disorders such as social phobia, generalized anxiety disorder and obsessive-compulsive disorder. The high medical costs are partly because panic disorder patients quite often present to their primary care physician or hospital emergency departments, thinking they are in imminent danger of dying or “going crazy.” In these settings, patients may undergo a series of extensive medical tests before panic disorder is, if ever, finally diagnosed. Ruling out general medical conditions is good clinical practice but the process contributes substantially to the costs that panic disorder places on health care systems.

### Comorbidity

Lifetime comorbidity (i.e., the cooccurrence of two or more disorders at any point in a person’s life, regardless of whether or not they overlap) in panic disorder is common, with over 90% of community-dwelling and treatment seeking patients having had symptoms meeting diagnostic threshold for at least one other disorder (Robins *et al.*, 1991). Comorbidity can pose considerable challenge to treatment. The most common comorbid diagnoses with panic disorder are other anxiety disorders, major

depression, somatoform, pain-related, substance use and personality disorders.

### Other Anxiety Disorders

The rates of lifetime comorbidity between panic disorder and other anxiety disorders, although variable across epidemiological studies, are high. The most common comorbid anxiety disorders are social phobia and generalized anxiety disorder (15–30%) followed by specific phobia (2–20%), obsessive compulsive disorder (10%), and post traumatic stress disorder (2–10%) (American Psychiatric Association, 2000). To date, there are no studies that have reported comorbid panic disorder and acute stress disorder. The most parsimonious explanation of high comorbidity between panic disorder and the other anxiety disorders is that they share a common diathesis.

### Major Depressive Disorder

Epidemiological studies indicate that major depressive disorder occurs in up to 65% of patients with panic disorder at some point in their lives. In approximately two-thirds of these cases, the symptoms of depression develop along with, or secondary to, panic disorder. However, since depression precedes panic disorder in the remaining third, depressive symptoms cooccurring with panic disorder cannot be considered simply as a demoralized response to paroxysms of anxiety. While the risk of developing secondary depression appears to be more closely associated with the severity of agoraphobia than with the severity or frequency of panic attacks, this may be a confound of misdiagnosing some behavioral manifestations of depression as agoraphobia. Panic disorder and depression do not appear to be identical disorders and their co-occurrence may be due to a shared diathesis or mutual exacerbation of symptoms.

### Somatoform and Pain-related Disorders

Somatoform and pain-related disorders are frequently comorbid with panic disorder. For example, hypochondriasis has been diagnosed in approximately 20% of panic disorder patients attending general medical clinics and in almost 50% of those attending anxiety disorders clinics. Acute and chronic musculoskeletal pain (i.e., pain that persists for six months or longer), respectively, are reported by approximately 85 and 40% of panic disorder patients attending anxiety disorders clinics. Irritable bowel syndrome, a condition characterized persistent abdominal pain and defecation difficulties, cooccurs in 17 to 41% of treatment seeking panic disorder patients. Emerging evidence suggests that comorbidity between panic disorder and both somatoform and pain-related disorders may be best explained by a shared diathesis model.

### Substance Use Disorders

Panic disorder can be precipitated by the use of psychotropic drugs and risk is higher with chronic use. Alcohol has been identified as playing a precipitating, maintaining and aggravating role in panic disorder. The 6-month prevalence of alcohol abuse or dependence in panic disorder has been reported to be 40% in men and 13% in women. These rates are higher than those observed in people with other anxiety disorders and those with no anxiety disorder. Although alcohol problems have been reported to precede panic disorder in a majority of cases, most reports indicate that alcohol problems develop secondary to panic disorder, often as a means of self-medication. Those having panic disorder with

agoraphobia appear to be at greater risk for comorbid alcohol abuse or dependence than those without agoraphobia.

## Personality Disorders

Lack of reliable assessment instruments for personality disorders as well as overlapping diagnostic criteria necessarily limit the degree of confidence in reports of comorbidity with panic disorder. Notwithstanding, 40 to 50% of panic disorder patients have been reported to qualify for one or more personality disorders, a rate which exceeds that of 13% observed in community control samples. The most commonly reported cooccurring personality disorders are avoidant, dependant, and histrionic personality disorders. These disorders do not cooccur uniquely with panic, also being common in patients with depression and other anxiety disorders, and they often persist despite remission of panic symptoms.

## Etiology

### Cognitive Models – The Vicious Cycle

There are several contemporary cognitive models of panic disorder which, for the most part, are based on variations of the “fear of anxiety” construct. Goldstein and Chambless (1978) proposed that fear of anxiety arises through the association of interoceptive cues with panic attacks. In other words, people with panic disorder are thought to learn to fear the recurrence of aversive panic episodes and thereby develop a fear of panic-related symptoms. Refuting the premise that fear of anxiety develops from the experience of panic attacks, Clark (1986) posited that panic attacks are the product of a tendency **catastrophically misinterpret** to autonomic arousal sensations that occur in the context of nonpathological anxiety (as well as physical illness, exercise and ingestion of certain substances). Reiss and colleagues (Reiss, 1999; Reiss and McNally, 1985), incorporating components of the Goldstein and Chambless and Clark models, proposed that panic attacks arise as a consequence of both:

1. a predispositional tendency to catastrophically misinterpret and respond with fear to the benign arousal sensations, and
2. a learned fear of anxiety that is maintained by the experience of panic episodes.

Most recently, Bouton, Mineka and Barlow (2001) have described a variant of the original fear of anxiety model, suggesting that panic disorder develops when exposure to panic attacks conditions a person to respond with anticipatory anxiety (and sometimes with panic) to internal arousal and contextual cues.

The vicious cycle model makes several assumptions. First, while recognizing that initial panic attacks may be caused by other factors (e.g., drug-related autonomic surges), it assumes that people prone to panic disorder have an enduring tendency catastrophically to misinterpret benign arousal sensations. Secondly, it assumes that misinterpretations can occur at the conscious and unconscious level. Thirdly, the cycle can be entered into at any point. For example, the cycle can be initiated by a contextual trigger or simply by having catastrophic thoughts about bodily sensations. Fourthly, physiological changes are viewed as one of several components in a process, rather than as a pathogenic mechanism.

Cognitive models can also account for agoraphobia. Agoraphobia has long been regarded as a product of operant

conditioning. As noted above, it most often develops as a consequence of panic attacks. These attacks typically occur in particular situations (e.g., when in line at a shopping mall, when driving) and motivate the person to avoid or escape these situations. The avoidance and escape behaviors are negatively reinforced by the reduction of aversive autonomic arousal and other anxiety-related sensations. Cognitive factors such as expectations that an attack will be imminent and harmful and that coping will be ineffective play a significant role by influencing and maintaining avoidance behavior.

A growing body of literature supports the vicious cycle model. Thoughts of imminent catastrophe have been identified as triggers of panic attacks. Patients with panic disorder relative to healthy and patient controls have been shown to be:

1. characterized by strategic and automatic information processing (i.e., memory, attention) biases for physical threat cues;
2. more accurate, in some instances, at detecting body sensations;
3. more likely to report fear of somatic sensations and beliefs in their harmful consequences; and
4. more susceptible to the influence of instructional manipulations of control in response to pharmacological panic provocation challenges, panicking less often under the illusion of greater control in some (but not all cases).

Research shows that treatments stemming from the cognitive model (reviewed later in this chapter) are effective.

### Biological Models

Evidence suggests that several neurotransmitter systems, involving neurotransmitters or neuromodulators such as serotonin, noradrenalin, adenosine, gamma-aminobutyric acid and cholecystokinin-4, play a role in panic disorder. Various brain structures in the limbic system and associated regions have also been implicated. Contemporary biological models of panic have grown in number and complexity in recent years in an effort to integrate and explain these findings. Recent emphasis has focused on the amygdala, a limbic structure that appears to be involved in coordinating the different neurotransmitters involved in anxiety disorders (Goddard and Charney, 1997). Today, there is no single, leading biological model of panic. However, there are a number of useful models that guide research and clinical practice. Among the most promising is the neuroanatomical hypothesis recently revised by Gorman and colleagues (2000). This hypothesis is useful for several reasons. First, it integrates a wide range of findings, including animal research and studies of humans. Secondly, it provides a unifying framework for understanding why panic disorder is associated with so many biological dysregularities such as abnormalities in neurotransmitter systems and irregularities on various indices of autonomic functioning. Thirdly, the model accounts for treatment-outcome data, which show that both pharmacological and psychological therapies are effective treatments for panic disorder (as reviewed later in this chapter).

### Neuroanatomical Hypothesis

Gorman and colleagues (2000) begin with the observation that there is a remarkable similarity between the physiological and behavioral consequences of panic attacks in humans and conditioned fear responses in animals. Similarities include autonomic

arousal, fear evoked by specific cues (i.e., contextual fear) and avoidance of these cues. Animal research indicates that conditioned fear responses are mediated by a “fear network” in the brain, consisting of the amygdala and its afferent and efferent projections, particularly its connections with the hippocampus, medial prefrontal cortex, hypothalamus and brainstem. Animal studies also show that activation of this network produces biological and behavioral reactions that are similar to those associated with panic attacks. Thus, Gorman and colleagues (2000) posit that a similar network is involved in panic disorder.

The fear network consists of a complex matrix of interconnections, implicating a number of brain structures and neurotransmitter systems. Sensory input passes through the anterior thalamus to the lateral nucleus of the amygdala. Input is then transferred to the central nucleus of the amygdala, which coordinates autonomic and behavioral responses. Direct sensory input to the amygdala from brainstem structures and the sensory thalamus enables a rapid response to potentially threatening stimuli. The central nucleus of the amygdala projects to the following structures:

1. the parabrachial nucleus, producing an increase in respiratory rate;
2. the lateral nucleus of the hypothalamus, causing autonomic arousal and sympathetic discharge;
3. the locus coeruleus, leading to an increase in norepinephrine and to increases in blood pressure, heart rate and behavioral fear responses (e.g., freezing);
4. the paraventricular nucleus of the hypothalamus, resulting in an increase in the release of adrenocorticoids; and
5. the periaqueductal gray region, leading to avoidance behaviors.

In addition, there are reciprocal connections between the amygdala and the sensory thalamus, prefrontal cortex, insula, and primary somatosensory cortex.

Panic attacks arise from excessive activation of the fear network (Gorman *et al.*, 2000). The fear network becomes sensitized (conditioned) to respond to noxious stimuli such as internal (bodily sensations) and external (contexts or situations) that the person associates with panic. Sensitization of the network may be manifested by the strengthening of various projections from the central nucleus of the amygdala to brainstem sites (such as the locus coeruleus, periaqueductal gray region and hypothalamus). The network could be over-activated if brainstem inputs to the amygdala are dysregulated. However, autonomic activation (e.g., increased respiration and heart rate) and neuroendocrine activation (e.g., increased cortisol secretion) does not occur in all panic attacks. Moreover, a variety of biological agents with diverse physiological properties can trigger panic attacks in people with panic disorder (e.g., sodium lactate, yohimbine, CO<sub>2</sub>, caffeine, cholecystokinin-4). It is, therefore, unlikely that a single brainstem dysregulation is responsible for panic or, in turn, that brainstem dysregulation is the only way of producing an over-active fear network.

There may be other ways of activating the fear network. For example, the amygdala receives input from cortical regions involved in the processing and evaluation of sensory information. Therefore, a neurocognitive deficit in these cortico-amygdala pathways could result in the catastrophic misinterpretation of sensory information (i.e., misinterpretation of bodily sensations), leading to an inappropriate activation of the fear network. Notice that this pathway resembles the cognitive model of panic

described earlier in this chapter. Thus, Gorman and colleagues (2000) model integrates the cognitive model and places it in a neuroanatomical context.

In addition to playing a role in panic disorder, the fear network is thought to play a role in other anxiety disorders and in mood disorders. This is consistent with the comorbidity between panic disorder and these disorders. Abnormalities in the fear network may vary from disorder to disorders. For example, the strength of various connections between components of the network may distinguish various disorders.

Medications, particularly selective serotonin reuptake inhibitors (SSRIs), are thought to desensitize the fear network. This may happen in a number of ways. SSRIs increase serotonergic transmission in the brain. Serotonergic neurons originate in the brainstem raphe and project throughout the central nervous system and some of these projections have inhibitory influences. For example, the greater the activity in the raphe, the greater the inhibition of noradrenergic neurons in the locus coeruleus, resulting in a reduction of cardiovascular symptoms associated with panic attacks, such as tachycardia. Similarly, the greater the activity in the raphe, the greater the inhibition in the periaqueductal gray region, resulting in a reduction in avoidance behavior. Increased serotonergic activity also may reduce hypothalamic release of corticotropin-releasing factor, thereby resulting in a reduction of cortisol and a reduction in activity of the locus coeruleus thereby leading to a reduction in fear. SSRIs may also directly inhibit activity of the lateral nucleus of the amygdala. Thus, there appear to be several ways in which SSRIs could desensitize the fear network. Effective psychological therapies are thought to reduce contextual fear and catastrophic misinterpretations at the level of the medial prefrontal cortex and hippocampus.

## Environmental and Genetic Factors

The fear network is thought to be influenced by genetic factors and stressful life events, particularly events in early childhood. The search for genetic markers and candidate genes for panic disorder has revealed several possible loci but, to date, none has been replicated across studies. Research with monozygotic and dizygotic twins show that panic disorder is moderately heritable, with 32 to 46% of variance in liability for panic being attributed to genetic factors (Kendler *et al.*, 1993).

Vulnerability to panic disorder appears to result from a combination of disorder-specific and disorder-nonspecific factors. The importance of nonspecific genetic factors is consistent with observation that panic disorder is often comorbid with other disorders. Twin studies suggest that nonspecific factors influence the vulnerability to several disorders, including panic disorder, bulimia nervosa, generalized anxiety disorder and alcohol dependence. Genetic factors specific to panic disorder may be those that influence the tendency catastrophically to misinterpret bodily sensations. This cognitive tendency is a distinguishing feature of panic disorder, as described above. Recent twin research indicates that it is moderately heritable in women but not men (Jang *et al.*, 1999). Thus, some specific genetic factors in panic disorder appear to be sex-linked.

Environmental events occurring during particular developmental phases such as separation from the primary caregiver during early childhood may activate the genes that modulate the fear network, thereby creating a vulnerability to panic disorder. Research suggests that later events, occurring during adolescence or early adulthood, then precipitate panic disorder in vulnerable

individuals. These events may stress the individual at a psychological or physiological level. Events commonly associated with the onset of panic disorder include:

1. separation, loss, or illness of a significant other;
2. being the victim of sexual assault or other forms of interpersonal violence;
3. financial or occupational stressors; and
4. intoxication with, or withdrawal from, a psychoactive substance such as marijuana, cocaine, or anesthetic.

## Dynamic Models

The most promising psychodynamic models for understanding panic disorder are those that focus specifically on this disorder. Rather than review all the models, we will summarize the model developed by the Cornell Panic-Anxiety Study Group (Milrod *et al.*, 1997; Shear *et al.*, 1993) because it has led to a promising treatment. According to the Cornell group, people at risk for panic disorder have 1) a neurophysiological vulnerability to panic attacks, and/or 2) multiple experiences of developmental trauma. These factors lead the child to become frightened of unfamiliar situations and to become excessively dependent on the primary caregiver to provide a sense of safety. The caregiver is unable to provide support always, so the child develops a fearful dependency. This leads, in turn, to the development of unconscious conflicts about dependency (independence versus reliance on others) and anger (expression versus inhibition). The dependency conflict is said to express itself in a number of ways. Some panic-vulnerable people are sensitive to separation and overly reliant on others, while others are sensitive to suffocation and overly reliant on a sense of independence. These conflicts can activate conscious or unconscious fantasies of catastrophic danger, which can trigger panic attacks. In addition, the conflicts evoke aversive emotions, such as anxiety, anger and guilt. The otherwise benign arousal sensations accompanying these emotions can become the focus of “conscious as well as unconscious cognitive catastrophizing” (Shear *et al.*, 1993, p. 862), thereby leading to panic attacks.

## Assessment

The most comprehensive and accurate diagnostic information emerges when the clinician uses open ended questions and empathic listening, combined with structured inquiry about specific events and symptoms. Useful structured interviews include the *Structured Clinical Interview for DSM-IV* (SCID-IV) and the *Anxiety Disorders Interview Schedule for DSM-IV* (ADIS-IV). A complete assessment for panic disorder also includes a general medical evaluation consisting of a medical history, review of organ systems, physical examination and blood tests. A general medical evaluation is important for identifying general medical conditions that mimic or exacerbate panic attacks or panic-like symptoms (e.g., seizure disorders, cardiac conditions, pheochromocytoma). These disorders should be investigated and treated before contemplating a course of panic disorder treatment. It is also important to rule out the other anxiety disorders and major depressive disorder as primary factors in the person’s panic attacks and avoidance prior to initiating treatment for panic disorder (Figure 49.1).

Diagnostic information can be usefully supplemented by short self-report questionnaires to assess the severity of symptoms and other variables. The **Beck Depression Inventory** and

**Beck Anxiety Inventory** (Beck and Steer, 1987, 1993) are quick, reliable and valid measures that can be administered at the start of each treatment session to assess the severity of past-week general anxiety and depression. The **Anxiety Sensitivity Index** (Peterson and Reiss, 1992) is another useful short questionnaire that can be used to gauge the severity of the patient’s fear of bodily sensations. Scores on this scale can be used to assess whether treatment is altering the patient’s tendency catastrophically to misinterpret bodily sensations. This scale has good reliability and validity, is sensitive to treatment-related effects, and its post treatment scores predict who is likely to relapse after panic treatment.

Another useful questionnaire to monitor treatment progress is the **Panic and Agoraphobia Scale** (Bandelow, 1995). This 13-item scale was designed as a short, sensitive measure for treatment outcome studies. The patient is asked to rate the past-week frequency and/or severity of the following: 1) panic attacks, 2) agoraphobia, 3) anticipatory anxiety (i.e., worry about having an panic attack), 4) panic-related disability in various areas of functioning, and 5) worry about the health-related implications of panic (e.g., worry that panic attacks will lead to a heart attack). The Panic and Agoraphobia Scale has good reliability and validity and is sensitive in detecting treatment-related change. It has the advantage of providing a broad assessment of many features of panic disorder and agoraphobia. A limitation is that it does not distinguish between full and limited symptom panic attacks or among the types of panics (i.e., unexpected, situationally bound, situationally predisposed). When asked to recall their attacks, patients may have difficulty making these distinctions. Prospective (ongoing) monitoring is needed to provide this information.

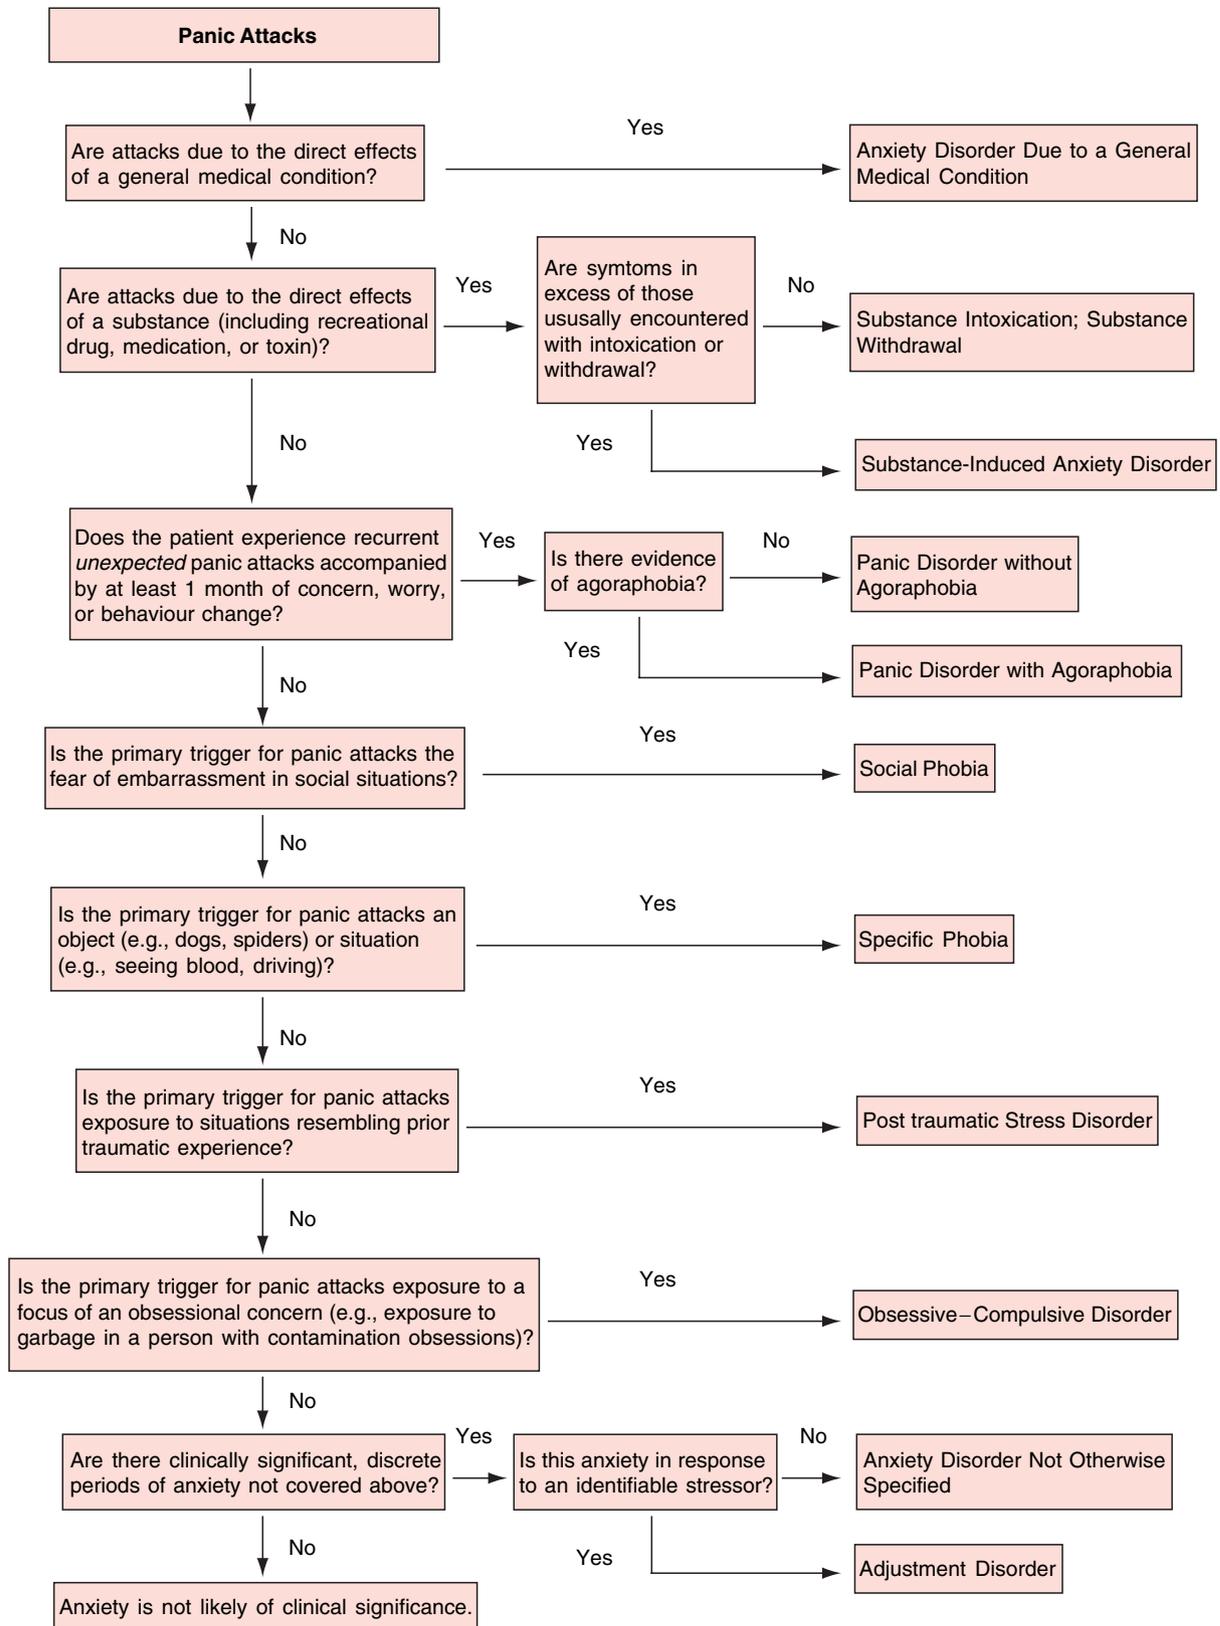

To gain more detailed information on panic attacks, clinicians and clinical researchers are increasingly including some form of prospective monitoring in their assessment batteries. The most widely used are the **panic attack records**. The patient is provided with a definition of a panic attack and then given a pad of panic attack records that can be readily carried in a purse or pocket. The patient is instructed to carry the records at all times and to complete one record (sheet) for each full-blown or limited symptom attack, soon after the attack occurs. Variants on the panic diaries developed by Barlow and colleagues (Barlow and Craske, 1994) are among the most informative and easy to use. These records are then reviewed during treatment sessions to glean information about the links among beliefs, bodily sensations and safety behaviors, and to assess treatment progress.

## Treatment

There are a number of approaches that can be taken in treating panic disorder with and without agoraphobia. Both single and combined treatment modalities are presented in Figure 49.2.

## Pharmacotherapies

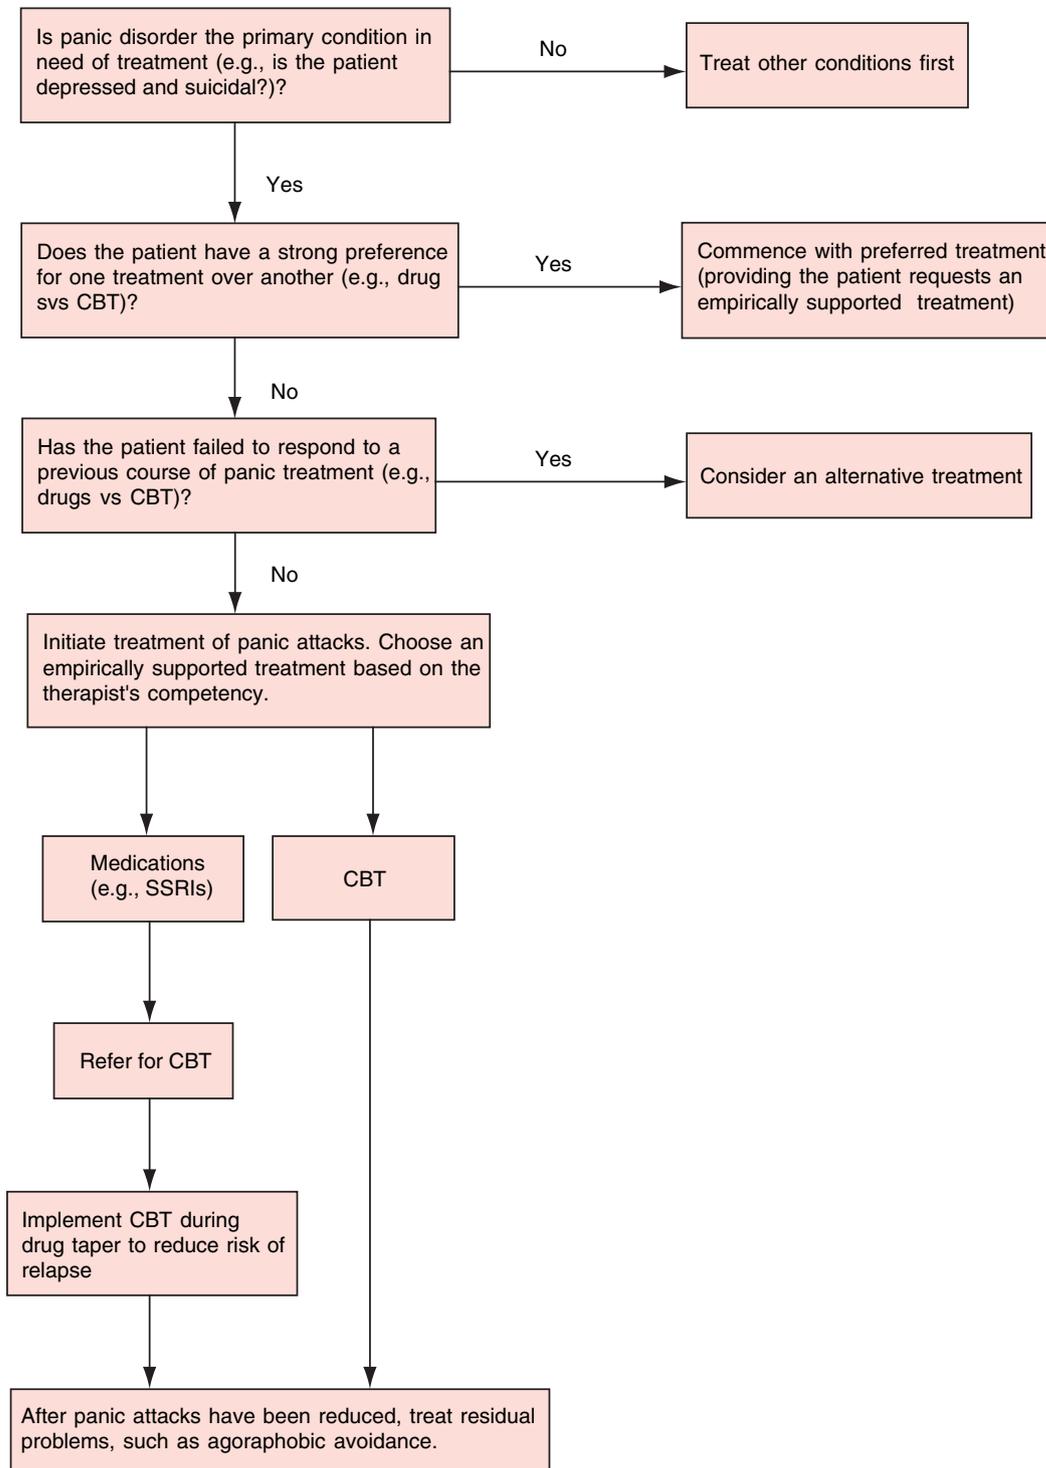

Controlled studies show that effective anti-panic medications include tricyclic antidepressants (e.g., imipramine), monoamine oxidase inhibitors (MAOIs; e.g., phenelzine), high-potency benzodiazepines (e.g., alprazolam) and SSRIs (e.g., fluvoxamine). These treatments have broadly similar efficacy, although there is some evidence that SSRIs tend to be most effective. The classes of medication differ in their side effects and their contraindications. Anticholinergic effects (e.g., blurred vision, dry mouth) are common problems with tricyclics. They are also contraindicated

**Figure 49.1** A decision tree for assessment of patients presenting with panic attacks.

in patients with particular comorbid cardiac disorders. Dietary restrictions (i.e., abstaining from foods containing tyramine) are a limitation of many MAOIs. Sedation, impaired motor coordination and addiction are concerns with benzodiazepines.

When efficacy and side effects are considered together, SSRIs emerge as the most promising drug treatments for panic disorder. However, even SSRIs have side effects, with the most problematic being a short-term increase in arousal-related

**Figure 49.2** A decision tree for treating panic disorder and agoraphobic avoidance.

sensations. To overcome this problem, SSRIs can be started at a low dose (e.g., 5–10 mg/d for paroxetine; 12.5–25 mg/d for sertraline) and then increased gradually (e.g., up to 10–50 mg/d for paroxetine; up to 25–200 mg/d for sertraline). The choice of SSRI is determined on the basis of several factors, including side effects, patient preference and the patient's history of responding (or not responding) to particular agents.

For drug refractory patients, or patients who are unable to tolerate SSRI side effects, combination medications are

sometimes used. For example, SSRIs can be augmented with benzodiazepines. The latter are used to dampen the side effects of SSRIs. Despite some positive preliminary reports supporting this strategy, its value in the treatment of panic disorder remains to be properly evaluated. An alternative strategy is to change the patient's medication. Some of the newer, nonSSRI antidepressants could be considered, such as venlafaxine, nefazodone, bupropion, duloxetine, or gabapentin. A concern with using these newer medications to treat panic disorder is that there are few data to guide

the clinician. Another approach to the drug refractory patient is to use a psychosocial treatment such as cognitive–behavioral therapy (CBT), as an alternative or adjunctive intervention.

### Cognitive–Behavioral Therapy

CBT treatment packages include a number of components, such as psychoeducation (e.g., information about the cognitive model of panic), breathing retraining, cognitive restructuring, relaxation exercises, interoceptive exposure and situational exposure. Breathing retraining involves teaching the patient to breathe with the diaphragm rather than with the chest muscles. Cognitive restructuring focuses on challenging patient's beliefs about the dangerousness of bodily sensations (e.g., challenging the belief that palpitations lead to heart attacks). Interoceptive exposure involves inducing feared bodily sensations to further teach patients that the sensations are harmless. Situational exposure involves activities that bring the patient into feared situations such as shopping malls, bridges, or tunnels. Despite the advantages of exposure exercises, they are medically contraindicated in some cases. For example, a hyperventilation exercise would not be used in a patient with severe asthma.

A large body of evidence shows that CBT is effective in reducing panic attacks, agoraphobia and associated symptoms such as depression. However, not all CBT interventions may be necessary. Interoceptive exposure, situational exposure and cognitive restructuring are the most widely used and supported interventions. Several studies suggest that breathing retraining reduces panic frequency. However, recent research casts doubt about the importance of hyperventilation in producing panic attacks. This suggests that breathing retraining may only be useful for a minority of patients, for which chest breathing or hyperventilation plays a role in producing panic symptoms. Breathing retraining may be counterproductive if it prevents patients from learning that their catastrophic beliefs are unfounded. Given these concerns, breathing retraining should be used sparingly in the treatment of panic disorder. If used at all, the clinician should ensure that the patient understands that breathing exercises are used to remove unpleasant but harmless sensations. Interoceptive exposure and cognitive restructuring are important for helping patients learn that the sensations are not dangerous.

How effective is CBT compared with other therapies? A small but growing literature suggests that the efficacy of CBT is equal to or greater than that of alprazolam and imipramine at post treatment. Future research is needed to compare CBT with other pharmacotherapies, such as SSRIs. Preliminary evidence suggests that CBT is effective in treating patients who have failed to respond to pharmacotherapies. Follow-up studies suggest that CBT is effective in the long term and is likely to be more effective than short-term pharmacological treatment. It is not known whether drug treatments would be as effective as CBT if patients remained on their medications. Any conclusions about the long-term efficacy of panic treatments are necessarily tentative because patients sometimes seek additional treatment during the follow-up interval.

### Other Psychosocial Interventions

Several other approaches have been used in the treatment of panic disorder, including psychodynamic psychotherapies (Milrod *et al.*, 2000; Wiborg and Dahl, 1996), hypnosis (e.g., Delmonte, 1995), Eye Movement Desensitization and Reprocessing (EMDR)

(Shapiro, 1995), and mindfulness meditation (Miller *et al.*, 1995). Support for these treatments is limited largely to case studies and uncontrolled trials. Controlled studies, although few in number, indicate that hypnosis and EMDR are of limited value in treating panic disorder, and may be no better than placebo. Interventions that look more promising are mindfulness meditation (Miller *et al.*, 1995) and psychodynamic psychotherapies modified specifically to focus on panic symptoms (Milrod *et al.*, 2000; Wiborg and Dahl, 1996). However, none have been extensively evaluated as panic treatments and none has been compared with empirically supported treatments such as CBT or SSRIs.

## Combining CBT with Pharmacotherapies

### Simultaneous Treatments

Many clinicians believe the optimal treatment consists of drugs combined with some form of psychosocial intervention. This view arose from observations that even the most effective drugs and the most effective psychosocial interventions do not eliminate panic disorder in all cases. It was thought that combination treatments might be a way to improve treatment outcome. The available evidence provides mixed support for this view. Evidence suggests that the efficacy of CBT is not improved when it is combined with either diazepam or alprazolam. In fact, some studies have found that the efficacy of situational exposure is **worsened** when alprazolam is added.

Several studies have compared CBT with CBT combined with imipramine. These results have also been mixed. Adding imipramine in the range of 150–300 mg/day to either situational exposure or CBT sometimes improves treatment outcome in the short term, provided that patients are able to tolerate the dose. Any advantage of combined treatment tends to be lost at follow-up. Similarly, studies of combining CBT with SSRIs (fluvoxamine or paroxetine) have produced mixed results, with some studies finding the combination is no better than CBT.

It remains unclear whether treatment outcome is enhanced by combining CBT with SSRIs. The neuroanatomical model with its dual emphasis on cortical and serotonergic mechanisms suggests that this combined treatment might be superior to CBT alone and to SSRIs alone. On the other hand, pharmacotherapies such as SSRIs might undermine the patient's confidence in implementing CBT, particularly if they attribute their gains to medications rather than to their own efforts at using the skills learned in CBT. Large, well-designed studies are needed to explore these important issues.

### Sequential Treatments

A more promising type of combined therapy is a sequential approach, where patients are treated with pharmacotherapy during the acute phase, and then are treated with CBT as the medication is phased out. Several studies have shown that adding CBT during the tapering period for alprazolam and clonazepam reduces the relapse rate associated with these drugs. It remains to be demonstrated that CBT can reduce relapse when patients are tapered off other antipanic drugs such as SSRIs. However, there is no reason to expect that CBT would not be helpful in these cases.

## Conclusion

Panic disorder with or without agoraphobia is a common condition with a lifetime prevalence of approximately 2%. Panic disorder

is often comorbid with major depressive disorder and also commonly co-occurs with other disorders such as anxiety disorders and substance use disorders. Treatment planning typically begins with a thorough assessment, including a medical history, a structured diagnostic interview and prospective monitoring of symptoms. Based on contemporary biological and cognitive-behavioral models, there are several treatment options that can be considered. These include various pharmacotherapies, particularly SSRIs and psychosocial interventions that have proven effective in controlled trials. While mixed, there is evidence to suggest that treatments that combine SSRIs and CBT may be more effective than either treatment alone, at least in some symptom domains.

### Comparison of DSM-IV/ICD-10 Diagnostic Criteria

The ICD-10 Diagnostic Criteria for Research for a panic attack are identical to the DSM-IV-TR criteria set except that ICD-10 includes an additional item (i.e., dry mouth). In contrast to the DSM-IV-TR algorithm which does not give special weight to any particular symptom, the ICD-10 algorithm requires that at least one of the symptoms be palpitations, sweating, trembling, or dry mouth. Like DSM-IV-TR, ICD-10 requires recurrent panic attacks but, in contrast to DSM-IV-TR, it does not include a criterion requiring that the panic attacks be clinically significant.

The ICD-10 Diagnostic Criteria for Research for Agoraphobia differ markedly from the DSM-IV-TR criteria. The ICD-10 Diagnostic Criteria for Research specify that there be fear or avoidance of at least two of the following situations: crowds, public places, traveling alone, or traveling away from home. Furthermore, ICD-10 requires that at least two symptoms of anxiety (i.e., from the list of 14 panic symptoms) be present together on at least one occasion and that these anxiety symptoms be “restricted to, or predominate in, the feared situations or contemplation of the feared situations”. In contrast, DSM-IV-TR Agoraphobia is defined in terms of “anxiety about being in places or situations from which escape might be difficult (or embarrassing) or in which help may not be available in the event of having an unexpected or situationally predisposed panic attack”. No specific avoided situations or specific types of anxiety symptoms are required for a diagnosis.

# Anxiety Disorders: Social and Specific Phobias

## Definition

The experience of fear and the related emotion of anxiety are universal and familiar to everyone. Fear exists in all cultures and appears to exist across species. Presumably, the purpose of fear is to protect an organism from immediate threat and to mobilize the body for quick action to avoid danger. Emotion theorists consider fear to be an alarm response that fires in the presence of imminent threat or danger. The function of the primarily noradrenergic mediated fear response is to facilitate immediate escape from threat (flight) or attack on the source of threat (fight). Therefore, fear is often referred to as a fight-or-flight response. All the manifestations of fear are consistent with its protective function. For example, heart rate and breathing rate increase to meet the increased oxygen needs of the body, increased perspiration helps to cool the body to facilitate escape, and pupils dilate to enhance visual acuity.

Anxiety, on the other hand, is a future-oriented mood state in which the individual anticipates the possibility of threat and experiences a sense of uncontrollability focused on the upcoming negative event. In the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR) (American Psychiatric Association, 2000), anxiety is defined as “the apprehensive anticipation of future danger or misfortune accompanied by a feeling of dysphoria or somatic symptoms of tension” (p. 820). If one were to put anxiety into words, one might say, “Something bad might happen soon. I am not sure I can cope with it but I have to be ready to try”. Anxiety is primarily mediated by the gamma-aminobutyric acid-benzodiazepine system.

Despite evidence that fear and anxiety are mediated by different brain systems, anxiety and fear are related, which makes sense ethologically. Experiencing anxiety after encountering signals of impending danger seems to lower the threshold for fear which is triggered when danger actually occurs (e.g., being attacked by a mugger or almost being hit by an automobile). Anxiety leads to a shift in attention toward the source of danger so that individuals become more vigilant for relevant threat cues and therefore are more likely to experience fear in the face of perceived immediate threat.

Fear and anxiety are not always adaptive. At times, the responses can occur in the absence of any realistic threat or out of proportion to the actual danger. Almost everyone has situations that arouse anxiety and fear despite the fact that the actual risk is minimal. It is not unusual to become anxious before a job interview or a speech. Many individuals feel fearful when exposed to situations such as dental visits, seeing certain animals, or being at certain heights. For some people, these fears reach extreme levels and

may cause significant distress or impairment in functioning. It is at this point that what we typically refer to as shyness and fearfulness might meet diagnostic criteria for social phobia or specific phobia, respectively (see DSM-IV-TR Criteria 300.23 and 300.29).

As discussed later, phobias are the most common of the anxiety disorders and among the most common of all mental disorders. However, despite the frequency with which phobias occur in the general population, they have tended to be relatively ignored by clinicians and researchers. The introduction of social phobia to the diagnostic nomenclature has led to a slow but steady increase in research on the disorder, so that social phobia has now become a more popular topic of study among researchers on anxiety disorders. In addition to being widespread, social phobia is associated with significant functional impairment. Also, social phobia often presents comorbidly with other mental disorders. Despite the high prevalence rate and significant impairment, generalized social phobia is rarely diagnosed or treated in a primary care setting

With respect to specific phobias, the lack of attention is probably due to several factors. First, many physicians and researchers may view specific phobias to be less severe than other disorders, therefore warranting less attention. In addition, few individuals with specific phobias present for treatment, and the ones who do seek help tend to differ from untreated individuals with phobias with respect to the number and types of specific phobias. As with social phobia, there has been an increase in attention paid to specific phobias, along with increased recognition that these phobias can interfere seriously with an individual's ability to function. It is not unusual for flying phobias to lead individuals to refuse job promotions that involve travel or to avoid visiting distant family members. Likewise, individuals with insect phobias may avoid being outside during the summer.

## Psychological Factors

### Psychoanalytic Perspectives

Historically, the etiology of phobic disorders was typically explained from a psychoanalytic perspective. Although the defense mechanism of repression is typically used to protect the individual from experiencing the anxiety (and the underlying conflict), when repression is insufficient the ego must use additional defense mechanisms. In the case of individuals with phobias, Freud proposed that displacement of the anxiety to a less relevant object or situation occurs (such as a dog or some other animal), so that the feared object is used to symbolize the primary source of the conflict. Patients with phobias use avoidance further to escape

**DSM-IV-TR Criteria 300.23****Social Phobia (Social Anxiety Disorder)**

- A. A marked and persistent fear of one or more social or performance situations in which the person is exposed to unfamiliar people or to possible scrutiny by others. The individual fears that he or she will act in a way (or show anxiety symptoms) that will be humiliating or embarrassing. **Note:** In children, there must be evidence of the capacity for age-appropriate social relationships with familiar people and the anxiety must occur in peer settings, not just in interactions with adults.
- B. Exposure to the feared social situation almost invariably provokes anxiety, which may take the form of a situationally bound or situationally predisposed panic attack. **Note:** In children, the anxiety may be expressed by crying, tantrums, freezing, or shrinking away from social situations with unfamiliar people.
- C. The person recognizes that the fear is excessive or unreasonable. **Note:** In children, this feature may be absent.
- D. The feared social or performance situations are avoided or else are endured with intense anxiety or distress.
- E. The avoidance, anxious anticipation, or distress in the feared social or performance situation(s) interferes significantly with the person's normal routine, occupational (or academic) functioning, or social activities or relationships, or there is marked distress about having the phobia.
- F. In individuals under age 18 years, the duration is at least 6 months.
- G. The fear or avoidance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition and is not better accounted for by another mental disorder (e.g., panic disorder with or without agoraphobia, separation anxiety disorder, body dysmorphic disorder, a pervasive developmental disorder, or schizoid personality disorder).
- H. If a general medical condition or another mental disorder is present, the fear in criterion A is unrelated to it, for example, the fear is not of stuttering, trembling in Parkinson's disease, exhibiting abnormal eating behavior in anorexia nervosa or bulimia nervosa.

*Specify if:*

**Generalized:** if the fears include most social situations (also consider the additional diagnosis of avoidant personality disorder)

the effects of the anxiety. Although Freud's theory was once influential, its impact on current thinking among researchers has waned. Rather, most current research on psychological factors in the development of phobias has tended to focus on conditioning and information-processing theories and their interaction with neurobiological processes.

**DSM-IV-TR Criteria 300.29****Specific Phobia**

- A. Marked and persistent fear that is excessive or unreasonable, cued by the presence or anticipation of a specific object or situation (e.g., flying, heights, animals, receiving an injection, seeing blood).
- B. Exposure to the phobic stimulus almost invariably provokes an immediate anxiety response, which may take the form of a situationally bound or situationally predisposed panic attack. **Note:** In children, the anxiety may be expressed by crying, tantrums, freezing, or clinging.
- C. The person recognizes that the fear is excessive or unreasonable. **Note:** In children, this feature may be absent.
- D. The phobic situation(s) is avoided or else is endured with intense anxiety or distress.
- E. The avoidance, anxious anticipation, or distress in the feared situation(s) interferes significantly with the person's normal routine, occupational (or academic) functioning, or social activities or relationships, or there is marked distress about having the phobia.
- F. In individuals under age 18 years, the duration is at least 6 months.
- G. The anxiety, panic attacks, and phobic avoidance associated with the specific object or situation are not better accounted for by another mental disorder, such as obsessive-compulsive disorder (e.g., fear of dirt in someone with an obsession about contamination), post traumatic stress disorder (e.g., avoidance of stimuli associated with a severe stressor), separation-anxiety disorder (e.g., avoidance of school), social phobia (e.g., avoidance of social situations because of fear of embarrassment), panic disorder with agoraphobia, or agoraphobia without history of panic disorder.

*Specify type:*

**Animal type**

**Natural environment type** (e.g., heights, storms, water)

**Blood-injection-injury type**

Situational type (e.g., airplanes, elevators, enclosed places)

**Other type** (e.g., fear of choking, vomiting, or contracting an illness; in children, fear of loud sounds or costumed characters)

**Learning and Conditioning Perspectives**

Emotions are "contagious". That is, we learn to respond to stimuli, in part, by observing other people's responses and also by our own experiences in these situations. In other words, we come to fear dangerous situations easily. This is important from an

ethological perspective because our ancestors who could learn to fear threatening objects or situations easily were more likely to survive and pass these genes to their offspring. This inherited tendency to learn to experience fear in particular situations is the basis of conditioning models of phobia development.

**Rachman's Pathways to Fear Development** Rachman (1977) proposed three pathways to the development of fear. The first of these is **direct conditioning**, which typically involves the experience of being hurt or frightened by the phobic object or situation. Examples include being involved in an automobile accident, being humiliated in front of a group, falling or almost falling from a high place, or fainting at the sight of blood. Rachman's second pathway is called **vicarious acquisition**, which involves witnessing some traumatic event or seeing someone behave fearfully in the presence of a phobic situation. For example, a child might develop a fear of snakes after seeing her father behave fearfully around snakes, or someone might develop a fear of public speaking after seeing another individual heckled by the audience during a presentation. For the third pathway, Rachman proposed that fears can develop through **informational and instructional pathways**. It is not surprising that individuals might develop flying phobias, given the frequency with which plane crashes are reported in the news. Similarly, a child might develop a fear of heights if his parents frequently warned him of the dangers of being near high places.

In addition to these pathways, Rachman acknowledged the role of biological constraints on the development of fear. Of particular relevance is the fact that fears are not randomly distributed. To explain this observation, Seligman (1971) proposed that organisms are predisposed to learn certain associations and not others. Seligman called his theory "preparedness" and hypothesized that individuals are "prepared" to develop some associations that lead to fear and not others. For example, an individual might be more likely to develop a fear of dogs after being bitten than to develop a fear of flowers after being pricked by a thorn. Seligman proposed that these associations evolved through natural selection processes to facilitate survival.

Evidence for the theory of preparedness is mixed. Although some authors have concluded that the studies to date do not support preparedness, it may be argued that these studies have not adequately tested the theory. Most studies examining preparedness have attempted to associate dangerous objects (e.g., snakes) and nondangerous objects (e.g., flowers) with an aversive electrical shock and have found few differences in the subsequent development of fear. However, preparedness predicts that some "associations" are more difficult to establish than others, not that some "objects" are more easily feared than others. The theory does not necessarily predict that shock should be more easily associated with snakes than with flowers. A more appropriate experiment might be to compare the effects of a minor snakebite to the effects of being pricked by a thorny flower on the development of fear of each object. In any event, there is now strong evidence that conditioning processes play an important role in the development of phobic disorders.

Numerous studies have examined the prevalence of Rachman's three pathways to fear development. Most of these studies have focused on the development of specific phobias, although a few studies included social phobia groups. The majority of studies have found support for the model, indicating that both direct and indirect forms of phobia acquisition occur frequently across a wide range of phobias. However, numerous people report onsets that are unrelated to these pathways (e.g., "I have had this fear for

as long as I can remember" or "I have always had this fear"). Overall, it appears that direct and indirect methods of fear development are relatively common, although the frequency of these onsets varies greatly across studies for a variety of reasons.

Despite the prevalence of direct and indirect conditioning events and informational onsets, it appears that they are not the whole story. In fact, studies have begun to include normal comparison groups and have found that these events are equally common in individuals who do not have phobias. Ultimately, to answer the question of how phobias begin, we must discover the variables that lead only certain individuals to develop phobias after experiencing conditioning events or receiving information that leads to fear. For example, several investigators have found that a tendency to feel "disgust" in response to certain stimuli may be important in the development of some animal phobias and blood phobias. In addition, heightened disgust sensitivity in parents has been found to predict fear of disgust-relevant animals (e.g., snakes, mice, slugs and cockroaches) in children. Several other variables have also been suggested as mediating factors in the development of fear. Stress at the time of the event may make individuals more likely to react fearfully. In addition, previous and subsequent exposure to the phobic object may protect an individual from the development of a phobia. For example, someone who grew up around dogs may be less likely to develop a phobia after being bitten than someone who has spent little time around dogs. The context of the event may also influence the reaction. For example, being with another supportive individual at the time of the trauma may protect an individual from developing fear. Finally, a number of individual difference variables such as perceived control, trait anxiety and various personality factors may influence an individual's likelihood of developing a phobia after a conditioning event. In fact, there is evidence that personality factors and parenting styles may be especially relevant to the development of social phobia.

It has been proposed that a fourth nonassociative pathway be added to Rachman's three associative pathways to fear development. Nonassociative fear models propose that a limited number of fears are not acquired by conditioning or other learning processes. Rather, these evolutionary adaptive fears are proposed to be innate or biologically determined. This is similar to preparedness theory, however, it maintains that fears are acquired through a learning or conditioning process and that some fears are more easily learned than others. The nonassociative pathway to fear acquisition helps to explain a number of research findings that run counter to associative models of fear development, including the nonrandom distribution of common fears, and the emergence of some fears without any prior specific associative learning experiences (i.e., direct conditioning, vicarious conditioning, or informational transmission).

**Personality Variables** It appears that at as early as 18 months of age children differ with respect to their tendency to interact with other individuals, toys and objects. Although about 70% of children are somewhat exploratory in these situations, about 15% of children are extremely exploratory, and the remaining 15% are quite shy and withdrawn. The behavior exhibited by the shy and withdrawn children has been called "behavioral inhibition" and has been proposed to be a predisposing factor in the development of social phobia and other anxiety disorders. One study found that the prevalence of social phobia was significantly greater (17%;  $N = 64$ ) in children with behavioral inhibition than without (5%;  $N = 152$ ) (Biederman *et al.*, 2001). In addition, compared

with nonanxious individuals, patients with social phobia describe their parents as having 1) discouraged them from socializing; 2) placed undue importance on the opinions of others; and 3) used shame as a means of discipline. Other predictors of the development of social phobia include a childhood history of separation anxiety, self-consciousness or shyness in childhood and adolescence, and a low frequency of dating in adolescence.

Perfectionism is another personality variable that has been associated with social phobia. Although several other anxiety disorders have also been associated with perfectionism, concern about making mistakes and a perception of having critical parents are highest among individuals with social phobia compared with individuals with other anxiety disorders (e.g., panic disorder, obsessive-compulsive disorder, or specific phobia).

**Cognitive Variables** Numerous studies have examined the role of cognitive variables in social and specific phobias and have consistently found that individuals with these disorders exhibit attentional and attributional biases regarding the phobic object or situation. In studies of information processing, people with social and specific phobias devote more attention to threat-related information than do nonphobic individuals. They also show perceptual and cognitive distortions consistent with their phobias. For example, individuals with snake or spider phobias tend to overestimate the degree of activity in the feared animal before treatment but not after treatment. Likewise, people with social phobia tend to rate their own performance during public speaking more critically than do nonphobic control subjects. Furthermore, the discrepancy between self-ratings and observer ratings is greater for people with social phobia than control subjects. In addition, individuals with social phobia tend to report more negative self-evaluative thoughts and underestimate their performance when interacting with others relative to nonanxious subjects. More recent research has found that compared with nonanxious individuals, individuals with social phobia are more likely to experience negative imagery and to take an observer's point of view (i.e., see themselves from an external perspective) when exposed to feared social situations. Other research has found that social phobia is associated with impaired thought suppression affecting both social phobia-related stimuli as well as nonsocial phobia-related stimuli. Although it is clear that cognitive biases exist in individuals with phobias and that attentional and attributional biases improve after effective treatment, it is not known whether the cognitive biases exhibited by patients contribute to the development of the fear or whether they are simply a manifestation of the fear.

## Genetic and Family Factors

Specific phobias and social phobia tend to run in families. It appears that being a first-degree relative of an individual with a specific phobia puts one at a greater risk for a specific phobia compared with first-degree relatives of never mentally ill controls (31% versus 11%). However, the particular phobia that is transmitted is usually different from that in the relative, although it is often from the same general type (e.g., animal, situational). Furthermore, relatives of people with specific phobias are not at increased risk for other types of anxiety disorders (including social phobia) or subclinical fears. There is no increased risk among relatives of people with social phobia to develop other anxiety disorders. A recent study found that in comparison to probands in a comparison group, the relative risk for generalized social phobia and avoidant personality disorder were tenfold for first-degree relatives of probands with social phobia.

Of course, the existence of a disorder in multiple family members does not necessarily imply genetic transmission. Family members often share learning experiences and other environmental factors. To establish a genetic relationship among family members with a particular disorder, twin studies, adoption studies and molecular genetics studies are typically conducted. Currently, there are no adoption or molecular genetics studies of social or specific phobias, and twin studies have yielded conflicting results.

Although there are conflicting findings on whether there is a general genetic factor (influencing risk for any anxiety disorder) or a specific genetic factor (influencing risk for specific anxiety disorders such as specific and social phobias), some general conclusions can be made. In the case of social phobia, there seems to be a moderate (based on the strength of the correlations from twin studies) disorder-specific genetic influence combined with specific and nonspecific environmental influences. In the case of specific phobia, evidence supports a disorder-specific genetic contribution combined with disorder-specific environmental influences (e.g., traumatic conditioning experiences involving the phobic object or situation).

Although the nature of the genetic contribution has yet to be specified (a low threshold for alarm reactions or vasovagal responses is one possibility), specific and social phobias may be related to personality factors that have been found to be highly heritable. Two traits that may be relevant are neuroticism (or emotionality) and extroversion (or sociability). Average heritability estimates for these traits are about 50% across a wide range of genetic studies. Emotionality probably predisposes individuals to develop a range of anxiety and mood disorders whereas sociability may be most relevant to social phobia. Furthermore, certain phobias may have other specific genetic contributions. Up to 70% of individuals with blood phobia report a history of fainting on exposure to blood. It has been suggested that an inherited overactive baroreflex may contribute to the high rate of familial transmission of blood phobias.

## Other Biological Factors

In contrast to the situation with other anxiety disorders, little is known about the physiological correlates of specific and social phobias. However, effective drug treatments have been identified for social phobia, leading to an increased interest in the biological factors underlying this disorder. There has been some evidence to suggest a relationship between dopamine and social phobia. Unlike panic disorder, which responds well to a variety of tricyclic antidepressants and monoamine oxidase inhibitors, social phobia tends to have a positive response to MAOIs and shows little response to tricyclic antidepressants. Whereas tricyclic antidepressants tend to act on noradrenergic and serotonergic systems, MAOIs affect noradrenergic, serotonergic and dopaminergic systems. This finding has led some investigators to suggest that the dopamine system is primarily involved in social phobia, which would explain why biological challenges that appear to affect noradrenergic activity (e.g., sodium lactate infusion, carbon dioxide inhalation) have little effect on patients with social phobia, despite having panicogenic effects in patients with panic disorder. The dopamine hypothesis is consistent with findings that dopamine metabolite levels correlate with measures of extroversion as well as findings that mice bred to be timid have been shown to be deficient in brain dopamine concentration.

With respect to neuroendocrine correlates in social phobia, studies of the hypothalamic-pituitary-thyroid and

hypothalamic–pituitary–adrenal axes in social phobia have found few differences between patients with social phobia and control persons. Some recent studies have found evidence of cortisol differences associated with social anxiety.

Recent imaging studies have found a number of differences between social phobia patients and controls. One study using functional magnetic resonance imaging (fMRI) found that conditioned aversive stimuli were associated with increased activation in the amygdala and hippocampus of social phobia patients, whereas decreased activation in these areas was observed in normal controls (Schneider *et al.*, 1999). Another study using single photon emission computer tomography (SPECT) found that after an 8-week trial of citalopram there was significantly decreased activity in the anterior and lateral part of the left temporal cortex, the left cingulum and the anterior, lateral and posterior part of the left midfrontal cortex in a small ( $N = 15$ ) sample of social phobia patients (Van der Linden *et al.*, 2000). Compared with treatment responders, treatment nonresponders had higher activity at baseline in the lateral left temporal cortex and the lateral left midfrontal regions. Further research is necessary to understand the significance of these imaging findings as well as their specificity to social phobia.

A few studies have examined patterns of brain activity associated with shyness. In a study on high and low shyness (anxious self-preoccupation and avoidance of social situations) and sociability (preference to be socially active and seek out social situations) in college students, it was found that shyness was associated with greater relative right frontal EEG activity, whereas sociability was associated with greater relative left frontal EEG.

Finally, there may be good reason to consider different underlying mechanisms in patients with performance-related phobias (e.g., public speaking) than in patients with generalized social phobia (i.e., those who fear most social situations). Individuals with performance-related phobias tend to show more autonomic reactivity (e.g., rapid heart beat) in the phobic situation than do patients with generalized social phobia. In addition, beta-blockers such as atenolol may be useful for decreasing performance anxiety in normal individuals, although they have little effect on patients with generalized social phobia. These facts have led some investigators to suggest that adrenergic hyperactivity may be involved in performance anxiety but not in generalized social phobia. However, it should be noted that despite limited evidence for the use of beta-blockers in normal groups (e.g., musicians with performance anxiety), their utility for treating patients with a diagnosis of social phobia (e.g., performance fears that lead to significant distress or impairment) has not been established.

## Assessment

### Special Issues in Psychiatric Examination and History

During all parts of the initial evaluation, the psychiatrist should be sensitive to several issues. First, for many patients with phobias, even discussing the phobic object can provoke anxiety. For example, some patients with spider phobias experience panic attacks when they discuss spiders. Some patients with blood phobias faint when they discuss surgical procedures. Therefore, the psychiatrist should ask the patient whether discussing the phobic object or situation will provoke anxiety. If the interview is likely to be a source of stress, the psychiatrist should emphasize the importance of the information that is being collected, as well as

the potential therapeutic value of discussing the feared object. As described in a later section, exposure to the feared stimulus is an essential component of the treatment of most specific phobias. Of course, the interviewer should use his or her judgment when deciding how much to push the patient in the first session. For treatment to be effective, establishing trust in the psychiatrist early in the course of treatment is essential.

With respect to social phobia, the assessment itself may be considered a phobic stimulus. Because individuals with social phobia fear the evaluation of others, a psychiatric interview may be especially frightening. Even completing self-report questionnaires in the waiting room may be difficult for patients who fear writing in front of others. The psychiatrist should be sensitive to this possibility and provide reassurance when appropriate.

### Structured and Semistructured Interviews

Although there are numerous structured and semistructured interviews available, two of the most commonly used interviews for diagnosing anxiety disorders are the Anxiety Disorders Interview Schedule for DSM-IV (ADIS-IV) (Brown *et al.*, 1994) and the Structured Clinical Interview for Axis I DSM-IV-TR Disorders–Patient Edition (SCID-I/P for DSM-IV-TR) (First *et al.*, 2001). Current and lifetime diagnoses of specific phobia and social phobia based on the ADIS-IV have been shown to have good to excellent reliability for the specific phobia types and the generalized type of social phobia. Each interview has advantages and disadvantages. Although the SCID-I provides detailed assessment of a broader range of disorders relative to the ADIS-IV (including eating disorders and psychotic disorders), the ADIS-IV provides more detailed information on each of the anxiety disorders and, like the SCID-I, includes sections to provide DSM-IV diagnoses for the mood disorders and other disorders that are typically associated with the anxiety disorders (e.g., substance use and somatoform disorders). In addition, the ADIS-IV includes more questions to help differentiate specific and social phobias from other disorders with which they share features.

### Self-report Measures

Numerous self-report measures have been created for the assessment of specific phobias and social anxiety. The main advantage of self-report measures is the time that they save for the psychiatrist. Relevant self-report measures are recommended before the clinical interview if possible. This will allow the interviewer to follow up specific responses during the interview. Measures can be administered again, periodically, to assess progress and outcome. It should be noted that questionnaire measures do not always correlate highly with performance on behavioral measures. Furthermore, there is evidence that men are more likely than women to underestimate their fear on specific phobia measures. The most common questionnaires used to screen for specific phobias are the various versions of the Fear Survey Schedule. In addition, a variety of measures exist to assess fear of specific objects and situations. For example, the Mutilation Questionnaire (Klorman *et al.*, 1974) is among the most common tests for assessing fear of situations involving blood and medical procedures. Self-report measures for assessing both specific phobia and social anxiety are listed in Table 50.1.

### Behavioral Tests

Behavioral testing is an important part of any comprehensive evaluation for a phobic disorder. This is particularly the case

**Table 50.1 Common Measures for Specific and Social Phobias**

Specific Phobia
Fear Survey Schedule (FSS)
Fear Questionnaire (FQ)
Fear of Flying Scale (FFS)
Acrophobia Questionnaire (AQ)
Mutilation Questionnaire (MQ)
Medical Fear Survey (MFS)
Dental Anxiety Inventory (DAI)
Claustrophobia Situations Questionnaire (CSQ)
Social Phobia
Social Phobia Inventory (SPIN)
Mini-Social Phobia Inventory (Mini-SPIN)
Social Phobia and Anxiety Inventory (SPAI)
Social Interaction Anxiety Scale (SIAS)
Social Phobia Scale (SPS)

if behavioral or cognitive-behavioral treatment will be used. Because most individuals with phobias avoid the objects and situations that they fear, patients may find it difficult to describe the subtle cues that affect their fear in the situation. In addition, it is not unusual for patients to misjudge the amount of fear that they typically experience in the phobic situation. A behavioral approach test can be useful for identifying specific fear triggers as well as for assessing the intensity of the patient's fear in the actual situation.

To conduct a behavioral approach test, patients should be instructed to enter the phobic situation for several minutes. For example, an individual with a snake phobia should be instructed to stand as close as possible to a live snake and note the specific cues that affect the fear (e.g., size of snake, color, movement) and the intensity of the fear (perhaps rating it on a 0–100-point scale). Patients should pay special attention to their physical sensations (e.g., palpitations, sweating, blushing), negative thoughts (e.g., “I will fall from this balcony”) and anxious coping strategies (e.g., escape, avoidance, distraction).

The behavioral approach test will help in the development of a specific treatment plan. However, before treatment patients will often be reluctant to enter the feared situation. If this is the case, the information collected during the behavioral approach test may be elicited during the early part of behavioral treatment.

## Differences in Sex, Cultural and Developmental Presentation

### Sex Differences

As mentioned earlier, specific phobias tend to be more common among women than men. This finding seems to be strongest for phobias from the animal type, whereas sex differences are smaller for height phobias and blood-injury-injection phobias. In addition, social phobia tends to be slightly more prevalent among women than men, although these differences are relatively small.

There are several reasons why women may be more likely than men to report specific phobias. First, men tend to underreport their fear. Also, women may be more likely than men to seek treatment for their difficulties, which would account for the fact that sex differences are often larger in treatment samples compared with epidemiological samples. In addition sex ratios for phobias differ across cultures, which may be explained by cultural differences in treatment seeking. Finally, the sex difference in prevalence may reflect actual differences between men and women in susceptibility to develop phobias.

Women and men are taught to deal differently with typical phobic stimuli. Traditionally, boys more than girls are often encouraged to play with spiders and toy snakes and to engage in more adventurous activities (e.g., hiking in high places). In addition, women may have more role models for the development of fear than do men. Images of women standing on chairs when they see a mouse or running away from spiders are common in children's cartoons and other media, but men are rarely depicted as being frightened by these objects. Therefore, it is possible that in Western cultures women learn to fear certain situations more strongly than do men. Of course, it is difficult to know whether culture and the media are responsible for sex differences or simply reflect differences that exist for other reasons (e.g., different predisposing factors). It will be interesting to see whether sex ratios for phobias change as traditional gender roles continue to change.

### Cultural Differences

Little is known about cultural differences in specific and social phobias. Nevertheless, a few studies bear on the issue of cultural differences in phobias. For example, there is evidence from epidemiological studies that African-Americans are 1.5 to 3 times as likely as whites to report phobic disorders, even after controlling for education and socioeconomic status. Several explanations for this finding have been provided. For example, some of the fears reported by African-American individuals may reflect realistic concerns that were misdiagnosed as phobias. For example, African-American persons in inner city communities may have more realistic reasons to fear violence. Furthermore, African-Americans experience more negative evaluation from others, and some of their social concerns may be realistic. Another possibility is that African-Americans experience more chronic stress than whites and therefore may be more susceptible to the development of phobias and other problems. Finally, there may be cultural differences in response biases on questionnaire measures of fear and during interviews.

Research has found that specific phobias, but not social phobias, are more common among US-born Mexican-Americans than in US-born whites or immigrant Mexican-Americans, after controlling for sex, age, socioeconomic status and various other variables. A variety of studies have shown that specific phobias, social phobia and related conditions exist across cultures. For example, in Japan, a condition exists called *taijin kyōfu* in which individuals have an “obsession of shame”. This condition has much overlap with social phobia in that it is often accompanied by fears of blushing, having improper facial expressions in the presence of others, looking at others, shaking and perspiring in front of others. In addition, studies have identified individuals with social and specific phobias in a variety of other nonWestern countries including Saudi Arabia, India, Japan and other East Asian countries. Interestingly, in some other cultures, the sex ratio for

phobias tends to be reversed. For example, in studies from Saudi Arabia and India, up to 80% of individuals reporting for treatment of phobias were male.

Psychiatrists treating patients from different cultures should be aware of cultural differences in presentation and response to treatment, such as cultural differences in verbal communication styles, proxemics (i.e., use of interpersonal space), nonverbal communication and other verbal cues (e.g., tone and loudness). Many cues that a psychiatrist might use to aid in the diagnosis of social phobia in white Americans may not be useful for diagnosing the condition in other cultures. For example, although many psychiatrists interpret a lack of eye contact as indicating shyness or a lack of assertiveness, avoidance of eye contact among Japanese and Mexican-Americans is often viewed as a sign of respect. In contrast to white Americans, Japanese are apparently more likely to view smiling as a sign of embarrassment or discomfort. Furthermore, cultural differences in tone and volume of speech may lead psychiatrists to misinterpret their patients. For example, whereas white Americans are often uncomfortable with silence in a conversation, British and Arab individuals may be more likely to use silence for privacy and other cultures use silence to indicate agreement among the parties or a sign of respect. In addition, Asian individuals have been reported to speak more quietly than white Americans, who in turn speak more quietly than those from Arab countries. Therefore, differences in the volume of speech should not be taken to imply differences in assertiveness or other indicators of social anxiety.

Treatment methods may have to be adapted for different cultures. For example, the direct style of many cognitive and behavioral therapists may be more likely to be perceived as rude or insensitive by individuals with certain cultural backgrounds than those with other backgrounds. It should be noted that individuals within a culture differ on these variables just as individuals across cultures differ. Therefore, although psychiatrists should be aware of cultural differences, these differences should not blind the psychiatrist to relevant factors that are unique to each individual patient.

### Developmental Differences

Among children, specific and social fears are common. Because these fears may be transient, DSM-IV-TR has included a provision that social and specific phobias not be assigned in children unless they are present for more than 6 months. In addition, children may be less likely than adults to recognize that their phobia is excessive or unrealistic. The specific objects feared by children are often similar to those feared by adults, although children may be more likely to fear objects and situations that are not easily classified in the four main specific phobia types in DSM-IV-TR (e.g., balloons or costumed characters). In addition, children often report specific and social phobias having to do with school. Children with social phobia tend to avoid changing for gym class in front of others, eating in the cafeteria, or speaking in front of the class. They may stay home sick on days when frightening situations arise or may make frequent trips to the school nurse. Whereas some investigators have found that boys and girls are equally likely to present for treatment of phobias, others have found social phobia to be more common among girls. In one prospective study of childhood anxiety disorders, Last and colleagues (1996) found that almost 70% of children with a specific phobia were recovered over a 3- to 4-year period compared with a

recovery rate of 86% for social phobia. Thus, almost a third of the clinical sample with specific phobia had symptoms that still met clinical criteria for specific phobia at the end of the follow-up period. This was the lowest recovery rate among the anxiety disorders that were studied. However, those in the clinical sample with specific phobia had the lowest rate of development of new psychiatric disorders (15%) compared with the other anxiety disorders studied (e.g., the rate of development for new psychiatric disorders was 22% for those in the clinical sample with social phobia).

### Diagnosis and Differential Diagnosis

Panic disorder with agoraphobia may easily be misdiagnosed as social phobia or a specific phobia (especially the situational type). For example, many patients with panic disorder avoid a variety of social situations because of anxiety about having others notice their symptoms. In addition, some individuals with panic disorder may avoid circumscribed situations, such as flying, despite reporting no other significant avoidance. Four variables should be considered in making the differential diagnosis: 1) type and number of panic attacks; 2) focus of apprehension; 3) number of situations avoided; and 4) level of intercurrent anxiety.

Patients with panic disorder experience unexpected panic attacks and heightened anxiety outside of the phobic situation, whereas those with specific and social phobias typically do not. In addition, individuals with panic disorder are more likely than those with specific and social phobias to report fear and avoidance of a broad range of situations typically associated with agoraphobia (e.g., flying, enclosed places, crowds, being alone, shopping malls). Finally, patients with panic disorder are typically concerned only about the possibility of panicking in the phobic situation or about the consequences of panicking (e.g., being embarrassed by one's panic symptoms). In contrast, individuals with specific and social phobias are usually concerned about other aspects of the situation as well (e.g., being hit by another driver, saying something foolish).

Consider two examples in which the differential diagnosis with panic disorder might be especially difficult. First, individuals with claustrophobia are typically extremely concerned about being unable to escape from the phobic situation as well as being unable to breathe in the situation. Therefore, like patients with panic disorder and agoraphobia, they usually report heightened anxiety about the possibility of panicking. The main variable to consider in such a case is the presence of panic attacks outside of claustrophobic situations. If panic attacks occur exclusively in enclosed places, a diagnosis of specific phobia might best describe the problem. In contrast, if the patient has unexpected or uncued panic attacks as well, a diagnosis of panic disorder might be more appropriate.

A second example is a patient who avoids a broad range of situations including shopping malls, supermarkets, walking on busy streets, and various social situations including parties, meetings and public speaking. Without more information, this patient's problem might appear to meet criteria for social phobia, panic disorder with agoraphobia, or both diagnoses. As mentioned earlier, patients with panic disorder often avoid social situations because of anxiety about panicking in public. In addition, patients with social phobia might avoid situations that are typically avoided by individuals with agoraphobia for fear of seeing

someone that they know or of being observed by strangers. To make the diagnosis in this case, it is necessary to assess the reasons for avoidance.

Other diagnoses that should be considered before a diagnosis of specific phobia is assigned include post traumatic stress disorder (PTSD) (if the fear follows a life-threatening trauma and is accompanied by other PTSD symptoms such as reexperiencing the trauma), obsessive–compulsive disorder (if the fear is related to an obsession, e.g., contamination), hypochondriasis (if the fear is related to a belief that he or she has some serious illness), separation-anxiety disorder (if the fear is of situations that might lead to separation from the family, for example, traveling on an airplane without one's parents), eating disorders (if the fear is of eating certain foods but not related to a fear of choking) and psychotic disorders (if the fear is related to a delusion).

Social phobia should not be diagnosed if the fear is related entirely to another disorder. For example, if an individual with obsessive–compulsive disorder avoids social situations only because of the embarrassment of having others notice her or his excessive hand washing, a diagnosis of social phobia would not be given. Furthermore, individuals with depression, schizoid personality disorder, or a pervasive developmental disorder may avoid social situations because of a lack of interest in spending time with others. To be considered social phobia, an individual must avoid these situations specifically because of anxiety about being evaluated negatively.

In the case of generalized social phobia, the diagnosis of avoidant personality disorder should be considered as well. Individuals with avoidant personality disorder tend to display more interpersonal sensitivity and have poorer social skills than social phobic patients without avoidant personality disorder. Furthermore, most studies suggest that the differences between avoidant personality disorder and social phobia are more quantitative than qualitative and that the former may simply be a more severe form of the latter. Therefore, most patients who meet criteria for avoidant personality disorder will meet criteria for social phobia as well.

Finally, social and specific phobias should be distinguished from normal states of fear and anxiety. Many individuals report mild fears of circumscribed situations or mild shyness in certain social situations. Others may report intense fears of public speaking or heights but insist that these situations rarely arise and that they have no interest in being in these situations. For the criteria for a specific or social phobia to be met, the individual must report significant distress about having the fear or must report significant impairment in functioning.

A variety of factors should be considered in deciding whether a patient's fear exceeds the threshold necessary for a diagnosis of specific or social phobia. To make the differential diagnosis between normal fears and clinical phobias, the psychiatrist should consider the extent of the individual's avoidance, the frequency with which the phobic stimulus is encountered, and the degree to which the individual is bothered by having the fear. For example, an individual who fears seeing snakes in the wild but who lives in the city never encounters snakes, and never even thinks about snakes would probably not be diagnosed with a specific phobia. In contrast, when an individual's fear of snakes leads to avoidance of walking through parks, camping, swimming and watching certain television programs, despite having an interest in doing these things, a diagnosis of specific phobia would be appropriate.

Similar factors should be considered in deciding at what point normal shyness reaches an intensity that warrants a diagnosis of social phobia. An individual who is somewhat quiet in groups or when meeting new people but does not avoid these situations and is not especially distressed by his or her shyness would probably not receive a diagnosis of social phobia. In contrast, an individual who frequently refuses invitations to socialize because of anxiety, quits a job because of anxiety about having to talk to customers, or is distressed about her or his social anxiety would be likely to receive a diagnosis of social phobia.

Diagnostic decision trees for social and specific phobias are presented in Figures 50.1 and 50.2.

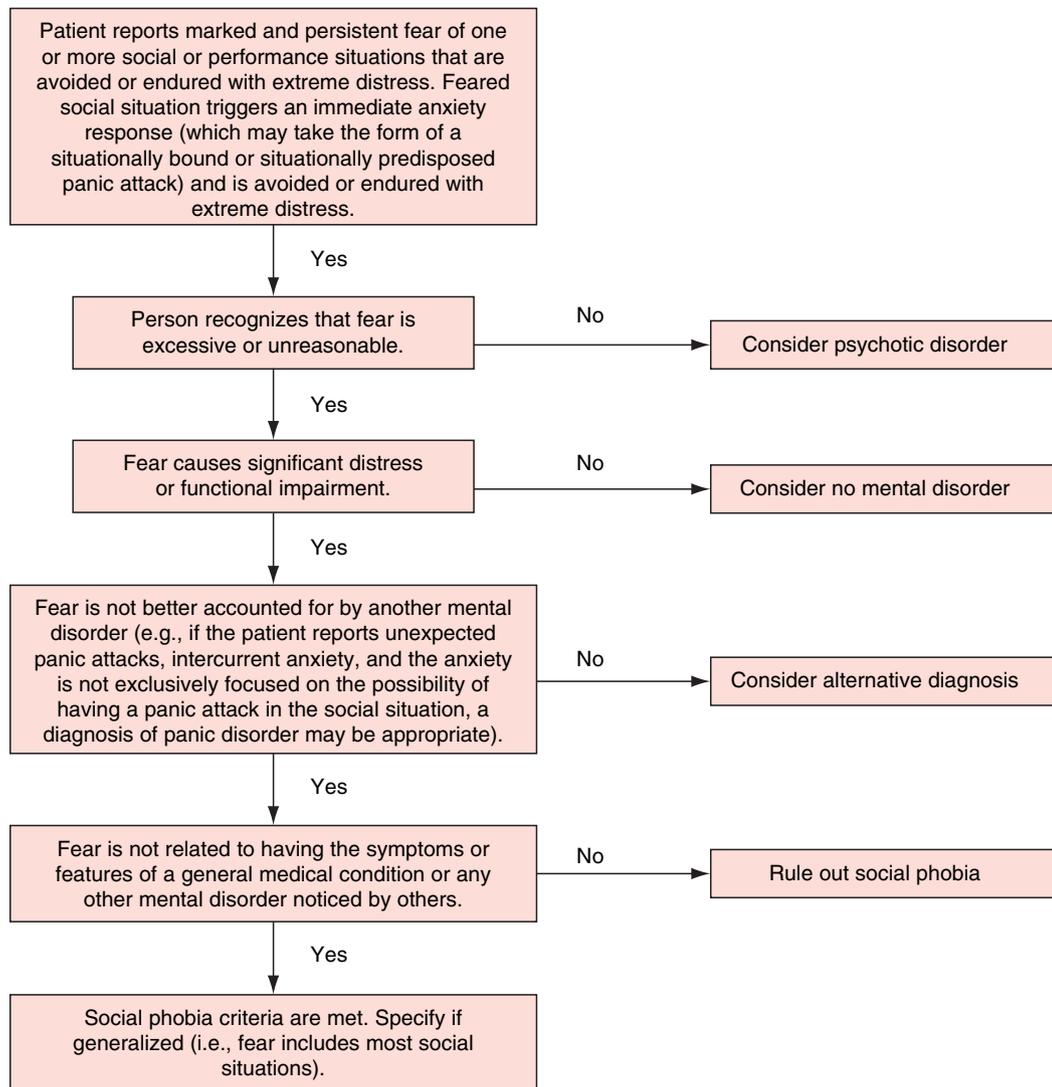

## Specific Phobia Phenomenology and Subtypes

DSM-IV defines five main types of specific phobia: animal, natural environment, blood-injection-injury, situational and other. These types were introduced on the basis of a series of reports showing that specific phobia types tend to differ on a variety of dimensions including age at onset, sex composition, patterns of covariation among phobias, focus of apprehension, timing and predictability of the phobic response, and type of physiological reaction during exposure to the phobic situation.

Although anxiety about physical sensations and the occurrence of panic is a feature typically associated with panic disorder, several studies have shown that panic-focused and symptom-focused apprehensions are not unique to panic disorder and agoraphobia. Individuals with specific phobias tend to report anxiety about the sensations (e.g., racing heart, breathlessness, dizziness) typically associated with their fear. Also, there is evidence that in addition to fearing danger from the phobic object (e.g., a plane crash, being bitten by a dog) many individuals with specific phobias fear danger as a result of their reaction in the phobic situation (e.g., having a panic attack, losing control, being embarrassed). Also, the few relevant studies that have been conducted suggest that there may be differences in sensation-focused apprehension across specific phobia types.

Data are converging to indicate that individuals with phobias from the situational (e.g., claustrophobia) and blood-injury-injection types may be especially internally focused on their fear. Whereas individuals with situational phobias tend to fear the possible consequences of panic, those with blood-injury-injection phobias seem uniquely concerned about sensations that indicate that fainting is imminent (e.g., lightheadedness, hot flashes). Delayed and unpredictable panic attacks may be more characteristic of situational phobias than of other phobia types, consistent with the argument that situational phobias share more features with agoraphobia than do other specific phobia types.

Perhaps the most consistent difference among specific phobia types is the tendency for individuals with blood-injury-injection phobias to report a history of fainting in the phobic situation. Although all phobia types are associated with panic attacks in the phobic situation, only patients with blood and injection phobias report fainting. The different responses experienced in different phobias have been explained from an evolutionary perspective. As mentioned earlier, the typical phobic responses of fear and panic are adaptive in that the increased arousal facilitates escape. In contrast, the most adaptive response during serious injury may be a drop in blood pressure to prevent excessive bleeding. It has been suggested that this response is mediated by an overactive

**Figure 50.1** Diagnostic decision tree for social phobia.

sinoaortic baroreflex that is triggered by heightened arousal in situations involving blood or needles. Of course, in people with blood and injection phobias, the response is excessive and unwarranted, as there is typically no danger of excessive blood loss.

### Social Phobia Phenomenology and Subtypes

Many researchers in the area of social phobia tend to classify the disorder into two main subtypes. DSM-IV requires that diagnosticians specify whether a social phobia diagnosis is “generalized”, or includes most social situations. In addition, a “discrete or circumscribed” subtype is often used by investigators to describe patients with only one domain of social anxiety, usually involving performance-related situations (e.g., public speaking).

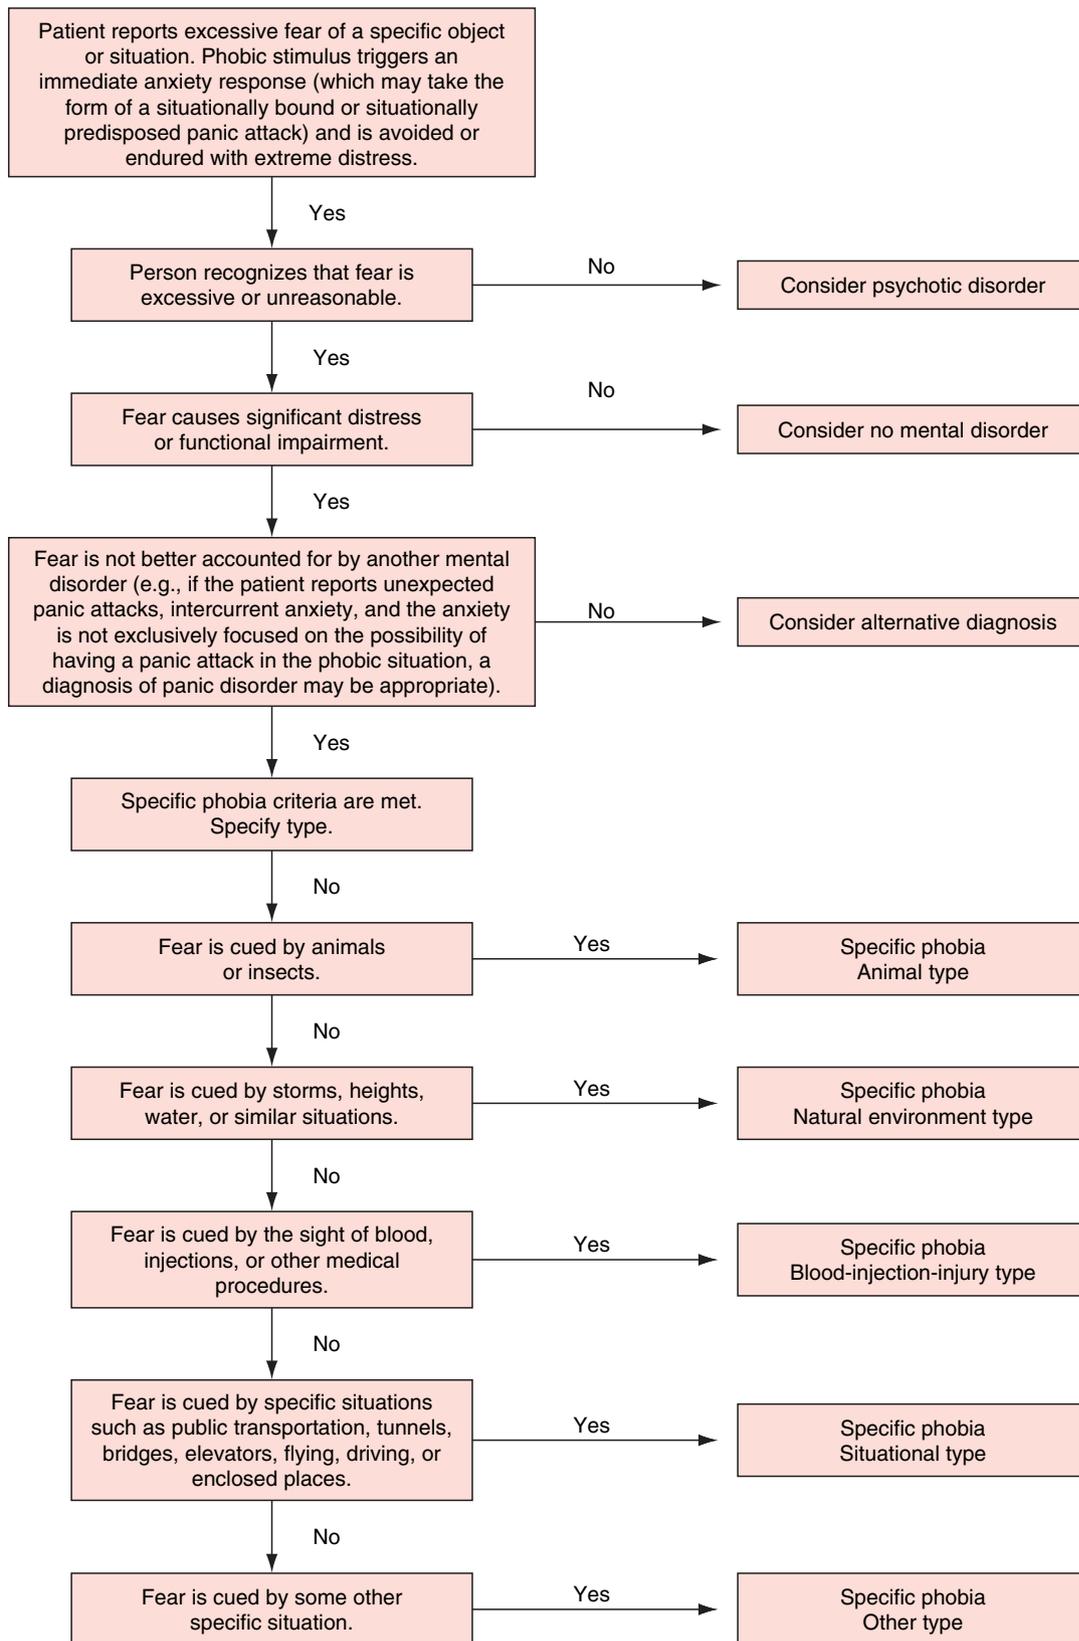

Several studies have examined differences among these subtypes. Specifically, patients with generalized social phobias tend to be younger, less educated and less likely to be employed than are patients with discrete social phobias. In addition, generalized social phobias are associated with more depression, anxiety, general distress and concerns about negative evaluation from others. Discrete social phobias appear to be associated with greater cardiac reactivity.

## Epidemiology and Comorbidity

### Prevalence and Incidence

Phobias are among the most common psychiatric disorders. Findings based on large community samples from five sites in the Epidemiological Catchment Area (ECA) study (Eaton *et al.*, 1991) yielded lifetime prevalence estimates of 11.25% for specific phobias and 2.73% for social phobia. Estimates from the National Comorbidity Survey (NCS) (Kessler *et al.*, 1994) were consistent with previous findings on specific phobias: a lifetime prevalence of 11.30% in a sample of more than 8000 individuals from across the USA. The recent NCS-Replication study found lifetime prevalence rates of 12.5% and 12.1 respectively for specific phobia and social phobia (Kessler *et al.*, 2005).

Specific phobias are more common in women than in men, although there are differences in sex ratio among phobia types. Specifically, the ratio of females to males is smaller for height phobias than for other specific phobia types. Among social phobia situations, sex differences are less pronounced than for most specific phobia types. In the NCS, relatively small sex differences in social phobia prevalence were confirmed, with lifetime estimates of 11.1% for males and 15.5% for females. In addition,

**Figure 50.2** Diagnostic decision tree for specific phobia.

the relatively equal numbers of men and women with social phobia in epidemiological studies is consistent with findings from samples of individuals presenting for treatment.

Most studies have found the mean age at onset of social phobia to be in the middle to late teens. This is supported by research finding that social phobia is common in children and is diagnosed in a significant percentage of children referred to a specialty anxiety disorders clinic. A history of childhood anxiety has been associated with an earlier age of onset of social phobia as well as greater severity and comorbidity. Mean age at onset for specific phobias appears to differ depending on the type of phobia. Phobias of animals, blood, storms and water tend to begin in early childhood, whereas phobias of heights tend to begin in the teens, and phobias of the situational type (e.g., claustrophobia) begin even later, with mean ages at onset in the late teens to middle twenties.

### Comorbidity Patterns

The issue of comorbidity is important for several reasons. First, covariation among disorders provides valuable information about the nature of specific disorders as well as the utility of current diagnostic nomenclature. For example, high rates of cooccurrence between two disorders could reflect overlap in the definitions of two disorders (as may be the case with social phobia and avoidant personality disorder) or shared etiological pathways. In addition, comorbidity may have implications for treatment. For example, an individual with social phobia who abuses alcohol might be less likely to benefit from treatment for social phobia if the alcohol abuse affects compliance with the social phobia treatment.

### Specific Phobias

About 70% of individuals with blood phobias tend to have injection phobias as well. In addition, numerous factor analytical studies have found that blood-injection-injury phobias tend to cluster together as do animal phobias, natural environment phobias and situational phobias. In other words, having a phobia of one specific phobia type makes an individual more likely to have additional phobias of the same type than of other types. However, the clustering is not perfect and many studies show exceptions to this pattern. The research on the classification of specific phobia types is inconsistent. For example, in several of these studies, height phobias tend to be associated with situational phobias (e.g., claustrophobia), despite height phobias being listed as an example of the natural environment type in DSM-IV.

Specific phobias tend to cooccur with other specific phobias. A recent methodologically rigorous study found that 15% of patients with a principal diagnosis of specific phobia also met criteria for another type of specific phobia and that 33% of patients presenting with a principal diagnosis of specific phobia had additional symptoms that met criteria for an Axis I anxiety or mood disorder (Brown *et al.*, 2001a). However, compared with individuals who have other anxiety disorders, individuals with principal diagnoses of a specific phobia are less likely to have additional diagnoses. Rather, specific phobias typically occur on their own or as additional diagnoses of lesser severity than the principal diagnosis. Studies confirm that specific phobias are a frequently occurring additional diagnosis, particularly with other anxiety disorders. However, specific phobias tend to occur less frequently in the context of other disorders such as depression (and alcohol use disorders).

Whereas the above mentioned studies reflect “syndrome” comorbidity, one can also discuss comorbidity at the “symptom”

level. In other words, one can examine the frequency with which specific fears are associated with disorders regardless of whether they meet criteria for specific phobia. It appears that specific phobias commonly occur as additional diagnoses, at both clinical and subclinical levels.

### Social Phobia

Social anxiety is a feature of many disorders. Individuals with panic disorder, obsessive–compulsive disorder, or eating disorders often avoid social situations because of the possibility of being judged negatively if their symptoms are noticed by others. However, to meet diagnostic criteria for social phobia, one’s concerns must not be exclusively related to the symptoms of another disorder. With this criterion in mind, social phobia still tends to be associated with a variety of other DSM-IV disorders. Furthermore, unlike specific phobias, social phobia is frequently associated with additional disorders of lesser severity. One study conducted in two outpatient clinics in a managed care setting found a comorbidity rate of 43.6% in patients with generalized social phobia (Katzelnick *et al.*, 2001). In another study, almost 60% of patients with social phobia had additional symptoms that met criteria for one or more additional diagnoses (Sanderson *et al.*, 1990). The most frequently assigned additional diagnoses in this study were specific phobias (25%), dysthymia (21%) and panic disorder with agoraphobia (17%). The presence of comorbid mood disorders has been associated with a greater duration of social phobia as well as more severe impairment before and after cognitive–behavioral therapy (CBT). Other studies have found that panic disorder with or without agoraphobia, generalized anxiety disorder, major depressive disorder and substance abuse are common additional diagnoses as well. In one prospective study, an estimated relative risk ratio of 2.30 for alcohol abuse or dependence was found in individuals with subclinical social phobia relative to individuals without social phobia or subclinical social fears, suggesting that individuals with subclinical social phobia were more than twice as likely to develop alcohol use disorders than were individuals without social phobia or subclinical social anxiety (Crum and Pratt, 2001).

As an additional diagnosis, social phobia is often assigned in patients with panic disorder with agoraphobia, generalized anxiety disorder, obsessive–compulsive disorder and major depressive disorder. Social phobia is also common among patients with eating disorders and alcohol abuse. When social phobia coexists with a mood disorder, substance abuse disorder, or another anxiety disorder, the social phobia tends to predate the other disorder. Treatment of these disorders should include components that address the social phobia when both disorders occur together.

### Course and Natural History

As discussed earlier, the mean age at onset of social phobia is in the middle teens. The age at onset of specific phobias varies depending on the phobia type, with phobias of animals, blood, storms and water tending to begin in early childhood, phobias of heights beginning in the teens, and situational phobias beginning in the late teens to middle twenties. Although childhood fears are often transient (e.g., most children outgrow fear of the dark without treatment), fears that persist into adulthood usually have a chronic course unless treated.

Although many phobias begin after a traumatic event, many patients do not recall the specific onset of their fear, and

### Clinical Vignette 1

Ms K is a 29-year-old student who presented with social phobia. She reported being shy as a child and could remember pretending to be ill to stay home from school. As she got older, she met more children and by high school was quite comfortable with her friends at school. Meeting new people was still difficult, as was public speaking in class. Fortunately, neither situation came up often.

In college, Ms K's problem became worse. Several of her classes required her to make presentations. In addition, because she lived off campus, she found it particularly difficult to meet friends. The few times she tried to talk to people in class, she felt as though she had nothing to say. Before long, she stopped trying. Ms K did not avoid her class presentations at first. Rather, she tended to overprepare for them and tried to use overheads when possible because the dark room helped to decrease her anxiety. Still during presentations she could feel her heart pounding and she tended to have difficulty breathing. Her mouth became dry and she was sure that her classmates could see her shaking and perspiring.

After her first year of college, Ms K began to avoid any class that required presentations. In addition, she found herself avoiding other situations in which people might notice her shaking. Specifically, she avoided writing in front of others, holding drinking glasses and other situations that might focus other people's attention on her hands. She also avoided engaging in conversation with others and when people approached her, she tried to end the conversation as quickly as possible. In addition to fearing that others would notice her anxiety, Ms K felt that others might see her as weak, unattractive, or foolish.

During a diagnostic interview, it was found that Ms K was suffering from social phobia. She seemed bright and motivated, and it was decided that she might benefit from CBGT for social phobia. However, the patient initially rejected this option because of anxiety about participating in a group. Therefore, she started 10 mg of paroxetine and gradually increased the dosage to 50 mg. Because of difficulties due to sexual dysfunction, the dosage was decreased to 40 mg and her sexual symptoms subsided.

During a period of 6 weeks, Ms K felt more comfortable around people and decided that she was willing to participate in a 12-session CBGT program. Treatment included a variety of components, including information about the nature of anxiety and social phobia, cognitive restructuring, role-play exposures to anxiety-provoking situations (e.g., group presentations) and homework assignments to enter feared situations. In addition, Ms K practiced purposely shaking in front of others, until the symptom was no longer frightening to her. Over the course of the CBGT, Ms K's medication was gradually discontinued. By the end of treatment, Ms K was essentially symptom free and criteria for social phobia were no longer met. Furthermore, she had met several new friends and had enrolled in a few classes that required her to make presentations. Although she still became nervous before speaking in public, she looked forward to the presentations. She rarely experienced shaking in front of others and was no longer particularly concerned about shaking.

few empirical data have examined the initial period after the fear onset. Clinically, however, some patients report a sudden onset of fear, whereas others report a more gradual onset. Studies examining the onset of phobias have tended to assess the onset of the **fear** rather than the onset of the **phobia** (i.e., the point at which the fear creates significant distress or functional impairment). A study by Antony and colleagues (1997) suggests that the fear and phobia onset are often not the same. Patients with specific phobias of heights, animals, blood-injection, or driving were asked to estimate the earliest age at which they could recall having their fear and the earliest age at which they could recall experiencing distress or functional impairment due to their fear. Anecdotally, the types of factors leading to the transition from fear to phobia included gradual increases in the intensity of fear, additional traumatic events (e.g., panic attacks, car accidents), increased life stress and changes in living situation (e.g., starting a job that requires exposure to heights). Similarly, it is not unusual for individuals with social phobia to report having been shy as children, although their anxiety may not have reached phobic proportions until later.

## Treatment

### Goals and Nature of Treatment

The main goal of treatment is to decrease fear and phobic avoidance to a level that no longer causes significant distress or functional impairment. In some cases, treatment includes strategies for improving specific skill deficits as well. For example, individuals with social phobia may lack adequate social skills and can sometimes benefit from social skills training. Likewise, some individuals with specific phobias of driving may have poor driving skills if their fear prevented them from learning how to drive properly. Typically, effective treatment for social phobia lasts several months, although treatment of discrete social phobias (e.g., public speaking) may take less time. Specific phobias can usually be treated relatively quickly. In fact, for certain phobias, the vast majority of individuals are able to achieve clinically significant, long-lasting improvement in as little as one session of behavioral treatment.

Effective treatments fall into one of two main categories: pharmacological treatment and CBT. Pharmacological treatments have been used effectively for treating social phobia, although it is generally accepted that they are of limited utility for treating specific phobias. In contrast, CBT has been used with success for the treatment of specific and social phobias. Despite the existence of effective treatments, fewer than half of those who seek treatment in an anxiety disorders specialty clinic have previously received evidence-based treatments for their social anxiety (Rowa *et al.*, 2000). Tables 50.2 and 50.3 summarize various treatments for social and specific phobias.

## Pharmacotherapy

### Specific Phobia

Pharmacotherapy is generally thought to be ineffective for specific phobias. However, little research has been conducted to assess the utility of medications for specific phobias, and it is not uncommon for phobic patients occasionally to be prescribed low dosages of benzodiazepines to be taken in the phobic situation (e.g., while flying). The few relevant studies that have been conducted have

**Table 50.2** Treatments for Social Phobia

Treatment	Advantages	Disadvantages	Rating
Cognitive-behavioral therapy (CBT) (e.g., exposure, cognitive restructuring, social skills training, education)	Good treatment response Brief course of treatment Treatment gains maintained at follow-up Considered first line	May lead to temporary increases in discomfort or fear.	++++
SSRIs (e.g., paroxetine, fluvoxamine, sertraline)	Good treatment response Early response, relative to CBT Broad spectrum efficacy for comorbid disorders (i.e., depression) Lack of abuse potential Considered first line	Side effects are common. Cost is a factor. May be a risk of relapse after discontinuation.	+++
Moclobemide	Good treatment response in some studies Fewer side effects than phenelzine Considered second line	Side effects common. Does not separate from placebo in some studies. Potential exists for relapse after discontinuation	++
Benzodiazepines (e.g., clonazepam, alprazolam)	Good treatment response Considered adjunctive or second line	Side effects and withdrawal occur. Potential for abuse. Relapse after discontinuation is likely. Does not treat certain comorbid conditions (i.e., depression)	++
MAOIs (e.g., phenelzine)	Good treatment response Early response Considered third line	Relatively high rate of adverse effects. Dietary restrictions must be followed. Numerous drug interactions. Potential exists for relapse after discontinuation.	++
Gabapentin	Possibly beneficial Considered third line	Side effects are common. More research is needed	++
$\beta$ -blockers (e.g., atenolol)	Appears to be useful for “stage fright” in actors, musicians, and other performers	Drugs are not effective for generalized social phobia. Benefits for discrete social phobias are questionable. Side effects occur. Potential exists for relapse after discontinuation.	+

+++++ First treatment of choice. Helpful for most patients, with few side effects. Good long-term benefits.

+++ Helpful for most patients. Potential for relapse after treatment is discontinued.

++ More controlled research needed, although preliminary studies suggest potential benefit OR research has been mixed.

+ Not especially effective for generalized social phobia.

examined the use of benzodiazepines and beta-blockers alone or in combination with behavioral treatments for specific phobias and in general have found that drugs do not contribute much to the treatment of specific phobias. However, one problem with the research to date is that it has not taken into account differences among specific phobia types. For example, claustrophobia and other phobias of the situational type appear to share more features with panic disorder than with the other specific phobia types. Therefore, medications that are effective for panic disorder (e.g., imipramine, alprazolam) may prove to be effective for situational phobias. Although there are few studies examining this hypothe-

sis, preliminary data suggest that benzodiazepines may be helpful in the short term but lead to greater relapse in the long term and possibly interfere with the therapeutic effects of exposure across sessions. There have been very few controlled studies to date examining the effectiveness of antidepressants for specific phobia.

### Social Phobia

In contrast to specific phobias, social phobia has been treated successfully with a variety of pharmacological interventions including SSRIs such as sertraline, fluvoxamine and paroxetine, benzodiazepines such as alprazolam, traditional monoamine

**Table 50.3** Treatments for Specific Phobias

Treatment	Advantages	Disadvantages	Rating
<i>In vivo</i> exposure	Highly effective Early response Treatment gains maintained at follow-up	May lead to temporary increases in discomfort or fear.	++++
Applied tension	Highly effective for patients with blood-injection phobias who faint Early response Treatment gains maintained at follow-up	Treatment is relevant for a small percentage of patients with specific phobias.	+++
Applied relaxation	May be effective for some patients	Treatment has not been extensively researched for specific phobias.	++
Cognitive therapy	May help to reduce anxiety about conducting exposure exercises	Treatment has not been extensively researched for specific phobias. Treatment is probably not effective alone.	++
Benzodiazepines	May reduce anticipatory anxiety before patient enters phobic situation, and may reduce fear, particularly in situational specific phobias	Treatment has not been extensively researched for specific phobias. Treatment is probably not effective alone, in many cases. Side effects (e.g., sedation) occur. Discontinuation of symptoms may undermine benefits of treatment.	
SSRIs	May reduce panic sensations for individuals with situational phobias that are similar to panic disorder (e.g., claustrophobia)	Treatment has not been extensively researched for specific phobias. There are a few studies (primarily case reports) with promising results. Discontinuation of medication may result in a return of fear.	++

++++ Treatment of choice. Effective for almost all patients.

+++ Very effective for a subset of patients.

++ May be helpful for some patients. More research needed.

oxidase inhibitors (MAOIs) such as phenelzine and reversible inhibitors of monoamine oxidase A (RIMA), such as moclobemide and brofaromine.

Numerous controlled trials across a range of SSRIs including sertraline, fluvoxamine and paroxetine have demonstrated their effectiveness in the treatment of social phobia, such that the SSRIs are currently considered the first-line medication treatment. Due to their tolerability and efficacy, the SSRIs have been referred to as “the new gold standard” in pharmacological treatment for social phobia. Uncontrolled open trials and case series studies with citalopram and fluoxetine suggest that these SSRIs may also be beneficial in the treatment of social phobia. Another benefit of SSRIs is their broad spectrum efficacy for common comorbid disorders such as depression and panic disorder.

Research on the use of anxiolytics for the treatment of social phobia have focused on high potency benzodiazepines (e.g., clonazepam, alprazolam) and the nonbenzodiazepine buspirone. Several studies have examined the significant utility of clonazepam for treating social phobia. Alprazolam may also be effective but there are too few studies to establish this. The findings on buspirone are mixed.

Due to the potentially severe side effects of MAOIs as well as the necessity for certain dietary restrictions, they are not

recommended as a first-line treatment. The findings from more recent trials involving RIMAs have been less encouraging than initial studies suggested. Discontinuation of MAOIs and RIMAs have been associated with a tendency to relapse.

Research on beta-blockers indicates that they are no better than placebo for most patients with generalized social phobia. Although beta-blockers have been used to treat individuals from nonpatient samples with heightened performance anxiety (e.g., people with public speaking anxiety, musicians with stage fright), their efficacy for treating individuals with discrete social phobia has not been established. Nevertheless, beta-blockers are often prescribed for discrete performance-related social phobias. Preliminary findings suggest that gabapentin, a medication typically used in the treatment of partial seizures, may be effective in the treatment of social phobia, but more research is needed to confirm this finding.

## Psychosocial Treatments

### Specific Phobias

Numerous studies have shown that exposure-based treatments are effective for helping patients to overcome a variety of specific

phobias including fears of blood, injections dentists, spiders, snakes, rats), enclosed places, thunder and lightning, water, flying, heights, choking and balloons. Furthermore, the way in which exposure is conducted may make a difference. Exposure-based treatments can vary on a variety of dimensions including the degree of therapist involvement, duration and intensity of exposure, frequency and number of sessions, and the degree to which the feared situation is confronted in imagination versus in real life. In addition, because individuals with certain specific phobias often report a fear of panicking in the feared situation, investigators have suggested that adding various panic management strategies (e.g., cognitive restructuring, exposure to feared sensations) may help to increase the efficacy of behavioral treatments for specific phobias. It remains to be shown whether the addition of these strategies will improve the efficacy of treatments that include only exposure.

Exposure seems to work best when sessions are spaced close together. Secondly, prolonged exposure seems to be more effective than exposure of shorter duration. Thirdly, during exposure sessions, patients should be discouraged from engaging in subtle avoidance strategies (e.g., distraction) and over-reliance on safety signals (e.g., being accompanied by one's spouse during exposure). Fourth, real-life exposure is more effective than exposure in imagination. Fifthly, exposure with some degree of therapist involvement seems to be more effective than exposure that is exclusively conducted without the therapist present. Exposure may be conducted gradually or quickly. Both approaches seem to work equally well, although patients may be more compliant with a gradual approach. Finally, in the case of blood and injection phobias, the technique called applied muscle tension should be considered as an alternative or addition to exposure therapy. Applied muscle tension involves having patients repeatedly tense their muscles, which leads to a temporary increase in blood pressure and prevents fainting upon exposure to blood or medical procedures.

Cognitive strategies have also been used either alone or in conjunction with exposure for treating specific phobias. The evidence suggests that the addition of cognitive strategies to exposure may provide added benefit for some individuals. For a detailed guide to integrating cognitive strategies with exposure see Antony and Swinson (2000).

Specific phobias are among the most treatable of the anxiety disorders. For example, in as little as one session of guided exposure lasting 2 to 3 hours, the majority of individuals with animal or injection phobias are judged much improved or completely recovered. A recent study demonstrated that one session of exposure treatment was effective in the treatment of children and adolescents with various specific phobias and exposure conducted with a parent present was equally effective as exposure treatment conducted alone. However, despite how straightforward the concept of exposure may seem, many subtle clinical issues can lead to problems in implementing exposure-based treatments. For example, although a patient might be compliant with therapist-assisted exposure practices, he or she may refuse to attempt exposure practices alone between sessions. In such cases, involving a spouse or other family member as a coach during practices at home may help. In addition, gradually increasing the distance between therapist and patient during the therapist-assisted exposures will help the patient to feel comfortable when practicing alone. However, to maintain the patient's trust and to maximize the effectiveness of behavioral interventions, it is important that exposure practices proceed in a predictable way, so that the patient is not surprised by unexpected events. Several

self-help books and manuals for treating a range of specific phobias have been published in the past decade. Whereas some of these manuals were developed to be used with the assistance of a therapist (Bourne, 1998; Antony *et al.*, 1995; Craske *et al.*, 1997), others were developed for self-administration (Brown, 1996).

Recent developments in technology have started to have an impact on the treatment of specific phobias. Videotapes are commonly used to show feared stimuli to patients during exposure. Computer administered treatments have also been used. More recent is the use of virtual reality to expose patients to simulated situations that are more difficult to replicate *in vivo* such as flying (Kahan *et al.*, 2000) and heights (Rothbaum *et al.*, 1995). Emerging data on the effectiveness of virtual reality is encouraging. However, other preliminary studies indicate that *in vivo* exposure is still superior (Dewis *et al.*, 2001).

## Social Phobia

Empirically validated psychosocial interventions for social phobia have primarily come from a cognitive-behavioral perspective and include four main types of treatment: 1) exposure-based strategies; 2) cognitive therapy; 3) social skills training; and 4) applied relaxation. Exposure-based treatments involve repeatedly approaching fear-provoking situations until they no longer elicit fear. Through repeated exposure, patients learn that their fearful predictions do not come true despite their having confronted the situation. Table 50.4 illustrates an example of an exposure hierarchy that might be used to structure a patient's exposure practices. An exposure hierarchy is a list of feared situations that are rank ordered by difficulty and used to guide exposure practices for phobic disorders including social phobia and specific phobia. The patient and therapist generate a list of situations that the patient finds anxiety provoking. Items are placed in descending order from most anxiety provoking to least anxiety provoking, and each item is rated with respect to how anxious the patient might be to practice the item. Exposure practices are designed to help the patient become more comfortable engaging in the activities from the hierarchy. Cognitive therapy helps patients identify and change anxious thoughts (e.g., "Others will think I am stupid

**Table 50.4 Exposure Hierarchy for Generalized Social Phobia**

Item	Fear Rating (0–100)
Have a party and invite everyone from work.	99
Go to work Christmas party for 1 h without drinking	90
Invite Cindy to have dinner and see a movie.	85
Go for a job interview	80
Ask boss for a day off from work	65
Ask questions in a meeting at work	65
Eat lunch with coworkers	60
Talk to a stranger on the bus	50
Talk to cousin on the telephone for 10 min	40
Ask for directions at the gas station.	35

if I participate in a conversation at work”) by teaching them to consider alternative ways of interpreting situations and to examine the evidence for their anxious beliefs. Social skills training is designed to help patients to become more socially competent when they interact with others. Treatment strategies may include modeling, behavioral rehearsal, corrective feedback, social reinforcement and homework assignments. Finally, applied relaxation involves learning to relax one’s muscles during rest, during movement and eventually in anxiety-provoking social situations.

Although these methods are presented as four distinct treatment approaches, there is often overlap among the various treatments. Social skills training typically requires exposure to the phobic situation so that new skills may be practiced (e.g., behavioral rehearsal). The same may be said of applied relaxation, which includes learning to conduct relaxation exercises in the phobic situation. In fact, most treatments for social phobia involve some type of exposure to anxiety-provoking social interactions and performance-related tasks. Furthermore, many cognitive-behavioral therapists treat patients using several different strategies delivered in a comprehensive package.

Studies demonstrating the efficacy of CBT for social phobia are too numerous to describe in detail. Several studies have compared various cognitive-behavioral strategies and their combinations for treating social phobia. For example, Wlazlo and colleagues (1990) compared social skills training to exposure therapy conducted either individually or in groups. All three treatments led to significant improvements and there were no differences between treatments. However, exposure therapy conducted in groups tended to be more effective for the subset of patients with social skills deficits, most likely by enabling those individuals with deficits to develop their skills through exposure to social situations and interactions in the group. There is conflicting evidence that guided exposure is more effective when cognitive therapy is included than when exposure is conducted without cognitive therapy.

Heimberg and colleagues (1990) compared supportive psychotherapy with a comprehensive CBGT package that included exposure to simulated and real social situations as well as cognitive restructuring for the treatment of social phobia. Although both groups improved on most measures, patients receiving CBGT were significantly more improved immediately after treatment and at 3- and 6-month follow-up. CBGT was more effective despite that patient ratings of treatment credibility and expectations for improvement were equal for both treatments. Patients receiving CBGT continued to be more improved at 5-year follow-up, although only 41% of the original sample participated in the follow-up study, which limited the validity of these findings.

Four treatments for social phobia have been compared: 1) CBGT, 2) phenelzine, 3) supportive psychotherapy, and 4) placebo. Overall, both phenelzine and CBGT were equally effective after 12 weeks of treatment and were significantly more effective than placebo or supportive psychotherapy. Phenelzine tended to work more quickly than CBGT and appeared to be more effective on a few measures. However, preliminary analyses of long-term outcome showed that after discontinuing treatment, patients receiving CBGT were more likely than patients who received phenelzine to maintain their gains, with approximately half of patients taking phenelzine relapsing, compared with none of the patients who responded to CBGT.

In a randomized clinical trial comparing cognitive therapy to moclobemide for social phobia, Oosterbaan and colleagues (2001) found that cognitive therapy was significantly better than

moclobemide, but not placebo, after 15 weeks of active treatment. After a 2-month follow-up period, cognitive therapy was significantly better than both moclobemide and placebo. In addition, treatment gains in the cognitive therapy group were maintained over a 15-month follow-up period.

Exposure therapy alone or in combination with sertraline for generalized social phobia in a primary care setting has been studied. Family physicians (FPs) were trained for 30 hours in assessment of social phobia and in the application of exposure therapy. FPs reported satisfaction with the training program and found that the exposure treatment was also useful for treating patients with other conditions. Although exposure therapy and sertraline were effective alone, the combination of exposure therapy and sertraline appeared to confer added benefit.

According to cognitive models of social phobia, one of the mechanisms by which CBT works is by causing a positive shift in an individual’s self-representation (e.g., decreased negative self-focused thoughts and increased task-focused thoughts and positive self-focused thoughts). Indeed, there is evidence that following CBT, individuals report significantly fewer negative self-focused thoughts. Similarly, cognitive biases are reduced following successful pharmacotherapy treatment as well and are related to the degree of symptomatic improvement in both psychological and pharmacological treatments.

In summary, it seems clear that effective psychosocial treatments and medications for social phobia exist. Although both types of treatments appear to be equally effective, each has advantages and disadvantages. Medication treatments may work more quickly and are less time-consuming for the patient and therapist. In contrast, improvement after CBT appears to last longer. Due to medication side effects, CBT may be more appropriate for some individuals. More studies are needed to examine the efficacy of combined medication and psychosocial treatments for social phobia. A meta-analysis of 24 studies examining cognitive-behavioral and medication treatments for social phobia found that both treatments were more effective than control conditions (Gould *et al.*, 1997). In this study, the SSRIs and benzodiazepines tended to have the largest effect sizes among medications and treatments involving exposure either alone or with cognitive therapy had the largest effect sizes among CBT. Another meta-analytic study of 108 psychological and pharmacological treatment-outcome trials found that the pharmacotherapies (SSRIs, benzodiazepines, MAO inhibitors) were the most consistently effective treatments, with both SSRIs and benzodiazepine treatments equally effective and more effective than control groups (Fedoroff and Taylor, 2001). Further, maintenance of treatment gains for CBT was moderate and continued during follow-up intervals. In comparison, it is not known the extent to which treatment gains for medication treatments are maintained following discontinuation. Treatment decision trees for social and specific phobias are presented in Figures 50.3 and 50.4.

### Predictors of Treatment Outcome

Few studies have examined predictors of outcome for treatment of specific and social phobias. However, the few studies that do exist fall into two main categories. First, several investigators have attempted to match treatment strategies to specific characteristics of patients. Secondly, several studies have examined the relationship between individual differences (e.g., duration and severity of illness, personality factors) and response to treatment.

Much more research is needed to identify predictors of outcome with CBT and especially with pharmacological treatment. For example, little is known about the effectiveness of treatments for specific and social phobias in special populations (e.g., elderly persons, culturally diverse groups). There has also been a lack of research on the impact of comorbidity on success of treatment with specific phobias.

### Relapse and Return of Fear

With respect to specific phobia, it is common for some return of fear to occur in the presence of the phobic stimulus. Relapse following treatment of a specific phobia is believed to be rare. A number of variables have been identified that predict return of fear including distraction during exposure, a relatively quick reduction in fear during exposure, a relatively slow reduction in fear during exposure, higher initial heart rate, spacing of exposure sessions and the degree to which the exposure stimuli are varied, the tendency to over associate fear-relevant stimuli with aversive.

### Refractory Patients and Nonresponse to Initial Treatment

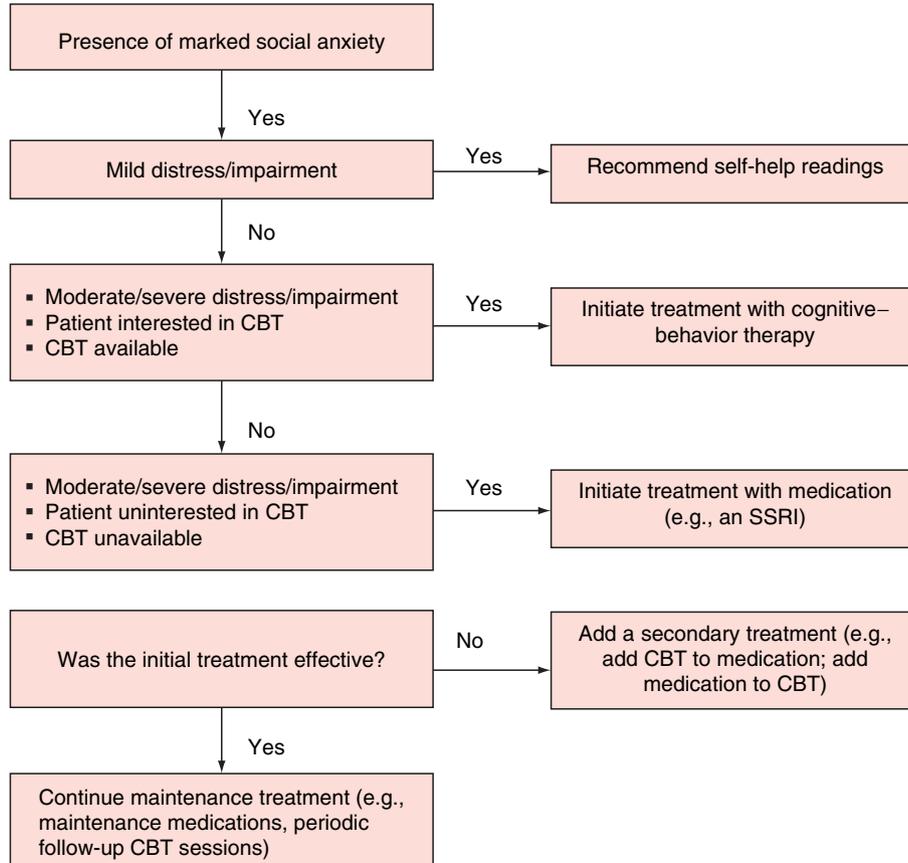

Several variables may lead to an initially poor treatment response. Anticipating potential difficulties will help increase treatment efficacy. Possible reasons for a worse outcome include poor compliance, poor motivation and poor understanding of the treatment procedures. In addition, interpersonal issues and other

possible conflicts may interfere with the successful treatment of specific and social phobias.

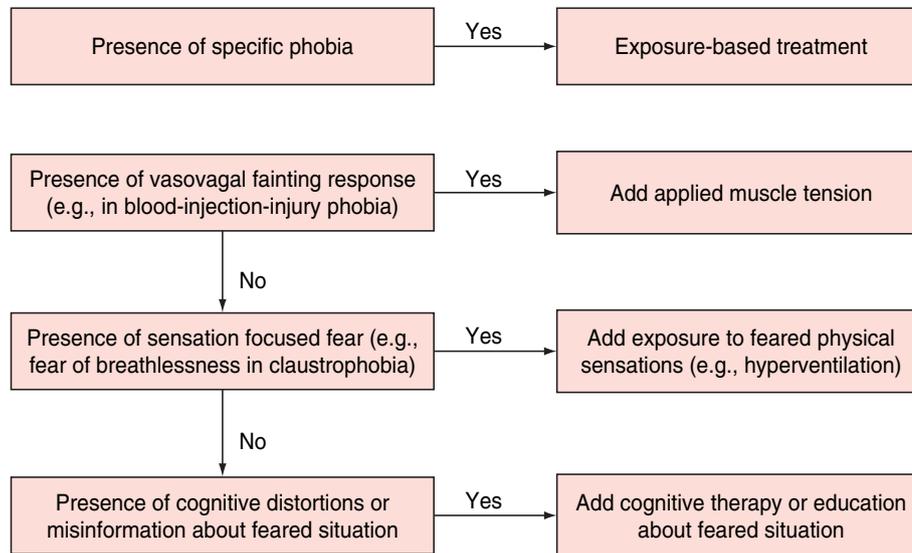

Patients fail to comply with treatment procedures for a variety of reasons. In the case of pharmacological treatments, patients may avoid taking medications because of side effects, lack of confidence in efficacy, or preference for an alternative type of treatment. If patients are not compliant with medications, the physician should attempt to identify the reasons for poor compliance and to suggest methods of increasing compliance or changing to another type of treatment.

In the case of CBT, common reasons for poor compliance are anxiety about conforming to treatment, lack of time and lack of motivation to conduct the treatment properly. Because CBT requires patients to confront the situations they fear most, patients often feel extreme anxiety about participating in the treatment. Patients should be reassured that their anxiety is normal and that they will never be forced to do anything that they are unwilling to try. Furthermore, the difficulty of exposure tasks should be increased gradually to maximize treatment compliance. If patients do not have the time or motivation to conduct treatment as suggested, therapists should be willing to find ways to make the treatment more accessible to the patient. For example, involvement of a friend or relative of the patient as a coach may allow the patient to conduct more practices without the therapist's assistance. The therapist could also explore the possibility that the patient consider beginning treatment later, when more time is available.

Poor motivation can lead to poor compliance with the treatment procedures. If a patient's symptoms are not especially se-

**Figure 50.3** Treatment decision tree for social phobia.

**Figure 50.4** Treatment decision tree for specific phobia.

vere, the distress and impairment created by the disorder may not be enough to motivate the patient to take medications regularly or to confront the phobic situation in a systematic way. Furthermore, as a patient improves in treatment, she or he may experience a decrease in motivation. Patients should be encouraged to continue with treatment assignments even after improvement. More complete improvements may protect against a return of symptoms.

Finally, treatment procedures may be complicated for some patients. This is especially the case for CBT. Patients may fail to complete homework assignments (e.g., monitoring anxious cognitions) simply because the treatment rationale and the specifics of how to conduct the treatment procedures were not made clear. Therefore, therapists should continually assess the patient's understanding of the treatment procedures.

### Comparison of DSM-IV/ICD-10 Diagnostic Criteria

The ICD-10 Diagnostic Criteria for Research for Social Phobia specify that at least two symptoms of anxiety (i.e., from the list of 14 panic symptoms) be present together on at least one occasion along with at least one of the following anxiety symptoms: blushing or shaking, fear of vomiting, and urgency or fear of micturition or defecation. Furthermore, these anxiety symptoms must be "restricted to, or predominated in, the feared situations or contemplation of the feared situations". In contrast, the DSM-IV criteria do not specify any particular types of anxiety symptoms nor is any restriction placed on whether anxiety can occur in situations other than social situations.

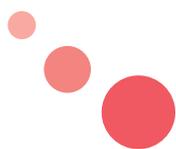

For specific phobia, the ICD-10 Diagnostic Criteria for Research also specify that the anxiety symptoms be "restricted to, or predominated in, the feared situations or contemplation of the feared situation". DSM-IV again does not impose any such restriction.

# Obsessive–Compulsive Disorder

## Definition and Overview

Obsessive–compulsive disorder (OCD) is an intriguing and often debilitating syndrome characterized by the presence of two distinct phenomena: obsessions and compulsions. Obsessions are intrusive, recurrent, unwanted ideas, thoughts, or impulses that are difficult to dismiss despite their disturbing nature. Compulsions are repetitive behaviors, either observable or mental, that are intended to reduce the anxiety engendered by obsessions. Both obsessions and compulsions have been described in a wide variety of psychiatric and neurological disorders. However, obsessions and compulsions that clearly interfere with functioning and/or cause significant distress are the hallmark of OCD.

Although OCD was originally considered rare, findings from the Epidemiologic Catchment Area (ECA) survey in 1984 demonstrated that OCD was 50 to 100 times more common than had been previously believed. With increasing recognition of OCD, both in the mental health field and in the media, many individuals with OCD have pursued treatment for this disorder. This has led to systematic investigation of clinical features such as symptom subtype, course, comorbidity, and the role of insight both descriptively and as mediators of treatment response.

These studies, conducted over the past 15 years, have greatly furthered our understanding of the clinical characteristics of this disorder. OCD is now considered a relatively common disorder that usually has its onset during puberty, although it may begin as early as age 2 years and infrequently begins after age 35 years. Women develop OCD slightly more often than men. Earlier studies found that the course of OCD is usually chronic, with symptom severity waxing and waning over time. However, those studies, which had a number of methodological limitations, were conducted prior to the availability of effective treatments for this disorder. More recent evidence suggests that some individuals have a more episodic and favorable course.

Several large studies have found that the most common obsession is contamination, and the most common compulsion is checking. However, most individuals with this disorder have multiple obsessions and compulsions over time. A number of psychiatric disorders cooccur with OCD, major depressive disorder being most frequent. Comorbidity with tic disorders is well established. That association plus a familial relationship between OCD and tic disorders has led to suggestions that tic-related OCD is a specific phenotype of OCD that is more closely related to tic disorders.

There has been considerable interest in the role of insight, or awareness, in OCD. An ability to recognize the senselessness of

the obsessions and the ability to resist obsessional ideas have been considered fundamental components of OCD. However, research findings during the past decade have demonstrated a continuum of insight in this disorder, which ranges from excellent (i.e., complete awareness of the senselessness of the content of the obsessions), through poor insight, to delusional thinking (i.e., the obsessions are held with delusional conviction). To reflect these findings, the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (DSM-IV) established a new OCD specifier – with poor insight – and also noted that, in cases of delusional OCD, an additional diagnosis of delusional disorder or psychotic disorder not otherwise specified may be appropriate (American Psychiatric Association, 1994).

## Epidemiology

The ECA study found that OCD was the fourth most common psychiatric disorder (after the phobias, substance use disorders and major depressive disorder), with a prevalence of 1.6% over 6 months and a lifetime prevalence of 2.5% (Myers *et al.*, 1984; Robins *et al.*, 1984). Although the ECA survey has been criticized as overestimating OCD's prevalence a subsequent study in the USA and several epidemiological studies in other countries have supported its findings. The National Comorbidity Survey Replication (NCS-R) found the lifetime prevalence for OCD to be 1.6% (Kessler *et al.*, 2005). Using the same instrument as the ECA, studies have been done in diverse cultures, including Puerto Rico, Canada, Germany, Taiwan, New Zealand and Korea, as part of the Cross National Collaborative Group (Weissman *et al.*, 1994). The lifetime (range 1.9–2.5%) and annual (range 1.1–1.8%) prevalence rates of OCD were remarkably consistent across countries with the exception of Taiwan. The rates in Taiwan were substantially lower than in all the other sites, paralleling Taiwan's low rates of other psychiatric disorders.

## Demographic Characteristics

### Gender Distribution

Women appear to develop OCD slightly more frequently than do men. A pooled sample from two studies with a total of 991 subjects found that 52% of the subjects were women. However, a study that assessed the presence of comorbid disorders characterized by psychosis (schizophrenia, delusional disorder) or psychosis-like features (schizotypal personality disorder) in 475 patients with OCD found a different sex ratio. Fifty-six percent of the patients with OCD who did not have one of these comorbid disorders were women, whereas 85% of those with one

**DSM-IV-TR Criteria 300.3****Definition of Obsessive–Compulsive Disorder**

Either obsessions or compulsions:

*Obsessions as defined by (1), (2), (3), and (4):*

- (1) recurrent and persistent thoughts, impulses, or images that are experienced, at some time during the disturbance, as intrusive and inappropriate and that cause marked anxiety or distress
- (2) the thoughts, impulses, or images are not simply excessive worries about real-life problems
- (3) the person attempts to ignore or suppress such thoughts, impulses, or images, or to neutralize them with some other thought or action
- (4) the person recognizes that the obsessional thoughts, impulses, or images are a product of his or her own mind (not imposed from without as in thought insertion)

*Compulsions as defined by (1) and (2):*

- (1) repetitive behaviors (e.g., hand washing, ordering, checking) or mental acts (e.g., praying, counting, repeating words silently) that the person feels driven to perform in response to an obsession, or according to rules that must be applied rigidly
- (2) the behaviors or mental acts are aimed at preventing or reducing distress or preventing some dreaded event or situation; however, these behaviors or mental acts either are not connected in a realistic way with what they are designed to neutralize or prevent or are clearly excessive

At some point during the course of the disorder, the person has recognized that the obsessions or compulsions are excessive or unreasonable. Note: This does not apply to children.

The obsessions or compulsions cause marked distress, are time consuming (take more than 1 hour a day), or significantly interfere with the person's normal routine, occupational (or academic) functioning, or usual social activities or relationships.

If another Axis I disorder is present, the content of the obsessions or compulsions is not restricted to it (e.g., preoccupation with food in the presence of an eating disorder; hair pulling in the presence of trichotillomania; concern with appearance in the presence of body dysmorphic disorder; preoccupation with drugs in the presence of a substance use disorder; preoccupation with having a serious illness in the presence of hypochondriasis; preoccupation with sexual urges or fantasies in the presence of a paraphilia; or guilty ruminations in the presence of major depressive disorder).

The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

*Specify if:*

**With poor insight:** if, for most of the time during the current episode, the person does not recognize that the obsessions and compulsions are excessive or unreasonable

of these comorbid disorders were men. A predominance of males has also been observed in child and adolescent OCD populations. In a study of 70 probands with OCD who were aged 6 to 18 years, 67% were males. This finding may be due to the fact that males develop OCD at a younger age than do females.

### Marital Status

Although marital status was not found to be a predictor of course in a number of earlier studies, a recent prospective study of 107 subjects with OCD found that being married significantly increased the probability of partial remission, with married patients more than twice as likely to remit as unmarried ones (Steketee *et al.*, 1999).

## Course and Natural History

### Age at Onset

Age at onset usually refers to the age when OCD symptoms (obsessions and compulsions) reach a severity level wherein they

lead to impaired functioning or significant distress or are time-consuming (i.e., meet DSM-IV criteria for the disorder). Reported age at onset is usually during late adolescence. In one study drawn from an OCD clinic sample ( $N = 560$ ), the onset for males occurred significantly earlier than for females ( $19.5 \pm 9.2$  years versus  $22.0 \pm 9.8$  years). In this study, 83% of patients experienced the onset of significant symptoms between ages 10 and 24 years, whereas less than 15% experienced onset after age 35 years (Rasmussen and Eisen, 1998). People with OCD, however, usually describe the onset of minor symptoms in childhood, well before the onset of symptoms meeting full criteria for the disorder.

In several studies, earlier age at onset has been associated with an increased rate of OCD in first-degree relatives and suggest that there is a familial type of OCD characterized by early onset. Age at onset of OCD may also be a predictor of course. The vast majority of patients report a gradual worsening of obsessions and compulsions prior to the onset of full-criteria OCD, which is followed by a chronic course (see later). However, Swedo and colleagues (1998) have described a subtype of OCD that begins

before puberty and is characterized by an episodic course with intense exacerbations. Exacerbations of OCD symptoms in this subtype have been linked with Group A beta-hemolytic streptococcal infections, which has led to the subtype designation of pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS). In their study of 50 children with PANDAS, the average age of onset was 7.4 years. Whether the course of illness in patients with PANDAS continues to be episodic into adulthood, or, as is the case with postpubertal onset, tends to be chronic, is not known.

In keeping with the older literature, a recent 2-year naturalistic prospective study of 65 adults with OCD, in which the effect of treatment was assessed, supported earlier findings that OCD is usually chronic with fluctuations in symptom intensity but no lasting remission; it is notable that this course was most common even during an era when effective treatments were available. Although 50% of the subjects achieved partial remission in the first year of the study, the probability of subsequent relapse was 48%. Only 12% achieved full and sustained remission (Eisen *et al.*, 1999). In contrast, a better outcome was found in a follow-up study of 144 people with OCD assessed in the 1950s and again in the 1990s (mean length of follow-up from illness onset was 47 years). Most subjects reported a significant decrease in OCD

symptom severity, which varied from complete recovery (20%), to recovery with continued subclinical symptoms (28%), to continued OCD but with clear improvement (35%). Better outcome was associated with later age of onset and poorer social functioning at baseline (Skoog and Skoog, 1999).

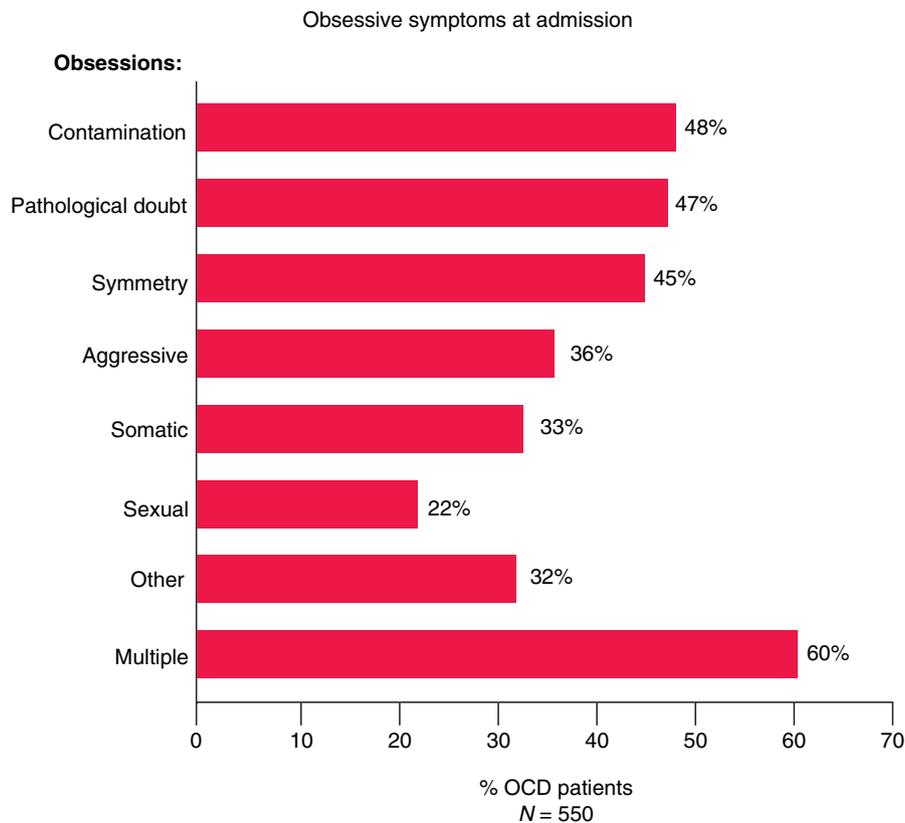

In a prospective study of children with OCD, the majority (52%) of the 25 patients had moderate to severe OCD in the 2- to 7-year follow-up period (Flament *et al.*, 1990), which is consistent with the data on adults. A more recent prospective study of 54 children with OCD who were treated with clomipramine yielded a more hopeful picture of OCD's course. At 2 to 7 years after initial referral, 43 of these patients still had symptoms that met criteria for OCD, but 73% were considered much or very much improved, and 11% were completely asymptomatic (Leonard *et al.*, 1993). This study suggested that appropriate somatic treatment may improve outcome only while the patient continues to receive this treatment (see later).

### Phenomenology

OCD's clinical presentation is characterized by phenomenological subtypes based on the content of the obsessions and corresponding compulsions. The list of subtypes in the Yale-Brown Obsessive–Compulsive Scale (Y-BOCS) (Table 51.1) was generated on

**Table 51.1** Yale-Brown Obsessive–Compulsive Scale Symptom Checklist

Aggressive obsessions	Obsession with need for symmetry or exactness
Fear might harm others	Miscellaneous obsessions
Fear might harm self	Need to know or remember
Violent or horrific images	Fear of saying certain things
Fear of blurting out obsessions or insults	Fear of not saying things just right
Fear of doing something embarrassing	Intrusive (neutral) images
Fear of acting on other impulses (e.g., robbing a bank, stealing groceries, overeating)	Intrusive nonsense sounds, words, or music
Fear of being responsible for things going wrong (e.g., others will lose their job because of patient)	Other
Fear something terrible might happen (e.g., fire, burglary)	Somatic obsession–compulsion
Other	Cleaning or washing compulsions
Contamination obsessions	Excessive or ritualized hand washing
Concerns or disgust with bodily waste (e.g., urine, feces, saliva)	Excessive or ritualized showering, bathing, brushing the teeth, or grooming
Concern with dirt or germs	Involves cleaning of household items or inanimate objects
Excessive concern with environmental contaminants (e.g., asbestos, radiation, toxic wastes)	Other measures to prevent contact with contaminants
Excessive concern with household items (e.g., cleansers, solvents, pets)	Counting compulsions
Concerned will become ill	Checking compulsions
Concerned will become ill (aggressive)	Checking that did not or will not harm others
Other	Checking that did not or will not harm self
Sexual obsessions	Checking that nothing terrible did or will happen
Forbidden or perverse sexual thoughts, images, or impulses	Checking for contaminants
Content involves children	Other
Content involves animals	Repeating rituals
Content involves incest	Ordering or arranging compulsions
Content involves homosexuality	Miscellaneous compulsions
Sexual behavior toward others (aggressive)	Mental rituals (other than checking or counting)
Other	Need to tell, ask, or confess
Hoarding or collecting obsessions	Need to touch
Religious obsessions	Measures to prevent
	Harm to self
	Harm to others
	Terrible consequences
	Other

**Figure 51.1** Obsessive symptoms at the time of initial evaluation in 550 patients with OCD.

the basis of clinical interviews with OCD patients in the 1980s. These subtypes are remarkably consistent with phenomenological descriptions in the psychiatric literature beginning with scrupulosity in the 15th century.

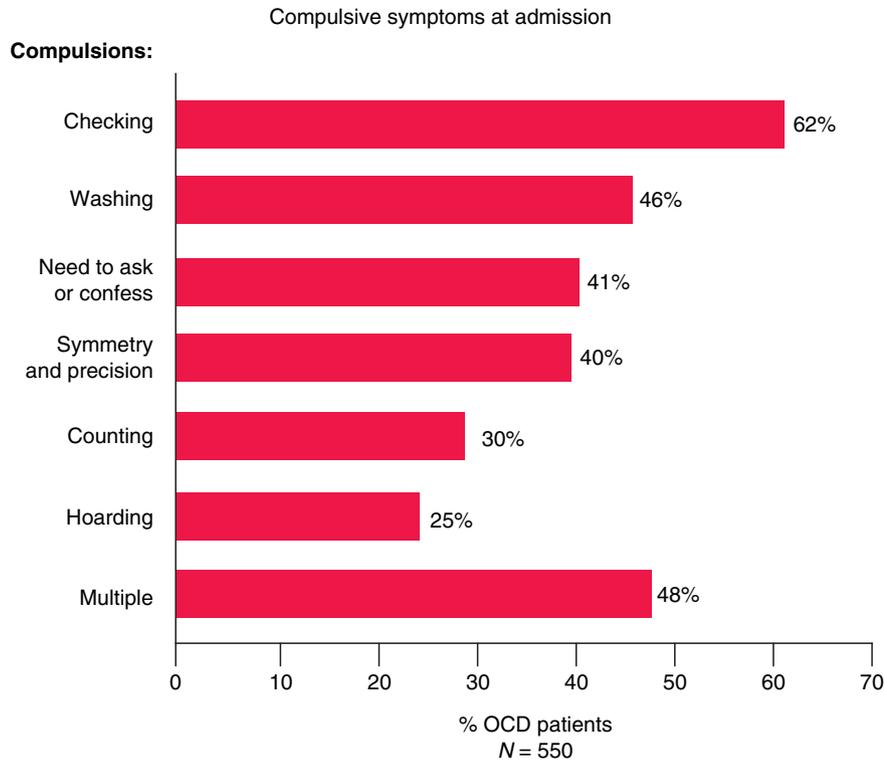

The basic types of obsessions and compulsions seem to be consistent across cultures. The most common obsession is fear of contamination, followed by pathological doubt, a need for symmetry and aggressive obsessions (Figure 51.1). The most common compulsion is checking, which is followed by washing, symmetry, the need to ask or confess and counting (Figure 51.2). Children with OCD present most commonly with washing compulsions, which are followed by repeating rituals.

Most patients have multiple obsessions and compulsions over time, with a particular fear or concern dominating the clinical picture at any one time. The presence of obsessions without compulsions, or compulsions without obsessions, is unusual. In the DSM-IV OCD field trial of 431 patients, only 2% had predominantly obsessions and 2% had predominantly compulsions; the remaining 96% endorsed both obsessions and compulsions (Foa and Kozak, 1995). Patients who appear to have obsessions without compulsions frequently have unrecognized reassurance rituals or mental compulsions, such as repetitive, ritualized praying, in addition to their obsessions. Pure compulsions are also unusual in adults, although they do occur in children, especially in the young (e.g., 6 to 8 years of age). Most people have both mental and behavioral compulsions; in the DSM-IV field trial 79.5% reported having both mental and behavioral compulsions, 20.3% had behavioral compulsions only and 0.2% had only mental compulsions.

The search for whether specific obsessions and compulsions have predictive value in terms of treatment response,

biologic markers, or genetic transmission has not been particularly fruitful. There has been considerable interest in exploring whether certain clusters of obsessions and compulsions represent specific OCD phenotypes. A number of studies have addressed this question systematically using the Y-BOCS Symptom Checklist to identify groups of obsessions and compulsions that cluster together on factor analysis. Several studies have found between three and five such symptom dimensions: *symmetry/ordering, hoarding, contamination/cleaning, aggressive obsessions/checking* and *sexual/religious obsessions*. The symmetry dimension has been associated with comorbid tic disorder; in one study, patients who scored high on this dimension had a relative risk for chronic tic disorder that was 8.5 times higher than those scoring low on this factor (Leckman *et al.*, 1997). It appears that these symptom dimensions are stable over time, that is, although a patient's specific obsessions and compulsions may change over time, new obsessions and compulsions that develop are often within the same symptom dimension as the previous symptoms. A study using positron emission tomography to evaluate neural correlates of these symptom dimensions suggests that dysfunction in separate regions of the brain (e.g., striatum and prefrontal cortex) may mediate these factors (Rauch *et al.*, 1998).

Data were analyzed from a number of placebo-controlled serotonin reuptake inhibitor (SRI) treatment studies to assess whether symptom factors or dimensions were associated with treatment response. No clear pattern emerged except that patients with hoarding obsession had a significantly poorer response to SRIs. Whether these identified dimensions are associated with response to behavioral treatment, biological markers, or genetic transmission has yet to be investigated.

**Figure 51.2** *Compulsive symptoms at the time of initial evaluation in 550 patients.*

The following descriptions of some common obsessions and compulsions illustrate the clinical presentation of these symptoms. In some cases a particular symptom may belong to more than one “type” of obsessive or compulsive grouping. Thus it is often up to the clinician to decide which category to place a symptom so that it best describes the patient’s symptoms overall; it may even be best to classify it in more than one category. For instance, a patient who has concerns about cancer may have handwashing as a compulsion related to her somatic obsession. If this is the only reason that she washes her hands, to avoid getting cancer, you might simply classify this as a somatic obsession with the accompanying compulsion. However if the patient also washes repeatedly to avoid contamination in general, not just for cancer, she would have both contamination and somatic obsessions and compulsions.

### Contamination

Contamination obsessions are the most frequently encountered obsessions in OCD. Such obsessions are usually characterized by a fear of dirt or germs. Contamination fears may also involve toxins or environmental hazards (e.g., asbestos or lead) or bodily waste or secretions. Patients usually describe a feared consequence of contacting a contaminated object, such as spreading a disease or contracting an illness themselves. Occasionally, however, the fear is based not on a fear of disease but on a fear of the sensory experience of not being clean. The content of the contamination obsession and the feared consequence commonly changes over time; for example, a fear of cancer may be replaced by a fear of a sexually transmitted disease.

Many patients with contamination fears use avoidance to prevent contact with contaminants, as is illustrated by a 58-year-old housewife who spent the entire day sitting in a chair to avoid

touching anything in the house that might be dirty. In some cases, a specific feared object and associated avoidance become more generalized. For example, a woman with a fear of acquired immunodeficiency syndrome (AIDS) initially avoided anything that looked like dried blood but eventually avoided anything red.

Excessive washing is the compulsion most commonly associated with contamination obsessions. This behavior usually occurs after contact with the feared object; however, proximity to the feared stimulus is often sufficient to engender severe anxiety and washing compulsions, even though the contaminated object has not been touched. Most patients with washing compulsions perform these rituals in response to a fear of contamination, but these behaviors occasionally occur in response to a drive for perfection or a need for symmetry. Some patients, for example, repeatedly wash themselves in the shower until they feel “right” or must wash their right arm and then their left arm the same number of times.

### Need for Symmetry

Need for symmetry is a term that describes a drive to order or arrange things perfectly or to perform certain behaviors symmetrically or in a balanced way. Patients describe an urge to repeat motor acts until they achieve a “just right” feeling that the act has been completed perfectly. Patients with a prominent need for symmetry may have little anxiety but rather describe feeling unsettled or uneasy if they cannot repeat actions or order things to their satisfaction. In addition to a need for perfection, the drive to achieve balance or symmetry may be connected with magical thinking. The desire to “even up” or balance movements may be present in patients with tapping or touching rituals. Such a patient may, for example, feel that the right side of the chair must be tapped after the left side has been tapped. Such urges

and behaviors are frequently seen in patients with comorbid tic disorders, who may, for example, describe an urge to tic on the right side of their body after experiencing a tic on the left side. Patients with a need for symmetry frequently present with obsessional slowness, taking hours to perform acts such as grooming or brushing their teeth.

### Somatic Obsessions

Patients with somatic obsessions are worried about the possibility that they have or will contract an illness or disease. In the past, the most common somatic obsessions consisted of fears of cancer or venereal diseases. However, a fear of developing AIDS has become increasingly common. Checking compulsions consisting of checking and rechecking the body part of concern, as well as reassurance seeking, are commonly associated with this fear. While it may be difficult to distinguish the somatic obsessions of OCD from those of hypochondriasis, there are several distinguishing features, which are discussed later in the chapter. Somatic obsessions are more easily distinguished from somatization disorder in which patients with somatic obsessions usually focus on one illness at a time and are not preoccupied with a diverse, apparently unrelated array of somatic symptoms.

### Sexual and Aggressive Obsessions

People with sexual or aggressive obsessions are plagued by fears that they might harm others or commit a sexually unacceptable act such as molestation. Often, they are fearful not only that they will commit a dreadful act in the future but also that they have already committed the act. Patients are usually horrified by the content of their obsessions and are reluctant to divulge them. It is striking that the content of these obsessions tends to consist of ideas that patients find particularly abhorrent. Patients with these highly distressing obsessions frequently have checking and confession or reassurance rituals. They may report themselves to the police or repeatedly seek out priests to confess their imagined crimes

### Pathological Doubt

Pathological doubt is a common feature of patients with OCD who have a variety of different obsessions and compulsions. Individuals with pathological doubt are plagued by the concern that, as a result of their carelessness, they will be responsible for a dire event. They may worry, for example, that they will start a fire because they neglected to turn off the stove before leaving the house. Although many patients report being fairly certain that they performed the act in question (e.g., locking the door, unplugging the hairdryer, paying the correct amount on a bill), they cannot dismiss the nagging doubt “What if?” Such patients often describe doubting their own perceptions. A 42-year-old man felt incapable of throwing grocery bags away because he feared he might not have completely emptied them. Immediately after staring into an empty bag, he inevitably thought, “What if I missed something important in there?”

Excessive doubt and associated feelings of excessive responsibility frequently lead to checking rituals. For example, individuals may spend several hours checking their home before they leave. As with contamination obsessions, pathological doubt can lead to marked avoidance behavior. Some patients

become housebound to avoid the responsibility of potentially leaving the house unlocked. Pathological doubt is also embedded in the cognitive framework of a number of other obsessions. Patients with aggressive obsessions may be plagued by the doubt that they inadvertently harmed someone without knowing that they did so.

### Insight

An awareness of the senselessness or unreasonableness of obsessions (often referred to as insight) and the accompanying struggle against the obsessions (referred to as resistance) have generally been considered fundamental components of OCD and its diagnosis. However, during the past century there have been numerous descriptions of patients with OCD who are completely convinced of the reasonableness of their obsessions and need to perform compulsions. In 1986, Insel and Akiskal described several such patients and presented the hypothesis that patients with OCD have varying degrees of insight and resistance, with obsessive-compulsive psychosis at one extreme of a hypothesized continuum. They also noted a fluidity between neurotic (i.e., associated with insight) and psychotic states in these patients.

Degree of insight in OCD was addressed during the DSM-IV field trial in which patients were asked if they feared consequences other than anxiety if they did not perform their compulsions (Foa and Kozak, 1995). Fifty-eight percent believed that harmful consequences would occur. The degree of certainty that their obsessions were reasonable ranged across the entire spectrum of insight: 30% were uncertain whether they actually needed to perform their compulsions to avoid harm; however, 4% were certain and 26% were mostly certain. Again, this finding supports the notion that patients with OCD do not always maintain good insight but rather have varying degrees of insight. Although patients may be aware that their obsessions are excessive – that is, recognizing that they spend too much time thinking about them – they may have little insight into the fact that the belief underlying their obsession (e.g., that they will get cancer from stepping on a chemically treated lawn) is senseless, unreasonable, or unrealistic.

To reflect these findings, DSM-IV established a new OCD specifier, with poor insight. This specifier applies to “an individual who, for most of the time in the current episode, does not recognize that the obsessions or compulsions are excessive or unreasonable”. DSM-IV also acknowledges that the beliefs that underlie OCD obsessions can be delusional and notes that in such cases an additional diagnosis of delusional disorder or psychotic disorder not otherwise specified may be appropriate. Most people with OCD are aware that other people think their symptoms are unrealistic and that the obsessions are caused by a psychiatric illness. Whether insight is an important predictor of prognosis and treatment response is an intriguing issue that has received little investigation. More studies are needed to determine the effect of insight on treatment response. For example, to our knowledge no studies have assessed whether adding an antipsychotic to an SRI is more effective in patients with poor insight than in those with good insight. Studies that assess the impact of insight on compliance with and refusal of behavioral therapy are also needed.

### Comorbidity

OCD frequently occurs in association with other Axis I disorders. In a study of 100 patients with primary OCD, 67 had a

lifetime history of major depressive disorder, and 31 had symptoms that met criteria for current major depressive disorder (Rasmussen and Eisen, 1991). Although it may be difficult to distinguish a primary from a secondary diagnosis, some individuals with OCD view their depressive symptoms as occurring secondary to the demoralization and hopelessness accompanying their OCD and report that they would not be depressed if they did not have OCD. However, others view their major depressive symptoms as occurring independently of their OCD symptoms, which may be less severe when they cycle into an episode of major depression, because they feel too apathetic to be as concerned with their obsessions and too fatigued to perform compulsions. Conversely, OCD symptoms may intensify during depressive episodes.

Although findings have varied, the generally accepted frequency of tic disorders in patients with OCD is far higher than in the general population, with a rate of approximately 5 to 10% for Tourette's disorder and 20% for any tic disorder. Conversely, patients with Tourette's disorder have a high rate of comorbid OCD, with 30 to 40% reporting obsessive–compulsive symptoms. The likelihood of childhood onset of OCD is greater in this group, and the presence of tics is associated with more severe OCD symptoms in children. There is an increased rate of both OCD and tic disorders in the first-degree relatives of OCD probands with a family lifetime history of tics, and an increased frequency of tic disorders in the first-degree relatives of OCD probands compared with controls. There are also phenomenologic observations that link OCD and tic disorders. Individuals with both OCD and tics have several features that distinguish them from individuals with OCD alone. They more frequently have symmetry, ordering and arranging, and hoarding compulsions, and they more frequently try to attain a “just right” feeling. These data strengthen the notion that tic disorders and OCD are highly related. In fact, it has been suggested that tic disorders are an alternative expression or phenotype of the familial OCD subtype.

Anxiety disorders frequently coexist with OCD, with relatively high lifetime rates of specific phobia (22%), social phobia (18%) and panic disorder (12%) in patients with OCD (Rasmussen and Eisen, 1991). In one study, 17 of 100 subjects with OCD had a lifetime history of an eating disorder. Conversely, in 93 subjects with an eating disorder, 37 had symptoms that met criteria for comorbid OCD.

Several studies of OCD and comorbid schizophrenia found that compared with subjects with OCD alone, those with comorbid schizophrenia have a worse prognosis in terms of long-term outcome (social relations, employment, psychopathology and global functioning). Similarly, treatment studies of patients with OCD and comorbid schizotypal personality disorder have shown a poorer prognosis and poorer response to psychotropic medications for the comorbid group. Thus, it appears important to differentiate OCD plus a comorbid psychotic disorder, which may have a relatively poor outcome, from delusional OCD, which may be more similar to OCD with insight and without comorbid psychosis.

Studies of patients with schizophrenia or schizoaffective disorder have found rates of OCD ranging from 8 to 46%. This strikingly large range is most likely due to the OCD criteria used (i.e., subclinical OCD symptoms versus OCD symptoms severe enough to cause significant impairment or distress). Regardless, it is clear that a significant number of people with schizophrenia have OCD symptoms which require assessment and may benefit from treatment.

The relationship between OCD and personality disorders, particularly obsessive–compulsive personality disorder (OCPD), has received considerable attention. Early observations noted the presence of OCPD traits in patients with OCD. Systematic studies have yielded inconsistent findings however. Although personality disorders are considered to be stable over time, one study found that of 17 OCD patients with a personality disorder, nine of the 10 treatment responders no longer met criteria for either avoidant or dependent personality disorder after successful pharmacotherapy, raising the question of whether these personality disorders actually represented a coping style in response to OCD (Ricciardi *et al.*, 1992).

## Differential Diagnosis

OCD is sometimes difficult to distinguish from certain other disorders. Obsessions and compulsions may appear in the context of other syndromes, which can raise the question whether the obsessions and compulsions are a symptom of another disorder or whether both OCD and another disorder are present (see section on Comorbidity). A general guideline is that if the content of the obsessions is not limited to the focus of concern of another disorder (e.g., an appearance concern, as in body dysmorphic disorder, or food concerns, as in an eating disorder) and if the obsessions or compulsions are preoccupying as well as distressing or impairing, OCD should generally be diagnosed.

Diagnostic dilemmas may also arise when it is unclear whether certain thoughts are obsessions or whether, instead, they are ordinary worries, ruminations, overvalued ideas, or delusions. In a similar vein, questions may develop about whether certain behaviors constitute true compulsions or whether they should instead be conceptualized as impulses, tics, or addictive behaviors.

## Obsessive–Compulsive Disorder Versus Other Anxiety Disorders

Both OCD and the other anxiety disorders are characterized by the use of avoidance to manage anxiety. However, OCD is distinguished from these disorders by the presence of compulsions. For OCD patients with preoccupying fears or worries but no rituals, several other features may be useful in establishing the diagnosis of OCD. In social phobia and specific phobia, fears are circumscribed and related to specific triggers (in specific phobia) or social situations (in social phobia). Although circumscribed situations may initially trigger obsessions and compulsions in OCD, triggers in OCD become more generalized over time, unlike the triggers in social and specific phobias, in which the evoking situations remain circumscribed.

As many as 60% of people with OCD experience full-blown panic symptoms. However, unlike panic disorder, in which panic attacks occur spontaneously, panic symptoms occur in OCD only during exposure to specific feared triggers such as contaminated objects. The worries that are present in generalized anxiety disorder (GAD) are more ego syntonic and involve an exaggeration of ordinary concerns, whereas the obsessional thinking of OCD is more intrusive, is limited to a specific set of concerns (e.g., contamination, blasphemy), and usually has an irrational, senseless, or unreasonable quality. Also, whereas the worry of GAD is considered primarily thoughtlike in nature, obsessional symptoms may consist of thoughts, impulses, or images.

### Obsessive–Compulsive Disorder Versus Psychotic Disorders

One question is how to differentiate OCD from psychotic disorders such as schizophrenia and delusional disorder. Another question is how to distinguish OCD with insight from OCD without insight (delusional OCD). One distinguishing feature between OCD and the psychotic disorders is that the latter are not characterized by prominent ritualistic behaviors. If compulsions are present in a patient with prominent psychotic symptoms, the possibility of a comorbid OCD diagnosis should be considered. Furthermore, although schizophrenia may be characterized by obsessional thinking, other characteristic features of the disorder, such as prominent hallucinations or thought disorder, are also present. With regard to delusional disorder, paranoid and grandiose concerns are generally not considered to fall under the OCD rubric. However, some other types of delusional disorder, such as the somatic and jealous types, seem to bear a close resemblance to OCD and are not always easily distinguished from it. It will be interesting to see whether future research indicates that certain types of somatic delusional disorder (e.g., the delusional variant of hypochondriasis) and the jealous type of delusional disorder (also referred to as pathological jealousy) are actually variants of OCD.

The second issue noted above – how to distinguish OCD with insight from OCD without insight – is complex. As previously discussed, insight in OCD is increasingly being recognized as spanning a spectrum from good to poor to absent. Both clinical observations and research findings indicate that some individuals hold their obsessional concerns with delusional intensity and believe that their concerns are reasonable. In DSM-IV, delusional OCD may be double-coded as both OCD and delusional disorder or as both OCD and psychotic disorder not otherwise specified, in other words, patients with delusional OCD would receive both diagnoses. This double coding reflects the fact that it is unclear whether OCD with insight and OCD without insight constitute the same or different disorders. Further research using validated scales to assess insight in OCD is needed to shed light on this question.

### Obsessive–Compulsive Disorder Versus Impulse Control Disorders

Differential diagnosis questions have been raised with regard to kleptomania, trichotillomania, pathological gambling and other disorders involving impulsive behaviors. Several features have been said to distinguish these disorders from OCD. For example, compulsions – unlike behaviors of the impulse control disorders – generally have no gratifying element, although they do diminish anxiety. In addition, the affective state that drives the behaviors associated with these disorders may differ. In OCD, fear is frequently the underlying drive that leads to compulsions, which, in turn, decrease anxiety. In the impulse control disorders, patients frequently describe heightened tension, but not fear, preceding an impulsive behavior. However, OCD and the impulse control disorders have some features in common. Research is ongoing to explore the relationship between OCD and the impulse control disorders by examining similarities and differences in treatment response, biological markers and familial transmission.

### Obsessive–Compulsive Disorder Versus Tourette’s Disorder

Complex motor tics of Tourette’s disorder may be difficult to distinguish from OCD compulsions. Both tics and compulsions are preceded by an intrusive urge and are followed by feelings of relief. However, OCD compulsions are usually preceded by both anxiety and obsessional concerns, whereas, in Tourette’s disorder, the urge to perform a tic is not preceded by an obsessional fear. This distinction breaks down to some extent when considering the “just right” perceptions of some patients with OCD. The “just right” perception refers to the need to perform a certain motor action, such as touching, tapping, checking, ordering, arranging, or counting, until it feels right. Determining when an action has been performed enough or perfectly may depend on tactile, visual, or auditory perceptions. In a study of patients with Tourette’s disorder and OCD symptoms, most patients could distinguish between the mental urge to do something repeatedly until it felt right and a physical urge to perform a motor tic. However, it is sometimes difficult for psychiatrists to distinguish between complex tics and compulsions, especially when a patient has both disorders.

### Obsessive–Compulsive Disorder Versus Hypochondriasis

Fears of illness that occur in OCD, referred to as somatic obsessions, may be difficult to distinguish from hypochondriasis. Usually, however, patients with somatic obsessions have other current or past classic OCD obsessions unrelated to illness concerns. Patients with OCD also often engage in classic OCD rituals, such as checking or reassurance seeking, in an attempt to diminish their illness concerns. Unlike patients with OCD, patients with hypochondriasis experience somatic and visceral sensations. Although insight and resistance have been used to distinguish OCD from hypochondriasis, with the concern in hypochondriasis being said to be egosyntonic (realistic and totally justified) and that of OCD to be egodystonic (unacceptable and undesirable thoughts, actions, or both), studies have demonstrated a range of insight in OCD. Attempting to differentiate these disorders by degree of insight or egosyntonicity may therefore be of limited usefulness.

### Obsessive–Compulsive Disorder Versus Body Dysmorphic Disorder

Body dysmorphic disorder (BDD), a preoccupation with an imagined or slight defect in appearance (e.g., thinning hair, facial scarring, or a large nose), has many similarities to OCD (Phillips, 1991). Patients with BDD experience obsessional thinking about the supposed defect and usually engage in associated repetitive ritualistic behaviors, such as mirror checking and reassurance seeking. Preliminary evidence suggests that BDD also appears similar to OCD in terms of age of onset, course of illness and other variables. Nonetheless, emerging data suggest that there are some important differences between the two disorders, and they are currently classified separately in DSM-IV. Insight, for example, is more frequently impaired in BDD than in OCD. If the content of a patient’s obsessions involves a concern about a supposed defect in appearance, BDD, rather than OCD, is the diagnosis that should be given.

## Obsessive–Compulsive Disorder Versus Obsessive–Compulsive Personality Disorder

Obsessive–compulsive personality disorder is a lifelong maladaptive personality style characterized by perfectionism, excessive attention to detail, indecisiveness, rigidity, excessive devotion to work, restricted affect, lack of generosity and hoarding. OCD and OCPD have historically been considered variants of the same disorder on a continuum of severity, with OCD viewed as the more severe manifestation of illness. Contrary to this notion, studies using structured interviews to establish diagnosis have found that not all patients with OCD also have OCPD. One reason for the perception that these disorders are linked lies in the frequency of several OCPD traits in patients with OCD. In one study, the majority of 114 patients with OCD had perfectionism and indecisiveness (82 and 70, respectively). In contrast, other OCPD traits, such as restricted affect, excessive devotion to work and rigidity, were seen infrequently.

Although perfectionism and indecisiveness are relatively common traits in patients with OCD, the distinction between OCD and OCPD is important, and several guidelines may be useful in distinguishing them. Unlike OCPD, OCD is characterized by distressing, time-consuming egodystonic obsessions and repetitive rituals aimed at diminishing the distress engendered by obsessional thinking. One of the hallmarks that traditionally has been used to distinguish OCD from OCPD is that, in contrast, OCPD features are considered egosyntonic. In addition, as previously noted, the traits of restricted affect, excessive devotion to work and rigidity are generally characteristic of OCPD but not OCD. Although useful, these guidelines are not absolute, and some patients defy easy categorization. Some patients, for example, spend hours each day engaged in egosyntonic behaviors such as excessive cleaning; such patients may seek treatment not because they are disturbed by their behaviors but because the behaviors cause problems in functioning or family friction. It is unclear whether some of these patients should be diagnosed with OCPD or subthreshold OCD.

## Obsessive–Compulsive Spectrum Disorders

Certain disorders other than OCD, such as BDD, hypochondriasis, and eating disorders, are characterized by obsessional thinking and/or ritualistic behaviors. On the basis of these apparent similarities with OCD, the concept of OCD spectrum disorders has been developed. They have been defined as disorders that share features with OCD (Hollander, 1993) and are posited to have “spectrum membership” on the basis of their similarities with OCD across multiple domains. These domains include not only symptoms but also treatment response, comorbidity, joint familial loading, sex ratio, age at onset, course, premorbid personality characteristics and presumed cause. Cause is inferred from characteristics such as neurological deficits, response to biological challenges, biochemical indices, brain imaging patterns (functional and anatomical) and epidemiological risk factors. It is worth noting that there are currently no operational criteria for what constitutes an OCD spectrum disorder; for example, in which of the preceding domains must similarities be documented, and how similar in each domain must the disorder be to OCD?

Disorders postulated to be OCD spectrum disorders include BDD, hypochondriasis, eating disorders, “grooming” disorders such as nail biting and trichotillomania, and the impulse

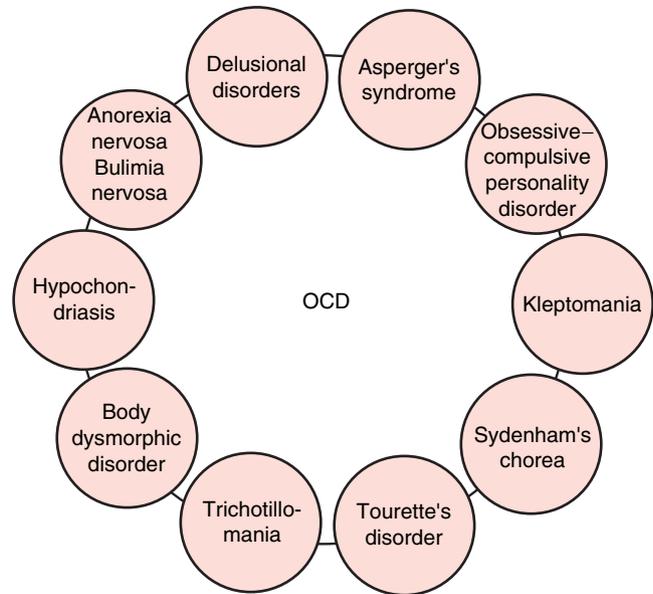

Figure 51.3 OCD spectrum disorders.

disorders (see Figure 51.3). Of interest is a recent study investigating the frequency of these disorders in first-degree relatives of people with OCD. BDD, hypochondriasis, any eating disorder (although not anorexia or bulimia individually) and grooming disorders (but not the impulse control disorders) were found more frequently in probands with OCD than in general population controls. In addition, BDD and grooming disorders (although not the other disorders) were significantly more common in the first-degree relatives of OCD probands than in relatives of controls (Bienvenu *et al.*, 2000). This finding suggests that certain of the proposed OCD spectrum disorders may have a familial link to OCD. The relationship of these disorders with OCD is an area in which exciting research will be conducted in coming years.

## Etiology and Pathophysiology

A number of intriguing avenues have been investigated to determine the etiology and pathophysiology of OCD. Although our understanding of what causes this disorder has continued to grow, there is still much to learn. It is likely that OCD is caused by a complex interaction of factors rather than a single defect. However, for the purpose of clarity, these factors are described separately.

## Genetic Factors

A number of approaches have been used to evaluate the role of heredity in OCD. Twin studies have examined rates of concordant monozygotic twins versus discordant monozygotic twins with OCD. A review of this literature reveals a concordance rate of 63% in monozygotic twins and supports the notion that genetic factors are implicated in the expression of OCD. Given the concordance rate of less than 100% in monozygotic twins, it is clear that environment also plays a role in OCD's phenotypic expression.

A second approach to examining the role of genetics in OCD has been to investigate the rate of OCD in family members of OCD probands. Evidence supporting familial transmission of OCD has been obtained by studying the frequency of OCD in relatives of patients with Gilles de la Tourette's Syndrome (TS). Available data

support familial transmission in some cases of OCD and suggest that genetic factors play an important role in its etiology, particularly in patients with comorbid tic disorder. Thus, in recent years a molecular genetics approach has begun to be applied to OCD, although there have been not significant findings to date.

## Neurobiological Factors

### Neuroanatomical Aspects

Brain imaging techniques have advanced the search for abnormalities in brain functioning and/or structure in patients with OCD. Numerous studies have now been done with both structural imaging – CT (computed tomography) and MRI (magnetic resonance imaging) – and functional imaging – PET (positron emission tomography), SPECT (single photon emission computed tomography), fMRI (functional magnetic resonance imaging) and MRS (magnetic resonance spectroscopy). These techniques have demonstrated abnormalities in OCD patients. These abnormalities occur at rest and with symptom provocation and they are “normalized” with effective treatment.

While not all results are in agreement, a majority of these studies have implicated abnormalities in the orbitofrontal cortex, anterior cingulate cortex, and structures of the basal ganglia and thalamus. These structures are proposed to be linked in neuroanatomical circuits. One well-articulated model by Saxena and colleagues (1998) proposes that OCD symptoms are mediated by hyperactivity in orbitofrontal–subcortical circuits, which might be due to an imbalance in tone between direct and indirect striato–pallidal pathways. Some studies have implicated a preferential role for right anterolateral orbitofrontal cortex in both OCD symptoms and symptom response. This view has neurocognitive implications because studies of executive function in OCD patients have shown that patients have difficulty with alternation tasks and tasks that involve making choices. A number of treatment studies (see later) with clomipramine, fluoxetine, paroxetine and cognitive–behavioral therapy (CBT) have shown a decrease in caudate glucose metabolism with successful treatment.

Further indirect evidence implicating a role for basal ganglia dysfunction in OCD lies in the clinical relationship between neurological insults to the basal ganglia and the subsequent development of obsessions and compulsions. There is an association between OCD and Tourette’s disorder, Sydenham’s chorea, bilateral necrosis of the globus pallidus and postencephalitic parkinsonian symptoms.

### Neurochemical Aspects

The hypothesis that OCD involves an abnormality in the serotonin neurotransmitter system has been called the serotonin hypothesis. Several different lines of investigation support this hypothesis: 1) therapeutic response of patients to chronic administration of medication; 2) measurements of central and peripheral neurotransmitter or metabolite concentration; and 3) pharmacologic challenge paradigms which measure behavioral and neuroendocrine effects produced by acute administration of selective pharmacologic agents.

All the evidence from treatment studies points to a role for serotonin and speaks of a need for prolonged administration to see a positive effect. All of the antidepressants that effectively treat OCD affect serotonin. These antidepressants are potent

inhibitors of the presynaptic reuptake of serotonin (i.e., SRIs). Those antidepressants that primarily affect the noradrenergic system have not been found to have antiobsessional properties. Exactly how the SRIs improve OCD symptoms remains unclear; while the immediate action of these agents may be to increase serotonin in the synapse, they undoubtedly cause a cascade of changes, both presynaptically and postsynaptically.

The role of the dopamine system in OCD’s pathophysiology has also been investigated. When added to the SRIs, dopamine antagonists (neuroleptic agents) decrease symptoms of OCD in patients with OCD and comorbid tics, as well as in patients with OCD and comorbid schizotypal personality disorder. It has been hypothesized that some forms of OCD, particularly OCD plus Tourette’s disorder, may involve an imbalance in activity between serotonergic and dopaminergic systems.

Given the complex interactions and overlap among monoaminergic and other receptors in the brain, it is likely that a number of neurotransmitters are involved in OCD’s pathophysiology and etiology. The effect of long-term treatment with SRIs is probably several: to change the ratio of dopamine to serotonin turnover, alter the gene expression of target neurons to stress-related neuropeptides, and decrease the sensitivity of subtypes of presynaptic serotonin auto- and heteroreceptors belonging to the 5-HT<sub>1</sub> receptor family. Ongoing research is expected to elucidate further the likely role of serotonin and the possible role of other neurotransmitters in OCD.

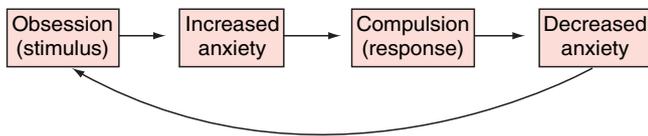

### Animal Models

Animal models may provide an important window on treatment efficacy and the influence of environmental and genetic factors in OCD. Because of the inherent difficulties in studying cognitive aspects of OCD (such as guilt, over-responsibility and doubt) in animals, attention has focused on repetitive motor actions that are similar to compulsions. Ethologists have observed that when specific, goal-directed actions are thwarted, animals may substitute unrelated behaviors, known as displacement behaviors, which frequently involve digging, pecking, or grooming. These motor actions have several elements: they are triggered by conflict over territory or by frustration, they continue in a stereotyped fashion, and they are excessive and/or inappropriate to the context in which they are performed. Thus, they are similar to the compulsive behaviors of OCD. Another animal model for OCD is acral lick disorder, in which dogs and cats groom themselves excessively, causing cutaneous lesions. As in OCD, stress increases these excessive grooming behaviors. Of interest is the positive response of acral lick disorder to clomipramine, fluoxetine and sertraline but not to placebo, which lends support to the hypothesis that this behavior represents an animal model of OCD.

A number of models implicate excessive dopaminergic activity in repetitive behaviors. For example, dopamine antagonists such as haloperidol decrease stereotyped behaviors in animals induced by amphetamine administration, stimulation, or stress. Animal models offer the advantage of accessibility and ease of manipulation for controlled trials and as such can play a valuable role in understanding OCD’s etiology.

### Learning Theory

A model based on the psychological concept of conditioning has also been used to understand the development of obsessions and

**Figure 51.4** Learning theory of OCD.

compulsions. Compulsions, whether mental or observable, usually decrease the anxiety engendered by obsessional thoughts. Thus, if a person is preoccupied with fears of contamination from germs, repetitive handwashing usually decreases the anxiety caused by these fears. The compulsion becomes a conditioned response to anxiety. Because of the tension-reducing aspect of the compulsion, this learned behavior becomes reinforced and eventually fixed. Compulsions, in turn, actually reinforce anxiety because they prevent habituation from occurring; that is, by performing a compulsion, contact with the fear-evoking stimulus (e.g., dirt) is not maintained, and habituation (a decrease in fear associated with the stimulus) does not occur. Thus, the vicious circle linking obsessions and compulsions is maintained (Figure 51.4). This learning theory model of OCD has had a major influence on the way behavioral therapy is used in its treatment.

### Psychoanalytic Theory

Much of the psychoanalytic literature on OCD does not distinguish between the phenomena observed in OCD (obsessions and compulsions) and the traits of OCPD. This distinction has relevance because of treatment implications. Although the clinical observations of earlier psychoanalysts, such as Freud's famous Ratman case (Freud, 1963), reflect current clinical presentations of Axis I OCD, understanding symptoms from the psychoanalytic perspective have not yielded improvement in this disorder's symptoms. Conversely, characterologic problems such as perfectionism, indecisiveness and rigidity, seen in OCPD, may benefit from a psychoanalytic orientation that focuses on the meaning of these symptoms or traits; such traits have typically not responded well to medications alone, although further investigation of this question is needed.

Recent theory has attempted to integrate the biology of OCD with psychological models by proposing a phylogenetic model based on systems theory. In this model, behavioral inhibition and harm-assessment systems, which develop early in human phylogeny, are disrupted. This disruption can occur at a hierarchically primary level of biological organization, resulting in neurobiologic disturbance, or at a hierarchically higher level of organization, leading to psychological disturbances. Such a model can help to explain the diversity of symptoms seen in OCD, from the more primitive biologically based behaviors based on fight/flight and risk to more psychologically sophisticated behaviors involving morality and guilt. This model might also explain why neither biological or psychological treatments alone always lead to complete remission of symptoms (Cohen *et al.*, 1997).

### Treatment

#### General Considerations

Both pharmacologic and behavioral therapies have proved effective for OCD. The majority of controlled treatment trials have

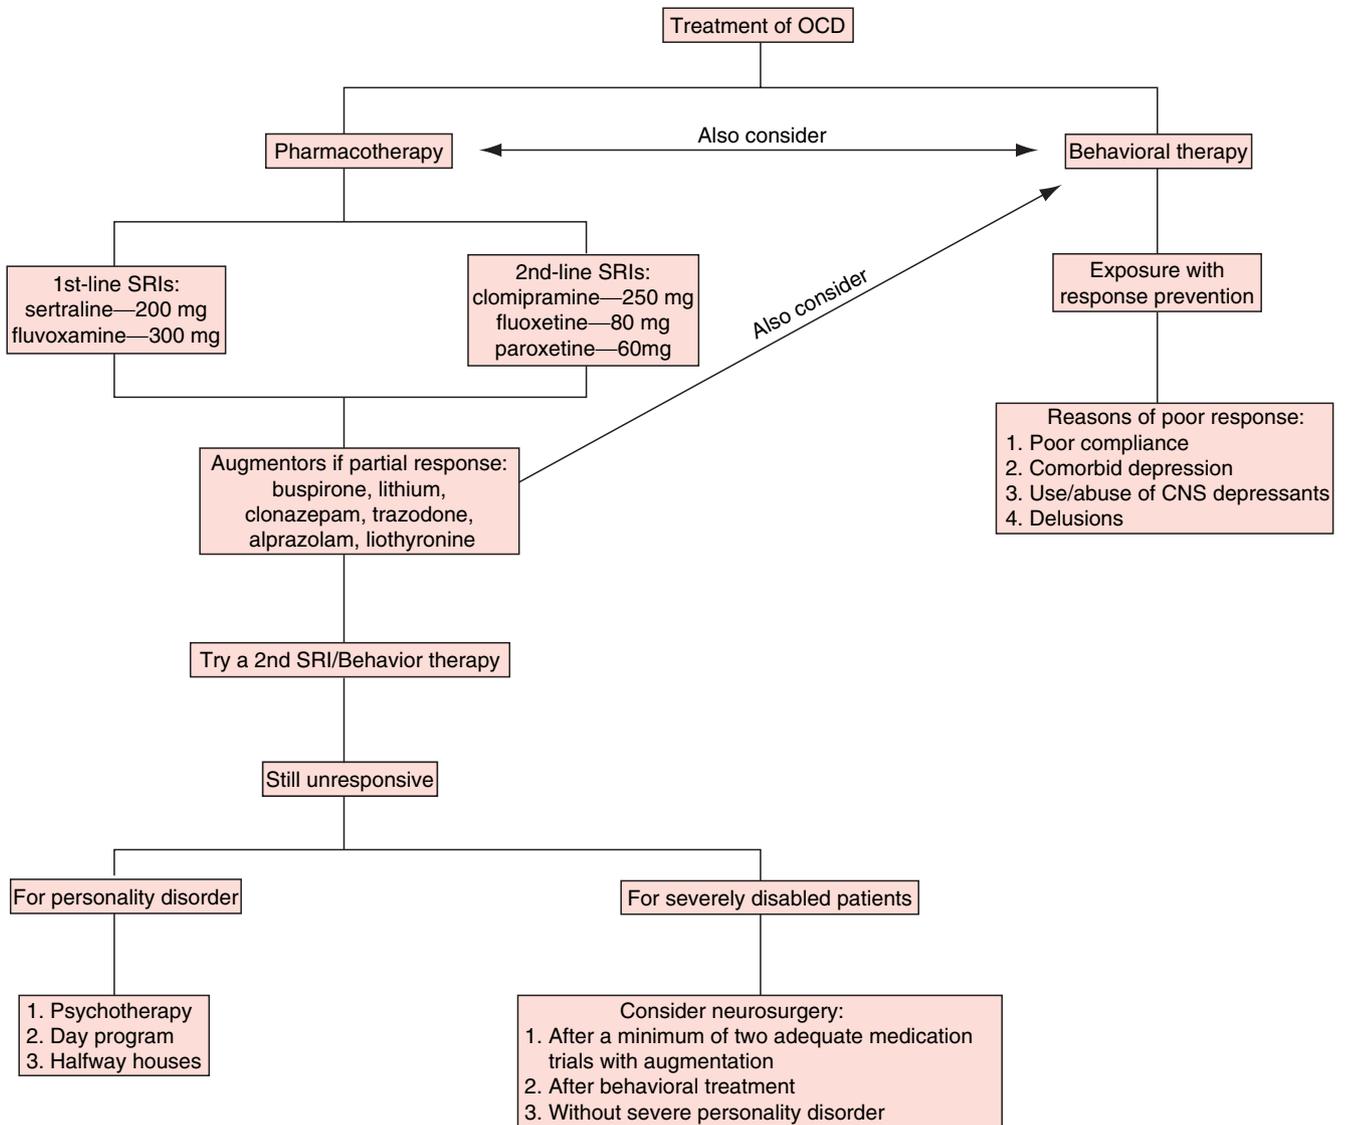

been performed with adults age 18 to 65 years. However, these therapies have been shown effective for patients of all ages. In general, children and the elderly tolerate most of these medications well. For children, lower doses are indicated because of lower body mass. For instance, the recommended dose for clomipramine in children is up to 150 mg/day (3 mg/kg/day) versus 250 mg/day in adults. Use of lower doses should also be considered in the elderly because their decreased ability to metabolize medications can increase the risk of side effects and toxicity. Behavioral therapy has also been used successfully in all age groups, although when treating children with this modality it is usually advisable to use a parent as a cotherapist. A flowchart that outlines treatment options for OCD is shown in Figure 51.5

In general, the goals of treatment are to reduce the frequency and intensity of symptoms as much as possible and to minimize the amount of interference the symptoms cause. It should be noted that few patients experience a cure or complete remission of symptoms. Instead, OCD should be viewed as a chronic illness with a waxing and waning course. Symptoms are often worse during times of psychosocial stress. Even when on medication, individuals with OCD are often upset when they experience even a mild symptom exacerbation, anticipating that their symptoms will revert to their worst, which is rarely the case. Anticipating with the patient that stress may make the symptoms worse can often be helpful in long-term treatment. Expert consensus guidelines, based on completion of a survey by 79 experts in the field, provide a reasonable approach to clinical practice in treating patients with OCD. However like any consensus report, based on clinical practice, not all of the recommendations are supported by empirical data (March *et al.*, 1997). Further work in neurosurgical techniques, particularly less invasive approaches like gamma knife and possibly trans-magnetic stimulation, may offer other options in the future for treating OCD.

### Pharmacological Treatments

The most extensively studied agents for OCD are medications that affect the serotonin system. Many studies implicate the serotonin system in OCD's pathophysiology, although comparative studies also seem to implicate other neurotransmitter systems, including the dopaminergic system, in treatment response. The principal pharmacologic agents used to treat OCD are the SRIs, which include clomipramine, fluoxetine, fluvoxamine, sertraline, paroxetine and citalopram.

Outcome measures in OCD treatment trials generally include the Yale-Brown Obsessive–Compulsive Scale (Y-BOCS; Goodman *et al.*, 1989), a reliable and valid 10-item, 40-point semi-structured instrument that assesses the severity of obsessions and rituals during the preceding week. Studies conducted since 1989 have generally used the Y-BOCS as one of the major outcome measures. Most studies have used Y-BOCS scores of 16 to 20 as a study entry criterion, although it has been argued that higher scores (e.g., 20–21) might reduce the increasing placebo response rates being obtained in OCD studies. Treatment response is generally considered to constitute at least a 25 to 35% reduction in OCD symptoms as measured by the Y-BOCS. Another frequently used global outcome measure is the National Institute of Mental Health Global Obsessive–Compulsive Scale (NIMH-OC) (Pato *et al.*, 1994).

**Figure 51.5** Flowchart of treatment options for OCD.

## Clomipramine

The tricyclic antidepressant clomipramine is among the most extensively studied pharmacological agents in OCD. This drug is unique among the antiobsessional agents in which in addition to its potency as an SRI, it has significant affinity for noradrenergic, dopaminergic, muscarinic and histaminic receptors. The most common side effects are those typical of the tricyclic antidepressants, including dry mouth, dizziness, tremor, fatigue, somnolence, constipation, nausea, increased sweating, headache, mental cloudiness and sexual dysfunction. Previous data have indicated that at doses of 300 mg/day or more, the risk of seizures is 2.1% but at doses of 250 mg/day or less, the risk of seizures is low (0.48%) and comparable to that of other tricyclic antidepressants. It is therefore recommended that doses of 250 mg/day or less be used. Elderly patients may be more prone to tricyclic side effects, such as orthostatic hypotension, constipation (which may lead to fecal impaction), forgetfulness and mental cloudiness, which might be confused with dementia. Most of these side effects can be treated by simply lowering the dose, although the cardiac conduction effects of tricyclic anti-

depressants may preclude the use of clomipramine in patients with preexisting cardiac conduction problems, especially atrioventricular block.

Recent studies of IV clomipramine have been particularly promising because it seems to have a quicker onset of action and fewer side effects than the oral form, and it may be effective even in patients who do not respond to oral clomipramine. Oral clomipramine, like other SRIs, usually takes a minimum of 4 to 6 weeks to produce a clinically significant clinical response, but in at least one study using IV pulse doses patients showed a response within 4.5 days. The reasons for this unique response are not fully understood, but it is postulated that the IV preparation avoids first-pass hepatoenteric metabolism, leading to increased bioavailability of the parent compound clomipramine. This in turn may play a role in rapidly desensitizing serotonergic receptors or initiating changes in postsynaptic serotonergic neurons. This preparation is still not FDA-approved for clinical use in the USA. Cardiac monitoring is recommended during the use of IV clomipramine.

## Fluoxetine

Despite their different chemical structures, all of the SSRIs appear to have similar efficacy in treating OCD. Fluoxetine has not been shown to be more effective than clomipramine. The fixed-dose trials of fluoxetine are particularly noteworthy because there are few published fixed-dose trials with any of the antiobsessional agents in OCD. Although these studies indicated that doses of 20, 40 and 60 mg/day were all effective when compared with placebo, there was a trend toward 60 mg/day being more effective. Some patients who did not respond at lower doses responded at higher doses, and others who responded at lower doses showed increased improvement at a higher dose. In addition, patients maintained their improvement or experienced increased improvement during the 5- to 6-month follow-up period.

Fluoxetine has fewer side effects than clomipramine, reflecting its more selective mechanism of action. The most common side effects are headache, nausea, insomnia, anorexia, dry mouth, somnolence, nervousness, tremor and diarrhea. Side effects occur more frequently at higher doses. Fluoxetine's long half-life, which is unique among the SRIs, is 2 to 4 days for the parent compound and 4 to 16 days for its active metabolite. This long half-life can be beneficial for patients who do not comply with treatment, because relatively high steady-state levels are maintained even when several doses are missed. However, the long half-life can present problems when switching or discontinuing fluoxetine, because 5 weeks or more may be required for the medication to be completely cleared from the body. Hence the added delay, 5 weeks rather than 2 weeks for the other SRIs, is required when switching from fluoxetine to an MAOI.

## Fluvoxamine

Fluvoxamine is a unicyclic agent which differs from the other SSRIs in that it does not have an active metabolite. A number of systematic blinded clinical trials, most of which were placebo-controlled, have demonstrated fluvoxamine's effectiveness in treating OCD. As has been demonstrated for the other SSRIs, relatively long treatment trials are indicated before concluding that an SSRI is ineffective in OCD.

The largest and most recent fluvoxamine study was a 10-week multicenter double-blind placebo-controlled study of 320 patients. The mean dose of fluvoxamine was 249 mg/day. As in the other studies, the fluvoxamine-treated patients had a significant reduction in OCD symptoms; however, unlike most of the earlier medication trials there was a relatively high placebo response rate of 11%. One of the important conclusions from this study was that prior failure to respond to another SSRI was associated with a lower likelihood of responding to fluvoxamine. All of the fluvoxamine studies show a similar side-effect profile, which included insomnia, nervousness, fatigue, somnolence, nausea, headache and sexual dysfunction. Insomnia and nervousness tended to occur early in treatment, whereas fatigue and somnolence occurred later. Overall, the medication is well tolerated, with only 10 to 15% of patients dropping out of treatment because of side effects.

## Sertraline

As is true of other studies, higher doses of sertraline 200 mg/day being is more effective than 50 mg/day or 100 mg/day. Typical side effects included nausea, headache, diarrhea, insomnia and dry mouth. A recent study compared sertraline with the non-SRI antidepressant desipramine for patients with OCD and comorbid depression. Although these medications were similarly

efficacious for depression, sertraline was more effective for OCD symptoms, supporting the use of an SRI-like sertraline rather than a norepinephrine reuptake inhibitor like desipramine in such patients. In addition, even though desipramine did improve depressive symptoms, a significantly greater number of patients treated with sertraline achieved remission from depression (Hoehn-Saric *et al.*, 2000).

## Paroxetine

Paroxetine is another SSRI that differs in structure from those previously discussed. It is a phenylpiperidine compound that is marketed as an antidepressant and, like sertraline, shows promise in the treatment of OCD. Results of a fixed-dose multicenter trial of 348 patients indicated that paroxetine is effective for OCD. As was suggested in the sertraline study, higher doses (40 or 60 mg/day) may be needed because 20 mg/day was no more effective than placebo (Wheadon *et al.*, 1993). Paroxetine's efficacy is comparable to that of other SRIs, and side effects are similar to those of other SSRIs and include lethargy, dry mouth, nausea, insomnia, somnolence, tremor, sexual dysfunction and decreased appetite. Reports of an acute discontinuation syndrome, which can include general malaise, asthenia, dizziness, vertigo, headache, myalgia, loss of appetite, nausea, diarrhea and abdominal cramps, warrant a gradual reduction in dose if this medication is to be discontinued. Occasional patients may experience some of these symptoms even if their dose is delayed by only a few hours.

## Citalopram

Citalopram is the newest SSRI available for the treatment of OCD and is unique in its selectivity for serotonin reuptake compared with the other SRIs. It has few significant secondary binding properties, and its minimal effect on hepatic metabolism probably makes it safer to combine with other medications. A multicenter fixed-dose-placebo-controlled trial with 401 patients showed that 52 to 65% of patients responded in the three dosage groups compared with a 37% response rate in the placebo group. While there was a trend for a higher dose to lead to a higher response rate, as with other SRIs, there was no statistical difference between the three doses used (20, 40 and 60 mg/day). Typical side effects included fatigue, sweating, dry mouth, ejaculation failure, nausea and insomnia, although many patients habituated to these side effects in 4 to 6 weeks. Thus, citalopram is a good choice for OCD treatment because of its side-effect profile and low probability of causing drug–drug interactions (Montgomery *et al.*, 2001).

## Other Agents

Most studies of other medications (venlafaxine, buspirone, trazodone, clonazepam and MAOIs for OCD) have consisted of only case reports or small samples. However, few of these agents have been promising enough to warrant large blinded efficacy trials.

## Which SRI to Choose?

The efficacy of each SRI – clomipramine, fluoxetine, fluvoxamine, sertraline, paroxetine, and citalopram – is supported by existing data. During the last 12 years at least seven head-to-head SRI comparison studies have been done, six of which compared clomipramine with fluoxetine, fluvoxamine, paroxetine and sertraline. All of the studies found that the agents studied were equally efficacious, although they may have been underpowered to detect differences among medications. However, several

meta-analyses of OCD trials, which compared SRIs across large placebo-controlled multicenter trials, lend some support to the notion that clomipramine might be more effective than the more selective agents. These meta-analyses support a trial of clomipramine in all patients who do not respond to SRIs, even though clomipramine tends to cause more side effects.

A number of studies have assessed predictors of medication response. Predictors of poor response include failure to respond to a previous SRI, early age of OCD onset, presence of schizotypal personality disorder and presence of hoarding. However, not all studies have had consistent findings, and more investigation of this issues is needed using larger and more narrowly defined samples.

It is worth noting that the SSRIs, via their effect on the liver cytochrome system, can inhibit the metabolism of certain other drugs. Fluoxetine can elevate blood levels of a variety of coadministered drugs, including tricyclic antidepressants (such as clomipramine), carbamazepine, phenytoin and trazodone. However, the other SSRIs (with the exception of citalopram) can theoretically cause similar elevations, although fewer reports on such interactions are currently available. Some clinicians have taken advantage of these interactions by carefully combining fluvoxamine with clomipramine in order to block clomipramine's metabolism to desmethylclomipramine; this in turn favors serotonin reuptake inhibition provided by the parent compound rather than the norepinephrine reuptake inhibition provided by the metabolite. However, caution should be used with this approach since the elevation in clomipramine levels, and perhaps other compounds, can be nonlinear and quickly lead to dangerous toxicity; at the very least, clomipramine levels should be carefully monitored.

All of the SSRIs are generally well tolerated, with a relatively low percentage of patients experiencing notable side effects or discontinuing them because of side effects. In addition, these compounds are unlikely to be lethal in overdose, except for clomipramine, which can lead to cardiac arrhythmias and death. All these agents can cause sexual side effects, ranging from anorgasmia to difficulty with ejaculatory function. However, such symptoms are not readily volunteered by the patient, thus it is important to ask. Should such symptoms be experienced, conservative measures may include dosage reduction, transient drug holidays for a special weekend or occasion, or switching to another SRI since patients may not have the same degree of dysfunction with a different agent. However if the clinician feels that it is critical to continue with same agent, various treatments have been reported in the literature. Usually taken within a few hours of sexual activity, no one agent has been shown to work consistently. Among those that have been tried are yohimbine, buspirone, cyproheptadine, bupropion, dextroamphetamine, methylphenidate, amantidine, nefazodone, to name but a few.

### Assessing Treatment Resistance

Before concluding that a patient is treatment-resistant, the adequacy of previous treatment trials must be assessed (see Table 51.2). In particular, it is critical to know both the duration and dose of every medication that has been used. Typically, patients who appear treatment-resistant have received an inadequate duration of treatment, which should be a minimum of 10 to 12 weeks, or an inadequate medication dose, which should be the maximum dose for any particular agent. Some psychiatrists consider patients truly treatment-resistant only if they have failed

**Table 51.2** Things to Consider in Patients with Obsessive–Compulsive Disorder in Whom Initial Treatment Fails

#### Was the diagnosis correct?

- Is there an Axis II disorder, especially schizotypal or obsessive–compulsive personality disorder?
- Are there comorbid diagnoses that could interfere with treatment response?
- Is there a major depressive disorder?
- Are there obsessive thoughts, overvalued ideas, or delusions?

#### Was the pharmacotherapy trial adequate?

- Was a known effective agent used?
- Was the dose adequate?
- Was the duration of treatment long enough?

#### Was behavioral therapy performed?

- Were an adequate number of sessions attended?
- Did the patient comply with homework assignment?
- Was there cognitive impairment inhibiting the ability to implement treatment?
- Was there concurrent use of central nervous system depressants that affect ability to attend to evoked anxiety?

several adequate pharmacologic trials, including one with clomipramine, and several augmentation strategies including behavioral therapy. With this kind of aggressive treatment, 80 to 90% of patients usually experience some improvement, although few patients become symptom-free.

When inadequate treatment is not the reason for poor treatment response, it is important to assess the accuracy of the diagnosis. Schizotypal personality disorder, borderline personality disorder, avoidant personality disorder and OCPD seem to be associated with poorer response to pharmacotherapy, particularly if the personality disorder is the primary diagnosis. Behavioral therapy seems less effective in patients with comorbid major depressive disorder. Comorbid depression may inhibit the ability to learn and to habituate to anxiety. Initial pharmacotherapy sometimes improves depression, as well as OCD symptoms, and may increase the likelihood of success with behavioral treatment.

### Augmentation Strategies

If a patient has had only a partial response to an antiobsessional agent of adequate dose and duration, the next question is whether to change the SRI or add an augmenting agent. Current clinical practice suggests that if there is no response at all to an SRI, it may be best to change to another SRI. However, if there has been some response to treatment, an augmentation trial of at least 2 to 8 weeks may be warranted. No augmentation agent has been firmly established as efficacious. Many questions about augmentation remain unanswered, including the optimal duration of augmentation, comparative efficacy of different agents, predictors of response and mechanism of action. Nonetheless, these agents do help some patients significantly, and thus their systematic use should be considered (see Table 51.3).

In patients with severe symptoms or comorbid psychosis or tic disorder, pimozide 1 to 3 mg/day, haldol 2 to 10 mg/day, and other neuroleptic agents (risperidone 2–8 mg/day and olanzapine 2.5–10 mg/day) have been used with some success.

**Table 51.3** Potential Augmenting Agents for Treatment-Resistant Obsessive–Compulsive Disorder

Augmenting Agent	Suggested Dosage Range*†
Lithium	300–600 mg/d†
Clonazepam	1–3 mg/d
Tryptophan	2–10 g/d‡
Trazodone	100–200 mg/d
Bupirone	15–60 mg/d
Alprazolam	0.5–2 mg/d
Methylphenidate	10–30 mg/d
Haloperidol	2–10 mg/d
Pimozide	2–10 mg/d
Nifedipine	10 mg t.i.d
Liothyronine sodium	10–25 mg/d
Clonidine	0.1–0.6 mg/d
Fenfluramine	Up to 60 mg/d

\*Add these to an ongoing trial of antidepressant medication. It should be noted that most of these dosages have not been tested with rigorous clinical trials but simply represent some of the reported doses tried in the current literature. Some would not recommend augmentation unless the initial treatment showed some response.

†Use with caution – there have been some reports of elevated lithium levels with ongoing fluoxetine treatment.

‡Because the use of l-tryptophan has been implicated in an increased incidence of eosinophilia, the authors advise against the prescribing and use of this agent until the issue is resolved.

Reprinted with permission from Management of patients with treatment-resistant obsessive–compulsive disorder, Jenike MA (1991). In Current Treatments of Obsessive–Compulsive Disorder, p. 146. Copyright 1991, American Psychiatric Press.

However, the use of a neuroleptic agent should be considered carefully in light of the risk of extrapyramidal symptoms and side effects such as weight gain, lethargy and tardive dyskinesia. Thus, when a neuroleptic drug is used, target symptoms should be established before beginning treatment, and the medication discontinued within several months if target symptoms do not improve.

The use of lithium (300–600 mg/day) and bupirone (up to 60 mg/day) as augmentation agents has also been explored. Both agents looked promising in open trials but failed to be effective in more systematic trials. Augmentation with fenfluramine (up to 60 mg/day), clonazepam (up to 5 mg/day), clonidine (0.1–0.6 mg/day) and trazodone (100–200 mg/day), as well as the combination of clomipramine with any of the SSRIs, has had anecdotal success but has not been evaluated in methodologically rigorous studies. Some potential augmenting agents and their dosage ranges are presented in Table 51.3.

## Behavioral Therapy

Behavioral therapy is effective for OCD both as a primary treatment and as an augmentation agent. This form of therapy is based on the principle of exposure and response prevention. The patient is asked to endure, in a graduated manner, the anxiety that a specific obsessional fear provokes while refraining from compulsions that allay that anxiety. The principles behind the efficacy of treatment are explained to the patient in the following way. Although compulsions, either covert or overt, usually immediately relieve anxiety, this is only a short-term solution; the

anxiety will ultimately return, requiring the performance of another compulsion. However, if the patient resists the anxiety and urge to ritualize, the anxiety will eventually decrease on its own (i.e., habituation will occur), and the need to perform the ritual will eventually disappear. Thus, behavioral therapy helps the patient habituate to the anxiety and extinguish the compulsions.

Compulsions, especially overt behaviors like washing rituals, are more successfully treated by behavioral therapy than are obsessions alone or covert rituals like mental checking. This is because covert rituals are physically harder to resist than are rituals like handwashing and checking a door. In fact washing rituals are the most amenable to behavioral treatment, followed by checking rituals and then mental rituals.

For rituals that do not constitute overt behaviors, techniques other than exposure and response prevention have been used in conjunction with exposure and response prevention. These approaches include imaginal flooding and thought stopping. In imaginal flooding, the anxiety provoked by the obsessions is evoked by continually repeating the thought, often with the help of a continuous-loop tape or the reading of a “script” composed by the patient and therapist, until the thought no longer provokes anxiety. In thought stopping, a compulsive mental ritual (e.g., continually repeating a short prayer in one’s head) is stopped by simply shouting, making a loud noise, or snapping a rubber band on the wrist in an attempt to interrupt the thought.

In the early stages of treatment, a behavioral assessment is performed. During this assessment, the content, frequency, duration, amount of interference and distress, and attempts to resist or ignore the obsessions and compulsions are catalogued. An attempt is made to clarify the types of symptoms, any triggers that bring on the obsessions and compulsions, and the amount and type of avoidance used to deal with the symptoms. For instance, in the clinical vignette described later, the fact that Ms Z stopped preparing meals to deal with her obsessional concerns about contamination was carefully documented. The patient, usually with the help of a therapist, then develops a hierarchy of situations according to the amount of anxiety they provoke. During treatment, patients gradually engage in the anxiety-provoking situations included in their hierarchy without performing anxiety-reducing rituals.

Behavioral therapy can be used with patients of any age and has been used in young children, often with the help of a parent as a cotherapist. However, systematic trials of behavioral treatment in children have not been performed. More recently, behavioral therapy in a group setting has been explored and found as effective as, and perhaps even more effective than, individual behavioral treatment. The group seems to act as a catalyst for change by promoting group cohesion, support and encouragement. Groups can include patients with different symptoms, though each has a personalized hierarchy, so that one patient can encourage another. Van Noppen and associates (1991) included family members in groups because families are often affected by the patient’s rituals and often function as unwilling participants in rituals. As members of the group, family members not only gain knowledge and understanding about OCD but can be cotherapists at home for homework assignments.

Despite its efficacy, behavioral therapy has limitations. To begin with, about 15 to 25% of patients refuse to engage in behavioral treatment initially or drop out early in treatment because it is so anxiety-provoking. Behavioral treatment fails in another 25% of patients for a variety of other reasons, including concomitant depression; the use of central nervous system depressants, which

**Clinical Vignette 1** *Pharmacology*

Ms M was a 38-year-old married teacher who had experienced OCD symptoms since age 10 years. At that time, she had a need to reread sentences, as well as a need to check things like doors and faucets to guard against something bad happening. Her symptoms subsided somewhat during her teenage years but resurfaced during her early twenties. She sought treatment from a hypnotherapist in her late twenties and subsequently did relatively well, with only minimal symptoms, for the next 10 years. She noted, however, that during that time she continued to be a nervous person who worried about everything.

At the time of her initial visit, she reported a significant worsening of her OCD symptoms during the previous weeks. In particular, she began to have trouble driving her car. She often found herself retracing her route to ascertain that she had not hit something or to pick up road debris that she was worried might get in her way. This behavior greatly lengthened her driving time and, as a result, Ms M began to drive less and to avoid unnecessary trips like driving to stores to shop. As her symptoms worsened, she began to avoid driving at night because she worried that she would not see debris and other objects in the road. In addition, much to her chagrin, she began to involve her husband in her rituals by asking him to drive back with her to make sure that nothing was wrong. She also experienced increased checking behavior, for example, rechecking how she had written a check or retracing her steps at school to ascertain that she had not kicked something down the stairs. Overall, she estimated that her symptoms were moderately severe and taking about 3 hours per day. Ms M had also begun to experience prominent neurovegetative symptoms of depression, including early morning awakening, decreased energy and initiative, psychomotor slowing and a 10-pound weight loss.

Ms M was entered in a 10-week placebo-controlled blinded clomipramine trial and received clomipramine 250 mg/day. Within 3 weeks of starting treatment, she began to show some signs of improvement. She reported less frequent episodes of driving back and less avoidance of driving to go shopping; however, she did not experience much change in other checking behaviors. After 5 to 6 weeks at 250 mg/day of clomipramine, Ms M noted marked improvement (approximately 85%) in her symptoms. She had only transient episodes of needing to drive back, which lasted less than 5 minutes, and no avoidance of driving; her checking had also improved. She began to have some symptom-free days. Ms M also had no depressive symptoms and experienced a general sense of well-being that was a significant improvement from her baseline. However, she began to complain of significant drowsiness and fatigue, despite adequate sleep, as well as dry mouth and tremor.

Within 10 weeks of beginning treatment, Ms M was virtually free of OCD symptoms, experiencing only a few mild and transient episodes. Because she was at the end of the blinded medication period, her clomipramine dose was decreased from 250 to 150 mg/day. Within 1 week, she reported that she had started retracing her route while driving and had other symptoms of OCD that occupied about 1 hour per day. Her dose was increased to 200 mg/day, but in 1 week she called her physician to say that she was distressed because her OCD symptoms had interfered with her ability to pick up her child and that her symptoms had increased to 3 hours per day. Her clomipramine was increased to 250 mg/day. Within 8 weeks, Ms M had returned to her previous level of good health. She was driving normally, was not checking or engaging in avoidance behavior, and had no obsessional fear of harm coming to others. Although on some days she experienced about 45 minutes of fleeting symptoms, on other days she was totally symptom-free. However, she was experiencing some side effects, such as dry mouth, tremor, weight gain and fatigue. Her fatigue became marked to the point that she came home from her job as a school teacher exhausted and slept 16 hours a day on the weekend.

After 1 year at 250 mg/day of clomipramine, a taper was again attempted, and the medication was discontinued within a month. Before the taper, Ms M's Y-BOCS score was 4 (out of a possible total score of 40), but after 2 weeks without medication it rose to 6, indicating an increased effort on her part to resist her obsessions and compulsions. After 7 weeks of not taking medication, her Y-BOCS score rose to 10, and after 15 weeks it rose to 16, indicating moderate symptom severity. She noted that she had 1 to 3 hours of obsessions and 1 hour of compulsions per day, with increasing effort needed to resist symptoms. In addition, she noted the return of her nervousness and tendency to worry. However, Ms M also had a lessening of her fatigue and lost five of the 10 pounds she had gained on the medication.

The return of symptoms was distressing to Ms M, and she decided to try another medication. Sertraline was begun, and after only 6 to 8 weeks of treatment, at 200 mg/day, she had a remission of all OCD symptoms and the return of a sense of well-being. She had no side effects. At 5 months of follow-up she remained symptom-free, and her Y-BOCS score had decreased to 1, with only 15 minutes of symptoms per week.

may inhibit the ability to habituate to anxiety; lack of insight; poor compliance with homework, resulting in inadequate exposure; and poor compliance on the part of the therapist in enforcing the behavioral paradigm. Thus, overall, 50 to 70% of patients are helped by this form of therapy.

One of the issues that has emerged in treating OCD with CBT is the lack of trained therapists and the cost of repeated individual exposure sessions. Thus, in addition to developing group treatments which allow therapists to treat a number of patients simultaneously, researchers have begun to develop computer-guided behavior therapy. Several recent reports have shown that while this modality is not as effective as individual behavior

therapy, it does allow for significant improvement in symptoms over a control condition like relaxation therapy.

Behavior therapy can be used as the sole treatment of OCD, particularly with patients whose contamination fears or somatic obsessions make them resistant to taking medications. Behavioral treatment is also a powerful adjunct to pharmacotherapy. Some research appears to indicate that combined treatment may be more effective than pharmacotherapy or behavioral therapy alone, although these findings are still preliminary. Some studies have even suggested that adding pharmacotherapy to behavior therapy may be particularly helpful in reducing obsessions while compulsions respond to behavior therapy. From a

clinical perspective, it may be useful to have patients begin treatment with medication to reduce the intensity of their symptoms or comorbid depressive symptoms if present; patients may then be more amenable to experiencing the anxiety that will be evoked by the behavioral challenges they perform.

Work by Baxter and colleagues (1992) has illustrated some interesting correlations between treatment response and changes in neuroanatomy and neurophysiology. Positron emission tomography scans with  $^{18}\text{F}$ -fluorodeoxyglucose were performed on all patients before and after treatment. Compared with nonresponders and control subjects, responders in both the medication and the behavioral treatment groups showed a decrease in activity in the right head of the caudate nucleus. This finding seems to support the notion that both forms of treatment bring about similar changes in neurophysiology which lead to improvement in symptoms. These results also provide important theoretical links with the serotonin hypothesis described earlier in this chapter, as basal ganglion structures like the caudate nucleus have been postulated to mediate serotonin function.

### Psychotherapy

The use of psychotherapeutic techniques of either a psychoanalytic or a supportive nature has not been proved successful in treating the specific obsessions and compulsions that are a hallmark of OCD. However, the more characterological aspects that are part of obsessive–compulsive personality disorder may be helped by a more psychoanalytically oriented approach. As noted earlier, the defense mechanisms of reaction formation, isolation and undoing, as well as a pervasive sense of doubt and need to be in control, are hallmarks of the obsessive–compulsive character. Salzman (1983) and MacKinnon and Michels (1971) have written elegantly on how to approach the maladaptive aspects of this character style in therapy. In essence, the patient must be encouraged to take risks and learn to feel comfortable with, or at least less anxious about, making mistakes and to accept anxiety as a natural and normal part of human experience. Techniques for meeting such goals in treatment may include the psychiatrist's being relatively active in therapy to ensure that the patient focuses on the present rather than getting lost in perfectly recounting the past, as well as the psychiatrist's being willing to take risks and present herself or himself as less than perfect.

### Neurosurgery

Occasionally, even after receiving adequate pharmacotherapy (including augmentation), adequate behavioral therapy, and a combination of behavioral therapy and pharmacotherapy, patients may still experience intractable OCD symptoms. Such patients may be candidates for neurosurgery. Although criteria for who should receive neurosurgery vary, it has been suggested that failure to respond to at least 5 years of systematic treatment is a reasonable criterion. Frequently used criteria are the following: a minimum of two adequate medication trials with augmentation plus adequate behavioral therapy in the absence of severe personality disorder.

The procedures that have been most successful interrupt tracts involved in the serotonin system. The surgical procedures used – anterior capsulotomy, cingulotomy and limbic leukotomy – all aim to interrupt the connection between the cortex and the basal ganglia and related structures. Current stereotactic surgical techniques involve the creation of precise lesions, which are often only 10 to 20 mm, to specific tracts. These procedures have often been done with radiofrequency heated electrodes and,

more recently, with gamma knife techniques. Postsurgical risks have been minimized, and in some cases cognitive function and personality traits improve along with symptoms of OCD.

Data compiled from a number of small studies have yielded success rates of 25 to 84% with treatment. However, most samples are small, and the procedures have often differed in both lesion location and size, making it difficult to compare them. However, in a recent prospective long-term follow-up study, all 44 patients received the same procedure (cingulotomy), although some had single procedures and others multiple procedures (Dougherty *et al.*, 2002). This study had several important findings. Clinical improvement occurred in 32 to 45% of patients, depending on the criteria used to rate full or partial response, and the average effect size was 1.27, comparable to that seen in pharmacologic trials (1.09–1.53). However, these changes were not immediately apparent postoperatively, and most patients were encouraged to engage in pharmacotherapy and/or behavior therapy postoperatively. The longitudinal follow-up component of the study, which was a mean duration of 32 months, allowed the researchers to assess the longer-term impact of the procedure in ways other studies could not. Of particular note, patients continued to show improvement for up to 29 months after surgery without receiving further procedures. As a result, the authors noted that the typical 6-month wait before deciding whether to repeat and extend the lesion may be too brief. In conclusion, neurosurgical treatments offer hope to some of the most severely ill and treatment-resistant patients and should therefore be considered. However, which surgical lesions are most effective in which patients still needs much more study.

### Issues in the Physician–Patient Relationship

Treatment for OCD is often effective, leading to at least some response in a majority of patients. However, treatment adherence is difficult for some patients, which may interfere with treatment efficacy. Short- and long-term compliance with treatment can be greatly facilitated by considering how the nature of the illness affects the treatment modalities used.

At the core of OCD are the concepts of obsessional doubt, risk aversion and a need to feel in control of one's environment. These three concepts affect behavioral and pharmacological treatment. In the initial phases of behavioral treatment, it may be difficult to engage the patient in treatment because of his or her doubt that the treatment will be effective and an unwillingness to experience the anxiety that results from exposure to feared stimuli. Extra time must often be spent convincing patients of the potential efficacy of treatment and lack of serious side effects from behavioral treatment. Unlike pharmacological treatment, in which the side effects can be quantified in medical terms, the side effects that patients fear from behavioral treatment are related to their cognitive distortions. For instance, those with contamination fears may be thoroughly convinced that simply walking by an AIDS clinic will put them at risk of contracting AIDS or that simply using a public bathroom will give them a communicable disease. Thus, reassurance that this is not the case and that it is safe to engage in behavioral treatment may first involve playing out the catastrophic consequences in their mind or role-playing and discussing the irrational nature of the fear to the fullest extent possible.

When behavioral treatment is started, it is customary to develop a hierarchy of subjective units of distress, which rate particular events according to how much anxiety they produce. For

some patients, the ability to develop this hierarchy and thereby obtain a sense of control over their fears, and the ability to begin with the least stressful challenges, can allow them to engage in behavioral treatment.

Similar concerns related to doubt, risk aversion and control must also be addressed when pharmacological treatment is undertaken. In the initial treatment phases, the major task is getting the patient to engage in treatment. Patients with OCD, particularly those with contamination and somatic obsessions, often have numerous questions about medication safety and may be hesitant to take them. Patients with contamination and somatic obsessions may be more likely to engage in behavioral treatment initially.

Although it is important that patients have a thorough understanding of side effects, the psychiatrist should not be thorough to an obsessional degree. Many patients with OCD want a detailed understanding of every side effect and have difficulty differentiating which side effects are of concern and which are not. Thus, it is critical when discussing side effects to present an objective assessment of the relative frequency and severity of various side effects. It is important to emphasize that even though some of the rare side effects are more serious than the more common side effects, they are unlikely to occur. It is also worth keeping in mind that the patient's concerns about a particular side effect may be different from the psychiatrist's. Again, it may help to elicit the catastrophic fears that the patient has and address the irrational obsessional qualities of those fears.

The initial phase of treatment is often the most difficult. This has to do with both risk aversion and a need to be in control. With pharmacologic treatment, patients may occasionally experience an initial worsening of symptoms in addition to side effects. This can be terrifying to the patient and can lead to an abrupt discontinuation of the medication. Warning the patient before treatment that this might occur increases the patient's sense of control. Similarly, the antiobsessional effects of treatment often take 6 to 10 weeks to be seen and are often gradual in onset. This gradual response is usually delayed until after the patient experiences side effects. Thus, the early phase of treatment may need to focus on encouraging the patient to stay on medication despite side effects and no improvement. Side effects can often be framed as a good sign that the medication is being actively absorbed by the body. Again, preparing patients in advance helps them feel in control and able to continue treatment. The gradual onset of improvement, although in some cases frustrating, is also reassuring to patients who might feel out of control if improvement occurred too rapidly.

Unlike many patients with mood disorders, most patients with OCD do not have full recovery from their symptoms. Although the majority of patients, perhaps as many as 85%, experience some improvement, most tend to remain symptomatic to some degree. Nonetheless, symptom improvement of even 10 to 15% can have a dramatic effect on their lives.

### Duration and Discontinuation of Treatment

Little systematic research has been performed to guide decisions about continuation, maintenance and discontinuation of treatment. The largest study of extended pharmacologic treatment involved fluoxetine (Tollefson *et al.*, 1994b). In this study, 70 patients who had responded to fluoxetine and 198 patients who had not responded during an acute 13-week trial were given the

opportunity to continue on medication for another 6 months. At the end of the 6 months, 74.3% of those who had responded initially experienced further improvement. In the nonresponder group, 91.7% experienced a decrease in symptoms when the medication dose was increased from the previous unsuccessful dose. Only 19% of patients ( $N = 13$ ) experienced a significant worsening of symptoms during the follow-up period. Similar to previous reports on fluoxetine, this study suggested that symptom improvement was maintained over time. Even more important, further improvement occurred in responders with longer treatment and in nonresponders with continued treatment at higher doses.

In another study, 85 patients who had been treated with a variety of antiobsessional medications were followed up 1 to 3.5 years after initial treatment (Orloff *et al.*, 1994). Ninety-four percent of the patients were still taking medication, and 87% had maintained previous gains or achieved further improvement. Thus, from a clinical point of view, it seems wise to continue medication for an extended period, perhaps for 6 months to a year after initiating treatment, because during this period improvement is maintained and some patients experience further improvement. Overall, this extended duration of treatment did not result in worsening side effects; in fact, in most cases patients habituated to side effects. In general, the most bothersome side effects that persist with SRI treatment appear to be fatigue, weight gain and sexual dysfunction.

In recent years a number of studies of long-term efficacy have emerged. One study that included a follow-up period of 2 years for 38 OCD patients on sertraline showed continued efficacy with fewer side effects with longer-term treatment. Another study assessed a larger group of patients and attempted to answer important clinical questions not only about long-term efficacy but about the effects of medication discontinuation after 1 year of treatment. The latter is an important question because few studies of systematic discontinuation have been carried out and in those that have been done relapse rates were quite high, above 90%. This sertraline study (Koran *et al.*, 2002) involved 223 patients who had been successfully treated with single-blind sertraline for 52 weeks who were then randomized in a double-blind manner to continue treatment for another 6 months or placebo. One-third of the patients in the placebo group relapsed; this was surprisingly lower than the percentage found in earlier studies. The authors offered several plausible explanations for this, which included the possibility that 1 year of effective treatment may provide sustained benefit for patients, and that patients may have engaged in self-directed behavior therapy, something that was not readily available at the time of the previous discontinuation studies. They also noted that while OCD symptom ratings did not worsen in the placebo-treated group as a whole, quality of life did significantly deteriorate. This finding points to the need for more sensitive measures of patient improvement and for further studies of long-term treatment efficacy.

Some preliminary data have suggested that in treatment responders it may be possible to decrease the dose of clomipramine over the longer term without subsequent relapse, although this important issue needs further investigation.

The data on discontinuation of behavioral therapy are also encouraging and overall, about 75% of patients continue to do well at follow-up. However, most studies also noted that few patients were symptom-free.

## Conclusion

For many patients with OCD the illness is life long, starting in early childhood and extending into adulthood. It is often familial and accompanied by comorbid conditions including depression, other anxiety disorders, Tourette's syndrome and even psychosis. However, with a combination of pharmacologic and behavioral treatment, at adequate dose and duration, patients can often have significant improvement in symptoms and overall function.

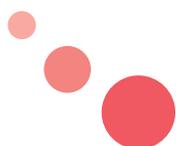

## Comparison of DSM-IV/ICD-10 Diagnostic Criteria

The ICD-10 Diagnostic Criteria for Research for Obsessive–Compulsive Disorder differentiate between obsessions and compulsions based on whether they are thoughts, ideas, or images (obsessions) or acts (compulsions). In contrast, DSM-IV-TR distinguishes between obsessions and compulsions based on whether the thought, idea, or image causes anxiety or distress or prevents or reduces it. Thus, in DSM-IV-TR, there can be cognitive compulsions which would be considered obsessions in ICD-10. In addition, ICD-10 sets a minimum duration of at least 2 weeks whereas DSM-IV-TR has no minimum duration.

# Anxiety Disorders: Traumatic Stress Disorders

## Post Traumatic Stress Disorder

### Definition

PTSD is defined in the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (DSM-IV) by six different criteria (American Psychiatric Association, 1994, see pp. 427–429). First, the disorder arises in a person who has been exposed to a traumatic event in which he or she experienced, witnessed, or was confronted with actual or threatened death or serious injury or a threat to the physical integrity of self or others. Furthermore, the response must have involved intense fear, helplessness, or horror. In children, it is allowed that the response may take the form of disorganized or agitated behavior.

Secondly, there must have been at least one of five possible intrusive symptoms occurring as a result of exposure to the trauma, as exhibited in either dream activity or waking life. These include recollections, images, thoughts, or perceptions of the event, recurrent distressing dreams, acting as if the trauma were recurring, and intense psychological or physical distress on exposure to internal or external cues resembling the trauma. Allowance is made for a different set of reactions in children, in whom intrusive symptoms may take the form of repetitive play, frightening dreams without recognizable content, or reenactment of the trauma.

Thirdly, persistent avoidance of stimuli associated with the trauma and numbing of general responsiveness must occur as exhibited by at least three of seven symptoms. Although grouped together as one criterion, it is likely that phobic avoidance, numbing and withdrawal do not reflect the same underlying phenomenon.

Fourthly, there must be at least two symptoms indicating the presence of increased arousal (i.e., difficulty sleeping, irritability or anger, difficulty concentrating, hypervigilance, or exaggerated startle response). Symptoms of PTSD should last at least 1 month, and it is necessary that the disturbances cause clinically significant distress or impairment in social, occupational, or other areas of functioning.

PTSD is considered to be “acute” if the duration of symptoms is between 1 and 3 months or “chronic” if it is 3 months or greater. If symptoms do not occur until at least 6 months have passed since the stressor, the delayed-onset subtype is given.

### Epidemiology

Community-based studies conducted in the USA have documented a lifetime prevalence rate for PTSD of approximately 8% of the adult population (Kessler *et al.*, 1995). In the National Comorbidity

## DSM-IV-TR Criteria 309.81

### Post Traumatic Stress Disorder

- A. The person has been exposed to a traumatic event in which both of the following were present:
  - (1) the person experienced, witnessed, or was confronted with an event or events that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others
  - (2) the person’s response involved intense fear, helplessness, or horror. **Note:** In children, this may be expressed instead by disorganized or agitated behavior
- B. The traumatic event is persistently reexperienced in one (or more) of the following ways:
  - (1) recurrent and intrusive distressing recollections of the event, including images, thoughts, or perceptions. **Note:** In young children, repetitive play may occur in which themes or aspects of the trauma are expressed
  - (2) recurrent distressing dreams of the event. **Note:** In children, there may be frightening dreams without recognizable content
  - (3) acting or feeling as if the traumatic event were recurring (includes a sense of reliving the experience, illusions, hallucinations, and dissociative flashback episodes, including those that occur on awakening or when intoxicated). **Note:** In young children, trauma-specific reenactment may occur
  - (4) intense psychological distress at exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event
  - (5) physiological reactivity on exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event
- C. Persistent avoidance of stimuli associated with the trauma and numbing of general responsiveness (not

present before the trauma), as indicated by three (or more) of the following:

- (1) efforts to avoid thoughts, feelings, or conversations associated with the trauma
- (2) efforts to avoid activities, places, or people that arouse recollections of the trauma
- (3) inability to recall an important aspect of the trauma
- (4) markedly diminished interest or participation in significant activities
- (5) feeling of detachment or estrangement from others
- (6) restricted range of affect (e.g., unable to have loving feelings)
- (7) sense of a foreshortened future (e.g., does not expect to have a career, marriage, children, or a normal life span)

D. Persistent symptoms of increased arousal (not present before the trauma), as indicated by two (or more) of the following:

- (1) difficulty falling or staying asleep
- (2) irritability or outbursts of anger
- (3) difficulty concentrating
- (4) hypervigilance
- (5) exaggerated startle response

E. Duration of the disturbance (symptoms in criteria B, C, and D) is more than 1 month.

F. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

*Specify if:*

**Acute:** if duration of symptoms is less than 3 months

**Chronic:** if duration of symptoms is 3 months or more

*Specify if:*

**With delayed onset:** if onset of symptoms is at least 6 months after the stressor

Survey replication this figure was 6.8% (Kessler *et al.*, 2005). The highest rates of PTSD occurrence for particular traumatic exposures (occurring in one-third to three-fourths of those exposed) are among survivors of rape, military combat and captivity, graves registration (i.e., registering dead bodies through the morgue), and ethnically or politically motivated internment and genocide.

Epidemiological studies show that PTSD often remains chronic, with a significant number of people remaining symptomatic several years after the initial event. In support of this view are epidemiological data that show that recovery frequently

does not occur. For example, the National Vietnam Veterans Readjustment study (Kulka *et al.*, 1990) found lifetime and current prevalence rates of PTSD to be, respectively, 30.9% and 15.2% in men and 26.9% and 8.5% in women. In a population of rape victims, Kilpatrick and colleagues (1987) found a lifetime prevalence rate of 75.8% and a current prevalence rate of 39.4%. In children, studies by Pynoos and associates (1993) revealed prevalence rates of 58.4% in children exposed to sniper attacks in the USA and 70.2% in those exposed to an earthquake in Armenia. Kessler and colleagues (1995) documented that one-third of those diagnosed with PTSD fail to recover even after many years. Therefore, chronicity of PTSD is not limited to the more severe treatment-seeking samples.

## Etiology and Pathophysiology

### The Event

PTSD is defined in terms of etiology as much as phenomenology. The disorder cannot exist unless the individual has been exposed to a traumatic event with a particular set of properties. Community-based epidemiological studies suggest that 70% of individuals will experience at least one traumatic event meeting criterion A(1) over the course of their lifetime. The relative severity of the traumatic event, predisposing factors and peritraumatic environmental factors must all be considered in understanding the etiology of PTSD. In most instances, occurrence of the disorder represents the outcome of an interaction among these three groups of factors. The likelihood of developing PTSD with regard to the nature of the event has shown consistent relationship occurred between magnitude of stress exposure and risk of developing PTSD. This association held up in many different trauma populations in adults and children.

Cognitive and affective responses to the stressor are also important in determining the likelihood that PTSD will develop. A traumatic event is defined as an event that involves experiencing or witnessing actual or threatened death or serious injury or learning about an unexpected or violent death and having a response that involves intense fear, helplessness, or horror.

### Biological Factors

Patients with chronic PTSD have increased circulating levels of norepinephrine and increased reactivity of the alpha-2-adrenergic receptors. These changes have been hypothesized possibly to account for some of the somatic symptoms that occur in individuals with PTSD. Neuroanatomical studies have implicated alterations in the amygdala and hippocampus in patients with PTSD. Functional magnetic resonance imaging and positron-emission tomography have demonstrated increased reactivity of the amygdala and anterior paralimbic region to trauma-related stimuli. Furthermore, in response to trauma-related stimuli, there is decreased reactivity of the anterior cingulate and orbitofrontal areas. These biological alterations suggest that there may be a neuroanatomical substrate for symptoms (intrusive recollections and other cognitive problems) that characterize PTSD. However, it is unknown whether these changes are preexisting, a result of traumatic exposure, or a result of having PTSD.

### Sympathetic Nervous System Alterations

There is a positive association between the diagnosis of PTSD and basal cardiovascular activity. Particularly, individuals with a current PTSD diagnosis have a higher resting heart rate relative to both trauma-exposed individuals without a PTSD diagnosis and

nontrauma-exposed controls and this appears to be greatest in studies with the most chronic PTSD samples. Along with increased 24-hour urinary catecholamines, results suggest an increase in sympathetic tone. There has been repeated demonstration that there is heightened sympathetic arousal in PTSD patients when reexposed to the original trauma in controlled settings.

Although a conditioning model provides a viable explanation of the process through which trauma-related cues may generate the heightened physiological responses characteristic of PTSD, it does not explain why some individuals develop PTSD when exposed to traumatic events, while others do not. It has been hypothesized that differential susceptibility to developing PTSD might be attributable in part to individual differences in conditionability, such that some individuals more readily acquire and maintain a conditioned response compared with others, and thus may be more likely to develop PTSD after a traumatic event.

There is evidence of brain dysfunction in individuals with PTSD as evidenced by abnormalities in evoked potentials. These ERP findings suggest that PTSD patients have increased cortical inhibition to high-intensity stimuli, impairments in memory and concentration, auditory gating deficits and heightened selective attention to trauma-related stimuli. However, whether these processing abnormalities are a precursor or a result of PTSD awaits further study.

Psychophysiological response to acute trauma exposure may predict the development of PTSD. Shalev and colleagues (1990) demonstrated that on arrival to the emergency department, regardless of whether PTSD ultimately developed, survivors of traumatic events showed elevated heart rates upon arrival to the emergency department, which at later assessment occasions were normal. However, those who subsequently developed PTSD showed higher emergency department and 1-week heart rates than those who did not.

### Neuroendocrine Factors

The hypothalamic–pituitary–adrenal (HPA) axis has been the most extensively studied neuroendocrine system in PTSD. The principal findings are as follows: reduced 24-hour urinary cortisol excretion, supersuppression of cortisol after low-dose dexamethasone administration, blunting of corticotropin in response to corticotropin-releasing hormone and increased numbers of glucocorticoid receptors. This suggests that chronic PTSD is accompanied by supersuppression of the emergency HPA response to acute stress. This may result from the organism's attempt to protect itself from the potentially toxic effect of high levels of corticosteroids that might occur with repeated exposure to stress or from reminders of the trauma. In further support of the importance of HPA axis alteration in PTSD is the finding that glucocorticoid receptor changes also correlate with the severity of PTSD symptoms, but not with the less specific anxiety and depressive symptoms measured on other rating scales. More recently, in a large sample of Vietnam veterans, combat-exposed veterans with current PTSD had lower cortisol compared with noncombat-exposed veterans without PTSD or combat-exposed veterans with lifetime PTSD but without current PTSD (Boscarino, 1996).

Further evidence for abnormalities in neurotransmitter regulation comes from provocation studies conducted with Vietnam veterans. Administration of yohimbine, an alpha<sub>2</sub>-adrenergic antagonist, provoked symptoms of PTSD in combat veterans who had PTSD as did the serotonergic challenge with *m*-chlorophenylpiperazine. Of considerable interest is that there was no

overlap between these two groups, suggesting some selectivity in the way in which neurotransmitter systems can be affected between individuals (Southwick *et al.*, 1993; Krystal *et al.*, 1989). Finally, evidence to support alteration of noradrenergic and serotonergic pathways in PTSD comes from the clinical effects of medications that are selective for these neurotransmitter systems, as discussed later. The opioid system has also been investigated, but less extensively and without any consensus being obtained.

### Sleep Studies

Studies support that there are two distinct, but possibly interrelated types of sleep complaints in individuals with PTSD: nightmares that replicate traumatic events and impairment in initiating and maintaining sleep. Data further suggest that sleep problems in PTSD can also include excessive motor activity and awakenings with somatic anxiety symptoms. There is support for these complaints using polysomnography (PSG) studies, particularly in reduced sleep time or efficiency, and increased awakenings in the PTSD patients. There has also been documentation of PTSD subgroups that evidence breathing-related sleep disorders. PTSD is associated with a more fragmented rapid eye movement sleep as well.

### Psychological Factors

#### Behavioral Models

Conditioning theory has been helpful in explaining the process through which stimuli that are associated with a traumatic event can alone elicit intense emotional responses in individuals who have PTSD. Cues (i.e., conditioned stimuli) that are present at the time of the trauma (the unconditioned stimulus) become associated with the unconditioned emotional response (fear, helplessness, or horror). Following the traumatic event, these cues alone can then repeatedly elicit the strong emotional response. For example, a woman who has been raped (unconditioned stimulus) in a dark alley (conditioned stimulus) by a man (conditioned stimulus) and has an intense fear response (unconditioned response) may demonstrate a fear response (now the conditioned response) when she sees a dark alley (conditioned stimulus) or is in the presence of a man (conditioned stimulus). Avoidance behaviors develop to decrease anxiety associated with the conditioned stimuli. For example, the woman who has been raped may avoid going outside when it is dark and also avoid being in the company of men. Behavioral treatments using exposure principles require confrontation with the feared situation and may ultimately lead to reduction of anxiety.

#### Cognitive and Information Processing

Exposure to a severe or unexpected event may result in an inability to process and assimilate the experience adequately or to deal effectively with its impact. A period of prolonged, difficult and often incomplete assimilation occurs. The experience is kept alive in active memory, intruding itself into awareness either during the day or at night. The pain of the unbidden experience is followed by active attempts to avoid reminders of the trauma. These intrusive and avoidance phases often alternate (Horowitz, 1973).

Fear can be considered a cognitive structure with three elements: stimulus, response and meaning. To reduce fear, the fear memory must first be activated and then new information provided to modify the fear structure. Cognitive interventions can be used to recognize and change maladaptive cognitions and to

replace interpretations of danger by realistic or safer interpretations, with the ultimate hope that the patient will integrate the new information into the fear structure, leading to a more realistic appraisal of the degree of danger.

### Genetic–Familial Factors

From the available literature, which is based on male combat veterans, general population surveys and rape-trauma-related PTSD, there is evidence to suggest that anxiety and depression in families is a risk factor for PTSD. A twin study of Vietnam veterans concordant and discordant for combat exposure has shown that a significant part of the variance is explained on the basis of genetic factors with respect to all three symptom clusters (i.e., intrusive, avoidant and hyperarousal symptoms) (True *et al.*, 1993). McLeod and colleagues (2001) examined the role of genetic and environmental influences on the relationship between combat exposure, post traumatic stress disorder symptoms and alcohol use in 4072 male–male twin pairs; the authors found that alcohol problems occur together because of a shared vulnerability that increases risk for both disorders. These findings are most consistent with the shared vulnerability hypothesis in which combat exposure, PTSD symptoms and alcohol use are associated because some portion of the genes that influence vulnerability to combat also influence vulnerability to PTSD symptoms and alcohol consumption. It is important to note, however, that specific unique environmental factors the twins did not share were more important than genetic factors for combat exposure and PTSD symptoms, whereas environmental influences appeared about equally important as genetic influences on alcohol use. Overall, the evidence suggests that psychiatric history, both personal or in family members, increases the likelihood of being exposed to a trauma and of developing PTSD once exposed.

### Other Factors

Although systematic research is scant, it may be that individuals exposed to repeated or continuous trauma, particularly of an interpersonal nature, may be more likely to develop PTSD. Trauma involving loss of community or support structures is likely to be particularly damaging. Because social support has been held to produce a buffering effect, lack of support might be considered an additional vulnerability factor. Women are at more risk than men for PTSD.

## Diagnosis

### Assessment and Diagnostic Features

The diagnosis of PTSD is based on a history of exposure to a traumatic stressor, the simultaneous appearance of three different symptom clusters, a minimal duration and the existence of functional disturbance. To qualify as traumatic the event must have involved actual or threatened death or serious injury or a threat to the patient or others, and exposure to this event must arouse an intense affective response characterized by fear, helplessness, or horror. In children, disorganized or agitated behavior can be seen in lieu of an intense affective response. Symptomatically, there must be at least one of five possible intrusive-reexperiencing symptoms. These have the quality of obsessive, recurring, intrusive and distressing recollections either in the form of imagery or thoughts, or in the form of recurrent distressing dreams. Intense psychological distress or physiological reactivity on exposure to either an external reminder or an internal reminder of the trauma

can also occur. The flashback experience, or reliving of the event, is less common.

Symptom cluster C in the DSM-IV-TR criteria in actuality embodies two somewhat different psychopathologies, namely, phobic avoidance and numbing or withdrawal. The phobic avoidance is expressed either in 1) efforts to avoid thoughts and feelings, and conversations associated with the trauma or 2) in efforts to avoid activities places or people that arouse recollections of the trauma; 3) psychogenic amnesia, a more dissociative symptom, is also in this symptom grouping, followed by 4) markedly diminished interest; 5) feeling detached or estranged; 6) having a restricted range of affect; and 7) having a sense of a foreshortened future. At least three of these seven symptoms must be present.

Hyperarousal symptoms, somewhat similar to those of generalized anxiety disorder, are also present in PTSD and at least one of five of the following symptoms is required: difficulty sleeping, irritability or anger, poor concentration, hypervigilance and exaggerated startle response.

With regard to the symptoms as a whole, it is evident that they embody features of different psychiatric disorders, including obsessive–compulsive processes, generalized anxiety disorder, panic attacks, phobic avoidance, dissociation and depression. Finally, it is necessary for symptoms to have lasted at least 1 month and for the disturbance to have caused clinically significant distress or impairment.

### Assessment and Differential Diagnosis

PTSD symptoms may overlap with symptoms of a number of other disorders in the DSM-IV. Both PTSD and adjustment disorder are etiologically related to stress exposure. PTSD may be distinguished from adjustment disorder by assessing whether the traumatic stress meets the severity criteria described earlier. Also, if there are an insufficient number of symptoms to qualify for the diagnosis, this might merit a diagnosis of adjustment disorder.

Specific phobia may arise after traumatic exposure. For example, after an automobile accident, victims may develop phobic avoidance of traveling, but without the intrusive or hyperarousal symptoms. In such cases, a diagnosis of specific phobia should be given instead of a diagnosis of PTSD.

The criteria set for generalized anxiety disorder include a list of six symptoms of hyperarousal, of which four are common to PTSD: being on edge, poor concentration, irritability and sleep disturbance. PTSD requires the additional symptoms as described earlier, and the worry in PTSD is focused on concerns about reexperiencing the trauma. In contrast, the worry in generalized anxiety disorder is about a number of different situations and concerns. However, it is possible for the two conditions to coexist.

In obsessive–compulsive disorder, recurring and intrusive thoughts occur, but the patient recognizes these to be inappropriate and unrelated to any particular life experience. Obsessive–compulsive disorder is a common comorbid condition in PTSD and may develop with generalization (e.g., compulsive washing for months after a rape to reduce contamination feelings). It may also develop by activation of an underlying obsessive–compulsive disorder diathesis.

Autonomic hyperarousal is a cardinal part of panic attack, which may indicate a diagnosis of panic disorder. To distinguish between panic disorder and PTSD, the therapist needs to assess whether panic attacks are related to the trauma or reminders of the same (in which case they would be subsumed under a diagnosis of

PTSD) or whether they occur unexpectedly and spontaneously (in which case a diagnosis of panic disorder would be justified).

Depression and PTSD share a significant overlap, including four of the criterion C cluster symptoms and three of the criterion D cluster symptoms. Thus, an individual who presents with reduced interest, estrangement, numbing, impaired concentration, insomnia, irritability and sense of a foreshortened future may manifest either disorder. PTSD may give rise to depression as well, and it is possible for the two conditions to coexist. In a few instances, a patient with prior depression may be more vulnerable to developing PTSD. Reexperiencing symptoms are present only in PTSD.

Dissociative disorders also overlap with PTSD. In the early aftermath of serious trauma, the clinical picture may be predominantly one of the dissociative states (see the section on acute stress disorder [ASD]). ASD differs from PTSD in that the symptom pattern occurs within the first few days after exposure to the trauma, lasts no longer than 4 weeks, and is typically accompanied by prominent dissociative symptoms.

More rarely, PTSD must be distinguished from other disorders producing perceptual alterations, such as schizophrenia and other psychotic disorders, delirium, substance use disorders and general medical conditions producing psychosis (e.g., brain tumors).

The differential diagnosis is important but, notwithstanding, PTSD is unlikely to occur in isolation. Psychiatric comorbidity is the rule rather than the exception, and a number of studies have demonstrated that, in both clinical and epidemiological populations, a wide range of disorders is likely to occur at an increased probability. These include major depressive disorder, all of the anxiety disorders, alcohol and substance use disorders, somatization disorder, and schizophrenia and schizophreniform disorder. A few studies have documented the course of comorbid conditions. Major depressive disorder cooccurs with PTSD, but can take a separate course. Comorbid substance abuse tends to be a consequence rather than a precursor of PTSD.

## Assessment

The comprehensive evaluation of PTSD should include information from the individual, collaterals, psychometric indices (such as self-reported questionnaires) and a clinical interview. The standard for diagnosis in clinical research studies is always to use a structured clinical interview. The use of self-report instruments can be used to corroborate information obtained in the clinical interview, or can be used as a screening assessment for a clinical interview. All information would then be integrated on the basis of clinical judgment, especially if discrepancies existed. A number of structured interviews exist, along with other self-rating scales. The “gold standard” of clinical interviewing is the Clinician-Administered PTSD scale (Blake *et al.*, 1990). Other instruments that have been used to evaluate PTSD are the Structured Clinical Interview for DSM-IV, the Diagnostic Interview Schedule and the Structured Interview for PTSD. Self-rated measures that can be used include self-rating psychometric assessments, such as the Davidson Trauma Scale, the Short PTSD Rating Instrument (SPRINT), the PTSD Checklist, the PK scale on the Minnesota Multiphasic Personality Inventory, the Mississippi Scale for Combat-Related PTSD, the Impact of Events Scale and the PTSD Scale.

Structured interview and psychometric measures are also available for children with PTSD but are less well developed with regard to validity and reliability. A version of the Clinician-Administered PTSD Scale for children and adolescents allows

for current and lifetime diagnoses as well as the dimensional assessment of PTSD symptoms and related psychopathology. It has also been suggested that the use of additional measures (such as the Conners Parent Rating Scale and Conners Teacher Rating Scale) are important adjuncts to assess externalizing collateral symptoms, whereas the Children’s Depression Inventory can be used to assess internalizing symptoms found in PTSD.

## Course and Natural History

Immediately following traumatic exposure, a high percentage of individuals develop a mixed symptom picture, which includes disorganized behavior, dissociative symptoms, psychomotor change and, sometimes, paranoia. The diagnosis of ASD (described later) accounts for many of these reactions. These reactions are generally short-lived, although by 1 month the symptom picture often settles into a more classic PTSD presentation, such that after rape, for example, as many as 90% of individuals may qualify for the diagnosis of PTSD. Approximately 50% of people with PTSD recover, and approximately 50% develop a persistent, chronic form of the illness still present 1 year following the traumatic event.

The longitudinal course of PTSD is variable and permanent recovery occurs in some people, whereas others show a relatively unchanging course with only mild fluctuation. Still others show a more obvious fluctuation with intermittent periods of well-being and recurrences of major symptoms. In a limited number of cases, the passage of time does not bring a resolution of symptoms, and the patient’s condition tends to deteriorate with age. Particular symptoms that have been noted to increase with time in many people include startle response, nightmares, irritability and depression. Clinicians during World War II also observed that the existence of marked startle response and hypervigilance in the acute aftermath of exposure to combat often represented a comparatively poor prognostic sign. In children, PTSD can be, and often is, chronic and debilitating.

General medical conditions may occur as a direct consequence of the trauma (e.g., head injury, burns). In addition, chronic PTSD may be associated with increased rates of adverse physical outcomes, including musculoskeletal problems and cardiovascular morbidity.

## Overall Goals of Treatment

General principles of treating PTSD involve explanation and destigmatization, which can be provided both to the patient and to family members. This often includes a description of the symptoms of PTSD and the way in which it can affect behaviors and relationships. Information can be given about general treatment principles, pointing out that sometimes cure is attainable but that at other times symptom containment is a more realistic treatment goal, particularly in chronic and severe PTSD. Regaining self-esteem and attaining greater control over impulses and affect are also desired in many instances. Information can be provided as to appropriate literature, local support groups and resources, and names and addresses of national advocacy organizations. If the therapist attends to these important issues early in treatment, the patient is able more readily to build trust and also to appreciate that the therapist shows a good understanding both of the condition and of the patient.

PTSD is sometimes comparatively straightforward to treat and at other times it is more complicated. However, treatment by a mental health provider (rather than a primary care provider) is almost always indicated. The initial history taking can evoke strong affect to a greater degree than is customarily found in other

disorders. In fact, it may take several interviews for the details to emerge. A sensitive yet persistent approach is needed on the part of the interviewer. During treatment, although the mental health care provider will clearly want to impart a sense of optimism to the patient, it is also a reflection of reality to point out early that recovery may be a slow process and that some symptoms (e.g., phobic avoidance, startle response) may persist. It is important for the mental health care provider to be comfortable in hearing and tolerating unpleasant affect and often horrifying stories. All these must take place in a noncritical and accepting manner.

### Pharmacotherapy

PTSD may be accompanied by enduring neurochemical and psychophysiological changes and can lead to substantial impairment and distress. Sometimes the intensity of symptoms is severe enough to preclude the effective use of trauma-focused psychotherapy. In these situations, the use of medication should not be delayed unnecessarily. Initial studies showed benefit for the tricyclic antidepressant and monoamine oxidase inhibitor medications, however, the selective serotonin reuptake inhibitors (SSRIs) have now replaced these as first-line agents, based upon evidence from several placebo-controlled trials. A suggested sequencing of treatment is outlined in Table 52.1.

Two double-blind clinical trials in more than 100 patients support the efficacy of amitriptyline and imipramine in combat veterans with PTSD (Frank *et al.*, 1988; Davidson *et al.*, 1990). In both studies, the medication was effective on intrusive PTSD symptoms and, to a weaker extent, on avoidant symptoms (Table 52.2). Of importance was that clinical efficacy occurred in patients who did not suffer from depressive illness, suggesting that the effect of tricyclic agents in PTSD is independent of

**Table 52.1** Pharmacotherapy Steps for Post Traumatic Stress Disorder

Step 1
Selective serotonin reuptake inhibitor (SSRI)
Adjunctive medications:
If prominent hyperarousal: benzodiazepine or buspirone
If prominent mood lability or explosiveness: anticonvulsant or lithium
If prominent dissociation: valproic acid
If persistent insomnia: trazodone
If psychotic: atypical antipsychotic
Step 2
If no response or intolerance to SSRI:
Dual action antidepressant, e.g., mirtazapine, venlafaxine
Adjunctive medications as above
Step 3
If no response to Step 1 or 2:
Monoamine oxidase inhibitor
Adjunctive medications as above
Step 4
Other useful drugs:
Propranolol – hyperarousal
Clonidine – startle response
Neuroleptics – psychosis, poor impulse control

**Table 52.2** Factors Associated with Good Response to Tricyclic Drug Therapy and Direct Therapeutic Exposure in Combat Veterans with Post traumatic Stress Disorder

	Pharmacotherapy	Psychotherapy
Older age	No effect	Yes
Lower level of trauma intensity	Yes	Yes
Fewer comorbid disorders	Yes	Yes
Low depression score	Yes	Yes
Low PTSD symptom severity score	Yes	Yes
Low anxiety symptom score	Yes	Yes
Low avoidance of trauma cues	Yes	Unknown
Low autonomic arousal	Yes	Unknown
Low neuroticism	Yes	Unknown
Good social adjustment	Unknown	Yes

antidepressant properties. In fact response was inversely correlated with baseline depression level.

Phenelzine has been found to be effective in symptom reduction and that avoidant symptoms improve to a much greater degree with phenelzine than with the tricyclic agents. However, the side effects of phenelzine limit its use to a third- or fourth-line drug to be used only when other, safer medications have failed to work. Several placebo-controlled trials have shown positive effects for the SSRI medications, including fluoxetine, sertraline and paroxetine. Long-term use of sertraline is associated with a substantial reduction in relapse over a 15-month period. Data support positive effects for SSRI in men and women and in adults who have survived all major classes of trauma (e.g., combat, sexual violence, nonsexual violence and accident). Each of these medications has broad-spectrum properties across the full symptom range of the disorder as well as improving function and, perhaps, resilience or stress-coping. They also support the benefit of SSRI in those with and without comorbid major.

At this point, the indications for antipsychotic and mood-stabilizing drugs are poorly defined, but clinical experience suggests that they continue to have a role in the pharmacologic treatment of PTSD. Antipsychotic medications can be useful in patients with poor impulse control or in those who manifest features of borderline personality disorder. Lithium and carbamazepine can also be useful in such patients but might benefit individuals who are subject to mood swings and angry or explosive outbursts. The appropriate role for the use of benzodiazepines is not well-defined. The antiphobic and antiarousal effects of the benzodiazepines should, in theory, be helpful in PTSD. However, withdrawal from short-acting benzodiazepines may also

introduce an additional set of problems with intense symptom rebound. In patients who have a propensity to abuse alcohol and other substances, benzodiazepines are not recommended.

Overall, the antidepressants, mood stabilizers and anticonvulsants are the medication groups that are generally considered primary for treating PTSD; beta-blockers, alpha<sub>2</sub>-agonists and anxiolytics have a less clearly defined place. Often, patients need a combination of drugs but polypharmacy should be utilized in a carefully planned fashion. Also, since the time course of response may be slow, it is advisable to persist with a particular course of action for at least 8 weeks before deciding that it has been unhelpful. It is possible that avoidance and numbing symptoms respond more effectively to SSRI drugs.

### Cognitive, Cognitive–Behavioral and Behavioral Therapies

Despite theoretical differences, most schools of psychotherapy recognize that cognitively oriented approaches to the treatment of anxiety must include an element of exposure. Because PTSD involves aberrant and voluntary programs for the avoidance of danger that are conditioned by real experience, correction of these “fear structures” requires exposure to ensure habituation. Although a range of possible PTSD interventions has recently been reviewed (Foa *et al.*, 2000) including group therapy, cognitive–behavioral therapy, eye movement desensitization and reprocessing, and psychodynamic therapy, the preponderance of current evidence suggests that the primary effective component of PTSD treatment is prolonged exposure (Rothbaum *et al.*, 2000). Prolonged exposure depends on the fact that anxiety will be extinguished in the absence of real threat, given a sufficient duration of exposure *in vivo* or in imagination to traumatic stimuli. In PTSD, the patient retells the traumatic experience as if it were happening again, until doing so becomes a pedestrian exercise and anxiety decreases. Between sessions, patients perform exposure homework, including listening to tapes of the flooding sessions and limited exposure *in vivo*. A review of 12 studies suggests that prolonged exposure is a component of the most well-controlled study designs and is associated with positive results (Rothbaum *et al.*, 2000). However, not every patient may be a candidate for exposure. Due to the high anxiety and temporarily increased symptoms associated with prolonged exposure, there are patients who will be reluctant to confront traumatic reminders. Patients in whom guilt or anger are primary emotional responses to the traumatic event (as opposed to anxiety) may not profit from prolonged exposure. More empirical research is needed to evaluate how this efficacious treatment can be most effectively implemented in nonacademic settings. In addition, additional research is needed to identify methods to increase patient tolerability of the treatment.

Anxiety management techniques are designed to reduce anxiety by providing patients with better skills for controlling worry and fear. Among such techniques are muscle relaxation, thought stopping, control of breathing and diaphragmatic breathing, communication skills, guided self-dialogue and stress inoculation training (SIT). Although these interventions have less empirical evidence regarding treatment efficacy for PTSD, generally the results are positive and further controlled evaluation across trauma population samples is needed.

Further, cognitive approaches to the treatment of PTSD have also gained empirical support. A cognitive approach to treatment includes training patients in challenging problematic cognitions such as self-blame. In a recent comparison

of cognitive therapy to imaginal exposure in the treatment of chronic PTSD, both treatments were associated with positive improvements at post treatment and follow-up, with no differences in outcome between treatments. However, patients who received imaginal exposure were more likely to experience an increase in PTSD symptoms during the treatment course, and those who did were more likely to miss treatment sessions, rate the therapy as less credible and be rated as less motivated by the therapist.

In contrast to the treatment-efficacy literature for adults with PTSD, the child-focused PTSD literature is limited to open trials and case reports. Treatment practices for childhood PTSD have recently been surveyed (Cohen *et al.*, 2001). Clearly, adult treatment approaches need to be empirically evaluated for use in children with PTSD. As no single treatment for PTSD has been shown to be curative, patient characteristics, characterization of the nature and range of stress responses of trauma victims, partial response, treatment combinations, sequencing of treatment approaches and further well-controlled investigations of current approaches are all important empirical topics to be addressed.

### Psychodynamic Therapy

Psychodynamically based approaches emphasize the interpretation of the traumatic event as being a critical determinant of symptoms. Treatment is geared to alter attributions, usually by means of slow exposure and through confrontation and awareness of the negative affect that have been generated by the trauma. Confictual meanings begin to appear, and it is the task of treatment to reinterpret the experience in a more realistic and adaptive fashion. During such treatment, it is important to ensure that the affect intensity is not overwhelming or disorganizing. Obviously, support needs to be provided throughout, and sometimes other treatment approaches are used adjunctively. Excessive and maladaptive behaviors such as avoidance, use of alcohol or work, or risk taking may occur as a means of coping with the experience and these need to be identified and addressed.

Using psychodynamic concepts, Horowitz (1973) developed a trauma-focused, time-limited, psychotherapeutic approach. Periods of intrusion are considered an attempt at mastery rather than a failure in defenses, whereas emotional numbness is seen as a result of defensive overcontrol. Overwhelmingly intrusive symptoms are counteracted by means of structuring, and avoidance and numbing are met with procedures to minimize such behavior. With this approach, as with any psychotherapeutic approach, the establishment of a safe therapeutic alliance is essential and medications are used sparingly. The goal of such trauma-focused therapy is to achieve an end point in which the trauma is meaningfully integrated into the survivor's life schema, with reduction of intensity and frequency of the intrusive and avoidant phases of PTSD. Although this approach awaits controlled testing, it aspires to reduce all aspects of PTSD symptoms.

Roth and Newman (1991) presented a conceptual framework for understanding the emotional impact of sexual trauma. The survivor must come to understand the affective impact of the event so that she or he is no longer preoccupied or driven by negative feelings or self-defeating behaviors. It is also important for the survivor to grapple with the meaning of the trauma so as to reach adaptive resolution. Preliminary studies utilizing this approach show promise of efficacy.

## Special Features Influencing Treatment

### Psychiatric Features

Several important issues of comorbidity need to be considered in the treatment of PTSD. These may suggest either a contraindication to a particular treatment or the need first to treat the comorbid state before embarking energetically on the PTSD problems. Thus, comorbid depression needs to be treated, as it is likely to interfere with the benefits of behavioral therapy or other psychotherapies. In fact, as mentioned earlier, in some instances guilt-bound issues may worsen with exposure. A suicidally depressive individual with PTSD needs to be adequately treated before dealing with issues of PTSD, which may in fact worsen suicidality in some instances.

Occasionally, severe depression comorbid with PTSD may need to be treated with electroconvulsive therapy. Although this form of treatment has no proven place as a major intervention for PTSD per se, in comorbid cases it has been noted that PTSD symptoms may also abate when they are tied to the presence of depression. Amitriptyline is less likely to help combat veterans with PTSD if they have been exposed to more severe forms of combat trauma, and also if they have more severe symptoms of depression, anxiety and PTSD. Antisocial and severe borderline personality disorder may be contraindications to various forms of psychotherapy and are unlikely to respond well to pharmacotherapy.

### General Medical Comorbidity

PTSD patients have been shown to have an increased risk of physical conditions, with particular conditions perhaps being more prevalent (gastrointestinal disease and cardiovascular disease). There is also evidence that chronic pain and PTSD are commonly associated, even when PTSD has not followed serious physical injury.

### Demographical Features

It is not known to what extent sex or age is likely to determine treatment outcome. However, it is generally believed that lack of psychosocial supports can interfere with successful adaptation to trauma and response to treatment.

### Nonresponse to Treatment

A stepwise sequence of approaches may be used in the treatment of PTSD but it must be said that there are no definitive guidelines currently in place. As a result, the particular order in which treatments are considered varies based on individual circumstances. Also, no uniform definition exists as to what constitutes a good or poor response to treatment. In general, some symptoms of chronic PTSD persist, albeit at a considerably reduced level, in people who have undergone treatment. A summary of the limited information available for predicting response to pharmacotherapy and behavioral therapy in PTSD arising from combat trauma is given elsewhere (Davidson and Fairbank, 1993).

Management problems are likely to occur as a result of both therapist-related factors and factors related to the patient. With regard to the therapist, it must be recognized that much of the material offered by the patient is charged with affect and, at times, may strain credibility and lead to high levels of doubt. The therapist may fall into the error of being unable to accept such an emotionally charged experience and thus rejecting or denying its validity. Equally, the therapist may fall into the error of over-identification with the patient such that impartiality is lost. It is

important for therapists not to become overinvolved with rescue or to break down customary therapist–patient boundaries.

Although not unique to PTSD, powerful violent urges may arise in the patient during treatment, which may challenge the therapist's feeling of safety. Simple strategies, such as where the patient and therapist sit with respect to proximity of escape, merit attention. For example, a female therapist dealing with a highly hostile and threatening male patient would do well to be sure that she can exit the room quickly if necessary and not be trapped behind a desk with the patient having control of the exit. Another simple yet important issue calling for attention is whether there is an available alarm if the therapist is dealing regularly with violent or threatening patients.

With respect to the patient, there are times when decompensation occurs to such an extent that the provider will have to judge whether hospitalization is indicated. Denial of particularly painful issues can lead to avoidance of therapy and missed appointments. Similarly, the emergence of unpleasant or troubling side effects with medication may also lead to treatment discontinuation. At all times, it is advisable for the therapist to remind the patient that difficult issues will arise periodically and that, rather than the patient taking unilateral action to drop out of treatment, these issues are best discussed with the therapist, with the hope that they can be resolved and further treatment progress can be made.

At times, it is helpful to engage the spouse or significant family member in treatment because of the difficulties and stresses to which they may be subjected. Furthermore, they can provide information that might help the therapist to acquire a better grasp of the severity of symptoms as well as their effects on the lives of others. For example, sleeping partners can give a more graphic account of the nocturnal disturbances that may occur in symptomatic patients with PTSD. They may also provide important supplementary information as to the effects of poor impulse regulation or impaired memory or concentration on daytime behaviors in an individual.

Given that many patients with PTSD are receiving more than one treatment, coordination of effort between providers is important. At times, different philosophical persuasions may result in one provider being somewhat less supportive of another's efforts, a situation in which everybody loses. Mutual respect for each other's efforts is essential if optimal progress is to be made by the patient.

## Summary of Treatment

Whatever the type of treatment administered, a number of goals are common to all and can be summarized as follows: 1) to reduce intrusive symptoms; 2) to reduce avoidance symptoms; 3) to reduce numbing and withdrawal; 4) to dampen hyperarousal; 5) to reduce psychotic symptoms when present; and 6) to improve impulse control when this is a problem.

By reducing troublesome symptoms, a number of other important goals can also be accomplished as follows: 1) to develop the capacity to interpret events more realistically with respect to their threat content; 2) to improve interpersonal work and leisure functioning; 3) to promote self-esteem, trust and feelings of safety; 4) to explore and clarify meanings attributed to the event; 5) to promote access to memories that have been dissociated or repressed when judged to be clinically appropriate; 6) to strengthen social support systems; and 7) to move from identification as a victim to that of a survivor.

The three major treatment approaches, pharmacotherapeutic, cognitive-behavioral and psychodynamic, all emphasize different aspects of the problem. Pharmacotherapy targets the underlying neurobiological alterations found in PTSD and attempts to control symptoms so that the above treatment goals can be more effectively accomplished. Cognitive-behavioral treatments emphasize the phobic avoidance and counterproductive reenactments that often occur, along with the identification of faulty beliefs that arise owing to the trauma, and replace them with more adaptive beliefs, usually in association with direct therapeutic exposure. The psychodynamic approach emphasizes the associations that arise from the trauma experience and that lead to unconscious and conscious representations. Defense mechanisms that lead to lack of memory, and the contributions from early development, are also brought into play in psychodynamic therapy.

## Acute Stress Disorder

### Definition

It has long been recognized that clinically significant dissociative states are seen in the immediate aftermath of overwhelming trauma. In addition, many individuals may experience less clinically severe dissociative symptoms or alterations of attention and time sense. Because such syndromes, even when short-lasting, can produce major disruption of everyday activities, they may require clinical attention. During triage situations after a disaster, it can be important to recognize this clinical picture, which may require treatment intervention and which may also be predictive of later PTSD. As a result of these considerations, a decision was made to include in DSM-IV a new entity, acute stress disorder (ASD), grouped together with PTSD in the anxiety disorders section. Essentially, it represents the clinical features of PTSD along with conspicuous dissociative symptoms, of which at least three must be present. The possible dissociative symptoms in ASD are a subjective sense of numbing; detachment or absence of emotional response; reduced awareness of one's surroundings; derealization; depersonalization; and dissociative amnesia.

However, there is a lack of empirical evidence for some of the assumptions inherent in the conceptualization of ASD, and there has been a call for empirical evidence of acutely traumatized individuals to address these assumptions. The current emphasis placed on acute dissociative responses may be flawed in that there are multiple pathways to PTSD, and most trauma survivors who display severe acute stress reactions without dissociation can develop PTSD.

### Epidemiology

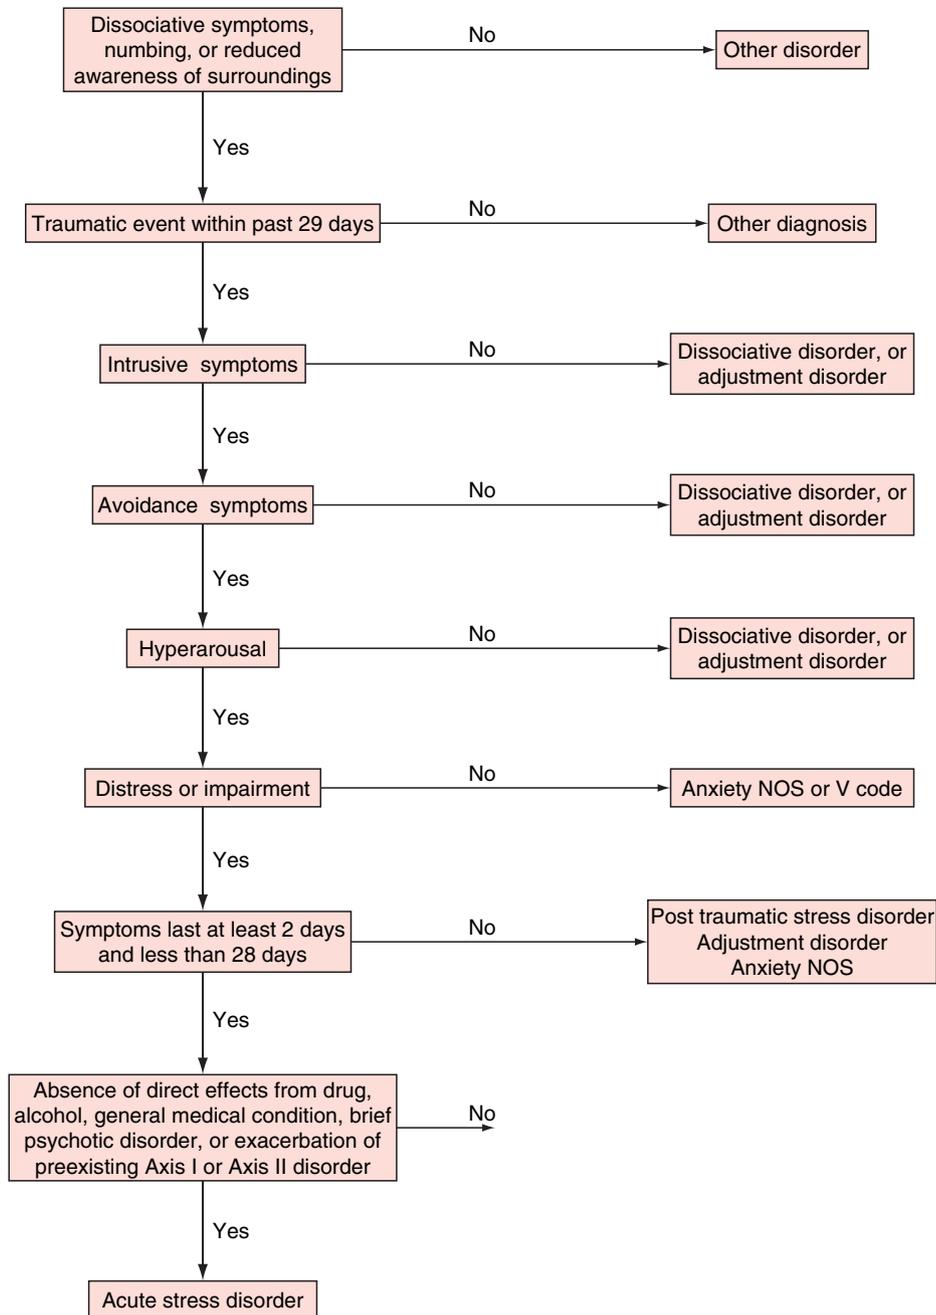

Little is known about the epidemiology of ASD as defined in DSM-IV, but after events such as rape and criminal assault, the clinical picture of acute PTSD is found in between 70 and 90% of individuals, although frequency of the particular dissociative symptoms is unknown. One problem of most postdisaster surveys is that they evaluate subjects at points several months or years after the event. This makes any meaningful assessment of acute stress syndromes difficult. One exception was the self-report-based assessment of morbidity 2 months after an earthquake in Ecuador, which found a 45% rate of caseness (being a clinical case), with most prominent symptoms being fear, nervousness, tenseness, worry, insomnia and fatigue (Lima *et al.*, 1989).

Retrospective reports of acute stress symptoms should be interpreted cautiously because of the influence of current

## DSM-IV-TR Criteria 308.3

### Acute Stress Disorder

- A. The person has been exposed to a traumatic event in which both of the following were present:
  - (1) the person experienced, witnessed, or was confronted with an event or events that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others
  - (2) the person's response involved intense fear, helplessness, or horror
- B. Either while experiencing or after experiencing the distressing event, the individual has three (or more) of the following dissociative symptoms:
  - (1) a subjective sense of numbing, detachment, or absence of emotional responsiveness
  - (2) a reduction in awareness of his or her surroundings (e.g., "being in a daze")
  - (3) derealization
  - (4) depersonalization
  - (5) dissociative amnesia (i.e., inability to recall an important aspect of the trauma)
- C. The traumatic event is persistently reexperienced in at least one of the following ways: recurrent images, thoughts, dreams, illusions, flashback episodes, or a sense of reliving the experience; or distress on exposure to reminders of the traumatic event.
- D. Marked avoidance of stimuli that arouse recollections of the trauma (e.g., thoughts, feelings, conversations, activities, places, people).
- E. Marked symptoms of anxiety or increased arousal (e.g., difficulty sleeping, irritability, poor concentration, hypervigilance, exaggerated startle response, motor restlessness).
- F. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning or impairs the individual's ability to pursue some necessary task, such as obtaining necessary assistance or mobilizing personal resources by telling family members about the traumatic experience.
- G. The disturbance lasts for a minimum of 2 days and a maximum of 4 weeks and occurs within 4 weeks of the traumatic event.
- H. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition is not better accounted for by brief psychotic disorder, and is not merely an exacerbation of a preexisting Axis I or Axis II disorder.

**Figure 52.1** Diagnostic decision tree for acute stress disorder.

symptoms on recall of acute symptoms. In a longitudinal study evaluating report of acute stress symptoms at 1 month and 2 years post trauma, at least one of the four ASD diagnostic clusters was recalled inaccurately by 75% of patients (Harvey and Bryant, 2000).

### Etiology

Little is known about the etiology of ASD specifically, but it is likely that many of the same factors that apply to PTSD are relevant for ASD that is, trauma intensity, preexisting psychopathology, family and genetic vulnerability, abnormal personality, lack of social supports at the time of the trauma and physical injury are all likely to increase vulnerability for ASD.

The role of acute arousal in the development of PTSD has been evaluated in one study (Bryant *et al.*, 2000). Resting heart rate (HR) and ASD symptoms together were found to account for 36% of the variance in PTSD prediction. Further, a formula using resting HR following the trauma exposure ( $HR > 90$  beats/minute) and the diagnosis of ASD to predict PTSD development possessed strong sensitivity (88%) and specificity (85%).

### Diagnosis and Differential Diagnosis

ASD may need to be distinguished from several related disorders (Figure 52.1). Brief psychotic disorder may be a more appropriate diagnosis if the predominant symptoms are psychotic. It is possible that major depressive disorder can develop post traumatically

and that there may be some overlap with ASD, in which case both disorders are appropriately diagnosed.

When ASD-like symptoms are caused by direct physiological perturbation, the symptoms may be more appropriately diagnosed with reference to the etiological agent. Thus, an ASD-like picture that develops secondary to head injury is more appropriately diagnosed as mental disorder due to a general medical condition, whereas a clinical picture related to substance use (e.g., alcohol intoxication) is appropriately diagnosed as substance-induced disorder. Substance-related ASD is confined to the period of intoxication or withdrawal. Head injury-induced ASD needs substantiating by evidence from the history, physical examination and laboratory testing that the symptoms are a direct physiological consequence of head trauma. Recently, a self-report scale of ASD has been developed, the Acute Stress Disorder Scale (ASDS). The scale has demonstrated good test–retest reliability ( $r = 0.94$ ), and in one sample (bushfire survivors), the ASDS predicted 91% of survivors who developed PTSD and 93% of those who did not (Bryant *et al.*, 2000).

Because ASD by definition cannot last longer than 1 month, if the clinical picture persists, a diagnosis of PTSD is appropriate. Some increased symptoms are expected in the great majority of subjects after exposure to major stress. These remit in most cases and only reach the level of clinical diagnosis if they are prolonged, exceed a tolerable quality, or interfere with everyday function. Resolution may be more difficult if there has been previous psychiatric morbidity, subsequent stress and lack of social support.

### Course and Natural History

Although data do not exist on the course and natural history of ASD as now defined, studies by Kooopman and coworkers (1994) indicated that dissociative and cognitive symptoms, which are so common in the immediate wake of trauma, improve spontaneously with time. However, they also found that the likelihood of developing PTSD symptoms at 7-month follow-up was more strongly related to the occurrence of dissociative symptoms than to anxiety symptoms immediately after exposure to the trauma. However, other studies have questioned the dissociative criteria as critical for the prediction of later PTSD.

### Treatment

There are six general principles involved in administering any treatment immediately after trauma. These include principles of brevity, immediacy, centrality, expectancy, proximity and simplicity. That is, treatment of acute trauma is generally aimed at being brief, provided immediately after the trauma whenever possible, administered in a centralized and coordinated fashion with the expectation of the person's return to normal function and as proximately as possible to the scene of the trauma, and not directed at any uncovering or explorative procedures but rather at maintaining a superficial, reintegrating approach.

People most highly at risk, and therefore perhaps most in need of treatment, are as follows: survivors with psychiatric disorders; traumatically bereaved people; children, especially when separated from their parents; individuals who are particularly dependent on psychosocial supports, such as the elderly, handicapped and mentally retarded individuals; and traumatized survivors and body handlers.

Different components of treatment include providing information, psychological support, crisis intervention and emotional first aid. Providing information about the trauma is

important as it can enable the survivor fully to recognize and accept all the details of what happened. Information needs to be given in a way that conveys hope and the possibility that psychological pain and threat of loss may be coped with. Unrealistic hope needs to be balanced by the provision of realistic explanations as to what happened. Psychological support helps to strengthen coping mechanisms and promotes adaptive defenses. The survivor benefits if he or she recognizes the need to take responsibility for a successful outcome and is as actively involved with this as possible. Crisis intervention is often used after disasters and acts of violence or other serious traumas. It has been described by a number of investigators. Emotional first aid has been described by Caplan (1984) using the six principles presented earlier and is used to achieve any of the following: acceptance of feelings, symptoms, reality and the need for help; recognition of psychologically distressing issues; identification of available resources; acceptance of responsibility and absence of blame; cultivation of an optimistic attitude; and efforts to resume activities of daily life as much as possible.

Civilian trauma survivors with ASD were found to engage in the cognitive strategies of punishment and worry more than survivors without ASD (Warda and Bryant, 1998), and cognitive-behavioral therapy has been shown to reduce these strategies and increase the use of reappraisal and social control strategies. However, the relation of these findings to the development of PTSD has not yet been determined.

There is little investigation as to whether early recognition and effective treatment of acute stress reactions prevent the development of PTSD, although it is safe to assume that they are likely to have beneficial effects in this regard. Nonetheless, as was recognized during World War II, rapid and effective treatment of acute combat stress did not always prevent veterans from developing subsequent chronicity. More recently, an intervention designed to prevent the development of PTSD and administered in the acute phase, critical incident stress debriefing, has been found to be ineffective in preventing the development of PTSD. However, there has been an initial study with motor vehicle accident survivors that suggested exposure therapy and exposure therapy with anxiety management training may be effective in preventing PTSD (Bryant *et al.*, 1999).

### Comparison of DSM-IV/ICD-10 Diagnostic Criteria

The ICD-10 Diagnostic Criteria for Research for Post traumatic Stress Disorder provides a different stressor criterion: a situation or event “of exceptionally threatening or catastrophic nature, which would be likely to cause pervasive distress in almost everyone” which is similar to the DSM-III-R definition of a traumatic stressor. DSM-IV-TR instead defines a traumatic stressor as “an event or events that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others”. Furthermore, the ICD-10 diagnostic algorithm differs from that specified in DSM-IV-TR in that the DSM-IV criterion D (i.e., symptoms of increased arousal) is not required. In contrast to DSM-IV-TR which requires that the symptoms persist for more than one month, the ICD-10 Diagnostic Criteria for Research do not specify a minimum duration.

For acute stress disorder, the ICD-10 Diagnostic Criteria for Research differs in several ways from the DSM-IV-TR criteria: 1) primarily anxiety symptoms are included; 2) it is required

that the onset of the symptoms be within 1 hour of the stressor; and 3) the symptoms must begin to diminish after not more than 8 hours (for transient stressors) or 48 hours (for extended stressors). In contrast to DSM-IV-TR, the ICD-10 Diagnostic Criteria for Research does not require dissociative symptoms or that the event be persistently reexperienced.

# Anxiety Disorders: Generalized Anxiety Disorder

## Definition

In the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV)* (American Psychiatric Association, 1994) GAD is currently defined as excessive anxiety and worry (apprehensive expectation) occurring for a majority of days during at least a 6-month period, about a number of events or activities (such as work or school performance; see DSM-IV). In individuals with GAD, the anxiety and worry are accompanied by at least three of six somatic symptoms (only one accompanying symptom is required in children), which include restlessness or feeling keyed up or on edge, being easily fatigued, difficulty concentrating or mind going blank, irritability, muscle tension and sleep disturbance. In addition, the affected individual has difficulty controlling his/her worry, and the anxiety, worry, or somatic symptoms cause clinically significant distress or impairment in social, occupational, and/or other important areas of functioning. Further, the GAD symptoms should not be due to the direct physiological effects of a substance such as drugs or alcohol or a general medical condition, and should not occur exclusively during a mood disorder, psychotic disorder, or pervasive developmental disorder.

Worry and anxiety are part of normal human behavior and it may be difficult to define a cutoff point distinguishing normal or trait anxiety (i.e., a relatively stable tendency to perceive various situations as threatening) from GAD. However, as described in the DSM-IV definition of GAD, individuals suffering from a “disorder” exhibit significant distress and impairment in functioning as a result of their anxiety symptoms.

## Etiology and Pathophysiology

### Family Studies

Family studies suggest a familial (and probably a genetic) basis for certain anxiety disorders such as panic disorder. Genetic transmission of a disorder suggests that certain gene-encoded changes in proteins and the resulting biological abnormalities may play a role in the pathophysiology of specific disorders. Skre and collaborators (1993) examined 20 monozygotic and 29 dizygotic twins with DSM-III-R-defined GAD. They found GAD to be diagnosed in 22% of first-degree relatives of 33 probands with anxiety disorders. In the largest twin study to date which included 1033 female twin pairs, Kendler and associates (1992) found that genetic factors play a significant, but not overwhelming role in the etiology of GAD, with the heritability of GAD estimated at

## DSM-IV-TR Criteria 300.02

### Generalized Anxiety Disorder

- A. Excessive anxiety and worry (apprehensive expectation), occurring more days than not for at least 6 months, about a number of events or activities (such as work or school performance).
- B. The person finds it difficult to control the worry.
- C. The anxiety and worry are associated with three (or more) of the following six symptoms (with at least some symptoms present for more days than not for the past 6 months).

**Note:** Only one item is required in children.

- (1) restlessness or feeling keyed up or on edge
  - (2) being easily fatigued
  - (3) difficulty concentrating or mind going blank
  - (4) irritability
  - (5) muscle tension
  - (6) sleep disturbance (difficulty falling or staying asleep, or restless unsatisfying sleep)
- D. The focus of anxiety and worry is not confined to features of an Axis I disorder, e.g., the anxiety or worry is not about having a panic attack (as in panic disorder), being embarrassed in public (as in social phobia), being contaminated (as in obsessive–compulsive disorder), being away from home or close relatives (as in separation anxiety disorder), gaining weight (as in anorexia nervosa), having multiple physical complaints (as in somatization disorder), or having a serious illness (as in hypochondriasis), and the anxiety and worry do not occur exclusively during posttraumatic stress disorder.
  - E. The anxiety, worry, or physical symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
  - F. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hyperthyroidism) and does not occur exclusively during a mood disorder, a psychotic disorder, or a pervasive developmental disorder.

around 30% in comparison to 70% heritability in major depression. In addition, the authors found that the vulnerability to GAD and major depression is influenced by the same genetic factors. In short, the available data suggest at most a modest genetic contribution to the etiology of GAD.

### Biological Studies

Relatively few studies have addressed issues regarding the biological aspects of GAD. Existing studies have focused on the evaluation of catecholamine and autonomic responses, neuroendocrine measures, sleep, neuroanatomical/neuroimaging studies, infusion studies and evaluation of other neurotransmitter systems. There is not strong evidence for abnormalities in catecholamine or thyroid function in GAD patients. Some studies have shown a higher prevalence of an “escape” (non-suppression) response in following dexamethasone administration (that was not attributable to the presence of depression) in GAD patients when compared with normal comparison subject. These data indicate that there may be dysregulation of the HPA axis in these patients, as observed following dexamethasone.

Although restless and decreased sleep are common complaints in GAD patients, there have been only a few polysomnographic studies in this patient population. There is some evidence suggesting that patients with GAD have a longer rapid eye movement (REM) latency, shorter REM duration, increased sleep onset latency and less total sleep time compared with control subjects (Papadimitriou *et al.*, 1988). These findings may differentiate patients with GAD from patients with depression, who show shorter REM latencies.

Alterations in different neurotransmitter systems have been implicated in the pathophysiology of various anxiety disorders. It is generally accepted that anxiety disorders are not associated with abnormalities in only one neurotransmitter system; rather dynamic interactions among several different neurotransmitter systems are believed likely to underlie different anxiety states. Presently, there are data suggesting that the catecholamine serotonin and GABA-benzodiazepine systems may be involved in the pathophysiology of anxiety disorders.

### GABA-benzodiazepines

Benzodiazepines have been the treatment of choice for many patients with GAD. They act at specific recognition sites in the brain, the benzodiazepine receptors, which are located in a subunit of a receptor for gamma-aminobutyric acid (GABA), the major inhibitory neurotransmitter in the brain. Several lines of evidence suggest that the GABA-benzodiazepine receptor complex may be involved in the mediation of anxiety responses. Studies with animals suggest a relationship between benzodiazepine receptors, and fear and anxiety. Models using gamma-2 knockout mice have shown a reduction in GABA<sub>A</sub> receptor clustering in the hippocampus and cerebral cortex along with behavioral inhibition to aversive stimuli and increased responsiveness in trace fear conditioning (Lesch, 2001).

### Serotonin

Alterations in serotonergic (5-HT) neurotransmission have been implicated in the mediation of fear and anxiety responses in animal models and in humans. Specifically, researchers hypothesize that anxiety may represent dysregulated serotonergic activity in critical brain areas. Given the available data, whether overactivity

or underactivity of the 5-HT system is the mechanism for GAD development remains unclear.

### Neuropeptides

Cholecystokinin (CCK), a highly abundant neurotransmitter in the brain, has also been implicated in anxiety in humans. CCK may be possibly involved in the pathophysiology of panic disorder and may also play a role in the biology of GAD. Corticotropin-releasing factor (CRF), a major physiological regulator of adrenocorticotropic hormone (ACTH), appears to be involved in stress and anxiety responses. Administration of CRF to various parts of animal brains has elicited anxiety and fear responses, e.g., suppression of exploratory behavior, shock-induced freezing. Interestingly, both these peptides are functionally antagonized by benzodiazepines. Neuropeptide Y, glutamate and tachykinins may also play a role in anxiety.

### Neuroanatomic Sites of Anxiety

Several potential neuroanatomic anxiogenic sites in the central nervous system (CNS) have been proposed based on brain imaging and neuroanatomic studies. The areas potentially involved in anxiety are the parts of the limbic system involving the hippocampus, prefrontal cortex, occipital lobes, basal ganglia and brain stem structures, specifically the locus coeruleus, nucleus paragigantocellularis and periaqueductal gray (Gray, 1988). These structures are rich in noradrenergic, GABAergic and serotonergic receptors which are believed to be involved in the pathophysiology of different anxiety states such as GAD.

### Cerebral Blood Flow and Metabolism Studies

Only a few imaging studies in GAD have appeared in the literature. In one study, patients with GAD displayed decreases in cortical blood flow compared with control subjects. Significant negative correlations between state anxiety and cerebral blood flow in most brain regions were observed. Wu and colleagues (1991) evaluated 18 patients who met DSM-III criteria for GAD using positron emission tomography (PET) measurements of cerebral glucose at “baseline” (during a passive viewing task), following a cognitive vigilance task designed to stimulate anxiety, and following treatment with benzodiazepines. They found a higher relative metabolic rate for GAD patients in parts of the occipital, temporal, frontal lobes and cerebellum relative to normal control subjects during a passive viewing task. The authors also found a decrease in absolute basal ganglia metabolic activity in GAD patients. During the vigilance task, GAD patients showed a significant increase in relative basal ganglia metabolism. The authors did not find a global decrease in cortical metabolism, as had been predicted by blood flow studies. Finally, benzodiazepine treatment resulted in a significant decrease in glucose metabolism in cortical surface (especially in the occipital cortex), the limbic system and basal ganglia compared with patients receiving placebo.

MRI and SPET studies have found that those with GAD have decreased benzodiazepine receptor binding in the left temporal pole as compared with matched healthy controls. In a study using functional MRI in GAD patients, Lorberbaum and colleagues (2001) found greater activity in the right cingulate, right medial prefrontal and orbitofrontal cortex, right temporal poles and right dorsomedial thalamus, during periods of anticipatory anxiety, compared with rest periods, than matched control subjects. Further, only matched control subjects displayed increased activity in the medial prefrontal cortex.

## Psychological Mechanisms

### Cognitive–Behavioral Model

Psychological models, which emphasize the cognitive–behavioral processes involved in the onset and maintenance of GAD, have emerged in recent years. Individuals' thoughts, cognitive style and behaviors are thought to instigate and maintain episodes of anxiety. In support of cognitive theories of GAD, anxious individuals with GAD are more likely to perceive ambiguous information as threatening and/or negative, and to perceive that they are more likely than others to experience threatening situations. Patients with GAD also pay more attention to the detection of potentially threatening information and incorporate this information into highly elaborate cognitive schemas, thus lowering their threshold for activation of an anxiety response. The threatening information then elicits anxious affect and the individual begins to worry in an attempt further to define the problem.

Patients with GAD are likely to be characterized by a perception of lack of control over threatening. In addition, these patients are likely to believe that they have little control over their emotions, especially their worrying, leading to further distress. It has been suggested that the interaction between perceived uncontrollability and a cognitive focus on negative/threatening stimuli may amplify the general worry to pathological.

### Psychodynamic Theories

Freud's concept of signal anxiety followed the development of Freud's structural model of the mind, which proposes three interacting psychological functions: ego (which mediates between the demands of primitive drives, the social and parental prohibitions, and reality), superego (representing the internalized parental and social prohibitions) and id (representing the primitive drives and urges). Freud believed that anxiety serves as a signal to the ego of a threat (in the form of an unconscious drive or wish arising from the id), which, if enacted, may be dangerous to the ego, signaling the potential punishment by the superego or the external world. According to this model, the ego can activate defense mechanisms, such as repression, and prevent the actualization of the forbidden urge either by preventing the expression of the wish or by avoiding the life situations in which the wish might be potentially expressed. Ideally, repression into the unconscious (i.e., out of subject's awareness) should successfully contain the drives. However, if the defenses fail, one may experience symptomatic anxiety and other distressing psychological symptoms. Implicit in this model is the concept that the individuals themselves are not consciously aware of these processes. Therefore, the promotion of subjects' insight into unconscious conflicts and the uncovering of the unconscious origins of anxiety through interpretation and other techniques is the primary goal (and method) of the psychoanalytic treatment approach.

Sullivan developed a theory of anxiety based on the importance of interpersonal relationships. He viewed affects (such as anxiety) as forms of interpersonal communication. According to this model, anxiety communicates the sense of insecurity in interpersonal relationships. For example, a mother who is insecure in her role may communicate her insecurity to the infant when she is anxious in her child's presence. The child in turn identifies her anxiety and expresses anxious affect himself. Another approach to the understanding of the origins of anxiety was offered by object relations theorists such as Klein and Bowlby. They believed that anxiety reflects a fear of the loss of the nurturing object or fear of being hurt by the antagonistic object.

Finally, self-psychology theorists, such as Kohut, believed that the individual strives to achieve and maintain an integrated, cohesive sense of self. Beginning in early age, the individual develops this sense of self through idealization of important others, such as important caregivers (called self-objects), and through a process of positive interaction with caregivers (called mirroring). He believed that inadequate provision of these experiences can lead to anxiety (fear of disintegration) and the loss of the cohesive self.

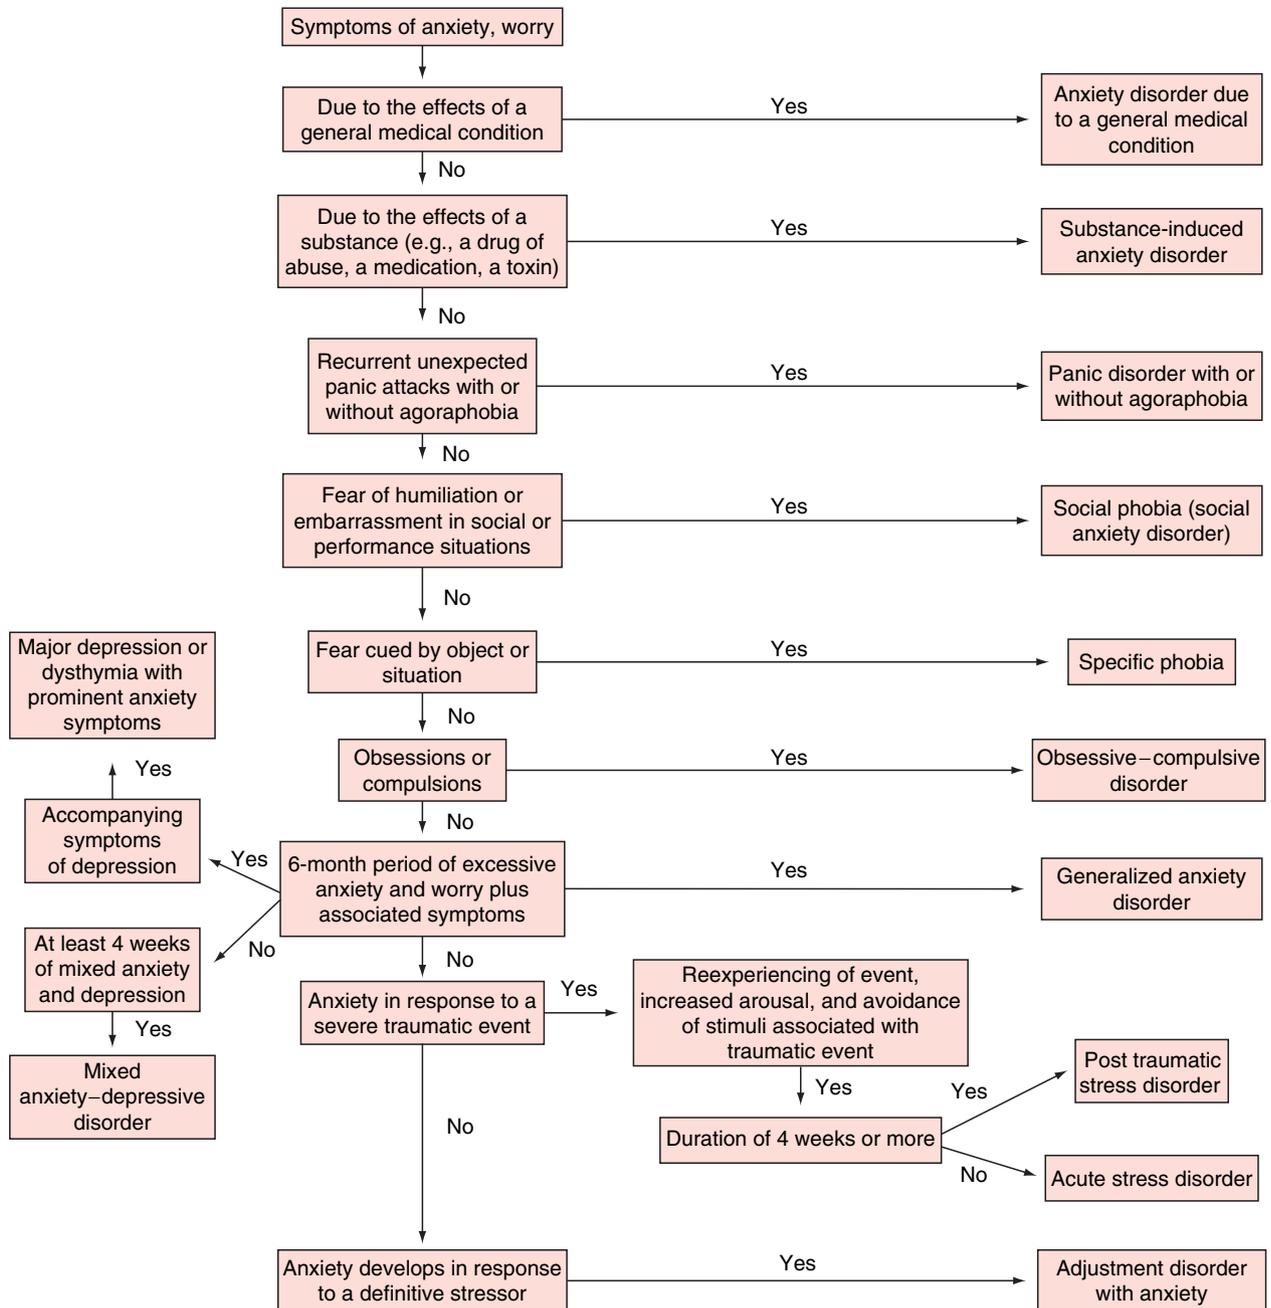

### Assessment and Differential Diagnosis

GAD patients frequently report that they have been anxious all their lives. Typically, they were moderately anxious during childhood, later developing full-blown GAD when their stress levels increased through activities such as attending college or starting to work. Patients with early onset of symptoms report experiencing significant anxiety and fears, social isolation, obsessiveness, more academic difficulties and disturbed home environment during their childhood. The social maladjustment and emotional overreactivity persist into adulthood. Epidemiological studies and clinical studies suggest that the onset of GAD typically begins between the late teens and late twenties. However, not all GAD patients have a lifelong history of excessive anxiety. Some patients develop their disorder at a later age, that is, in one's thirties or later. These patients frequently report identifiable, precipitating stressful events, specifically unexpected, negative, important events in the year preceding development of GAD.

Patients with GAD experience chronic anxiety and tension. They find the worry as being uncontrollable. However, some patients intentionally initiate and maintain worry with an almost superstitious assumption that, by doing so, they can avert a negative event. Patients tend to worry predominantly about family, personal finances, work and illness. They are also likely to report worrying over minor matters, such as making a slight social faux pas. The majority report being anxious for at least 50% of the time during an average day. In children and adolescents, the worries often revolve around quality of performance in school/competitive areas; catastrophic events; and physical/mental inadequacies. They typically require excessive reassurance and often appear shy, overcompliant and perfectionistic. Frequent multiple physical complaints are common. They may have an unusually mature and serious manner and appear older than their actual age. These children are often the eldest in small, competitive, achievement-oriented families.

Individuals with GAD commonly complain of feeling tense, jumpy and irritable. They have difficulty falling or staying asleep, and tire easily during the day. Particularly distressing to patients is the difficulty in concentrating and collecting their thoughts. Cognitions appear to play a central role in GAD, as well as other anxiety disorders. Patterns of cognitions, however, appear to be disorder-specific. Cognitions about interpersonal conflict or acceptance by others are quite common.

Patients may present complaining of muscular tension, especially in their neck and shoulders and headaches which frequently are described as frontal and occipital pressure or tension. Patients commonly experience sweaty palms, feel shaky and tremulous, complain of dryness of the mouth, and experience palpitations and difficulty breathing. They may also experience gastrointestinal symptoms such as heartburn and epigastric fullness and approximately 30% of patients experience severe gastrointestinal symptoms of irritable bowel syndrome. Physical complaints frequently lead patients to seek medical attention,

**Figure 53.1** Diagnostic decision tree for GAD.

and most will initially consult a primary care physician. Although chest pain is more frequently reported by patients with panic disorder, Carter and Maddock (1992) observed that 34% of patients with GAD without panic attacks experienced chest pain. They also found that these patients were predominantly males and many had undergone extensive cardiac evaluations that revealed no demonstrable cardiac pathology.

## Differential Diagnosis

### Psychiatric Conditions

Anxiety can be a prominent feature of many psychiatric disorders. In addition, the substantial overlap of symptoms between

GAD and other psychiatric disorders such as major depressive disorder, often creates diagnostic and treatment dilemmas for the clinician and may complicate the difficult task of differential diagnosis and treatment planning. This section will highlight the major disorders that should be considered in the differential diagnosis of GAD (Figure 53.1).

### Major Depressive Disorder and Dysthymic Disorder

Several symptom profiles discriminate between major depressive disorder or dysthymic disorder and GAD. Patients with major depressive disorder exhibit higher rates of dysphoric mood, psychomotor retardation, suicidal ideation, guilt, hopelessness and helplessness, as well as more work impairment than patients

with GAD. In contrast, patients with GAD show higher rates of somatic symptoms, specifically, muscle tension and autonomic symptoms (e.g., respiratory or cardiac complaints) than depressed patients.

### **Panic Disorder With/Without Agoraphobia**

Some researchers have suggested that GAD is attributable to panic disorder. However, clear differences exist between GAD and panic disorder. For example, panic disorder is characterized by the presence of panic attacks; that is, recurrent, discrete episodes of intense anxiety or fear associated with a cluster of somatic symptoms reflecting autonomic hyperactivity such as rapid heartbeat, dizziness, numbness or tingling, trouble breathing or choking, and nausea or vomiting. In contrast, patients with GAD experience predominantly symptoms of muscle tension and vigilance such as fatigue, muscle soreness, insomnia, difficulty concentrating, restlessness and irritability. Patients with panic disorder tend to seek treatment earlier in life than patients with GAD. Additionally, reports of types of worry differ between those diagnosed with GAD and those with panic disorder. For example, panic patients worry about having additional panic attacks, whereas GAD patients worry unrealistically about a number of everyday issues.

### **Obsessive–Compulsive Disorder**

Anxiety is part of the clinical picture of obsessive–compulsive disorder (OCD) and may be a central factor in initiating and maintaining obsessions and compulsions. Interestingly there are also some data suggesting that OCD and GAD may be related. For example, Black and associates (1992) found an increased prevalence of GAD among relatives of patients with OCD. However, several features distinguish the excessive worry that accompanies GAD from the obsessional thoughts of OCD. Obsessive thoughts are described as ego-dystonic intrusions that often take the form of urges, impulses, or images. They are often senseless and are frequently accompanied by time-consuming compulsions designed to reduce mounting anxiety. In contrast, the worries in GAD are about realistic concerns, such as health and finances.

### **Other Anxiety Disorders**

In phobic disorders, the anxiety is characteristically associated with a specific phobic object or situation that is frequently avoided by the patient. Such is the case with social anxiety disorder as well, in which the individual is afraid of or avoids situations in which he or she may be the focus of potential scrutiny by others. Anxiety is also a characteristic part of the presentation of post traumatic stress disorder (PTSD) and acute stress disorder. However, unlike in GAD, the principal symptoms experienced in PTSD and acute stress disorder follow exposure to a traumatic event and are characterized by avoidance of reminders of the event and persistent reexperiencing of the traumatic event. In addition, in contrast to GAD which must last at least 6 months, acute stress disorder does not persist for more than 4 weeks. Finally, in adjustment disorders anxiety when present occurs in response to a specific life stressor or stressors and generally does not persist for more than 6 months (American Psychiatric Association, 1994).

### **Normal Anxiety**

Worry and anxiety are part of normal human behavior, and it may be difficult to define a cutoff point distinguishing normal or trait anxiety (i.e., a relatively stable tendency to perceive

various situations as threatening) from GAD. However, individuals suffering from a “disorder” exhibit significant distress and impairment in functioning as a result of their anxiety symptoms.

### **Anxiety Disorder due to a General Medical Condition**

Many general medical conditions may present with prominent anxiety symptoms. If not identified and properly addressed, these conditions may adversely affect the treatment outcome of the anxious patient. In this section we will highlight important medical conditions in the differential diagnosis of generalized anxiety (see Table 53.2).

### **Cardiovascular Disorders**

Patients with GAD may complain of palpitations, skipped heartbeats and chest pain. In addition, many GAD patients, especially males, fear having an acute myocardial infarction and often present to the emergency room for evaluation. However, most patients with GAD without a concomitant cardiovascular disease do not experience severe chest pain. Following the controversial evidence suggesting an association between mitral valve prolapse (MVP) and panic disorder, researchers evaluated the prevalence of MVP in patients with GAD and found no evidence of increased prevalence in patients with GAD. Nevertheless, patients with anxiety symptoms associated with unexplained chest pain should be evaluated for possible cardiovascular disease.

### **Hyperthyroidism**

Anxiety is a prominent feature of hyperthyroidism with some overlap in the symptomatology of thyrotoxicosis and GAD. Symptoms such as tachycardia, tremulousness, irritability, weakness and fatigue are common to both disorders. In GAD, however, the peripheral manifestations of excessive concentrations of circulating thyroid hormones are absent, including symptoms such as weight loss, increased appetite, warm and moist skin, heat intolerance and dyspnea on effort. Presence of goiter makes the diagnosis of hyperthyroidism likely; however, the absence of thyroid enlargement does not exclude it. Thus, confirmatory laboratory tests (free  $T_4$ ,  $T_3$  and TSH) assume significant diagnostic importance. In mild cases, laboratory tests may be within the upper limit of the normal range, in which case a thyroid releasing hormone stimulation test is indicated.

### **Pheochromocytomas**

Pheochromocytomas, also known as chromaffin tumors, produce, store and secrete catecholamines. They are derived most often from the adrenal medulla, as well as the sympathetic ganglia and occasionally from other sites. The clinical features of these tumors, most commonly hypertension and hypertensive paroxysms, are predominantly due to the release of catecholamines. Patients may also experience diaphoresis, tachycardia, chest pain, flushing, nausea and vomiting, headache and significant apprehension. Although the clinical presentation frequently mimics spontaneous panic attacks, pheochromocytomas should also be considered in the differential diagnosis of GAD. The diagnosis of pheochromocytoma can be confirmed by increased levels of catecholamines (epinephrine and norepinephrine) or catecholamine metabolites (metanephrines and vanillylmandelic acid) in a 24-hour urine collection.

## Other Medical Conditions

Menopause is commonly referred to as the period that encompasses the transition between the reproductive years and beyond the last episode of menstrual bleeding. Frequently associated with significant anxiety, menopause should be considered in the differential diagnosis of GAD. However, other associated symptoms such as vasomotor instability, atrophy of urogenital epithelium and skin, and osteoporosis make the diagnosis of menopause probable. Another endocrinologic disorder, hyperparathyroidism, can present with anxiety symptoms, and the initial evaluation of serum calcium levels may be indicated. Finally, certain neurologic conditions such as complex partial seizures, intracranial tumors and strokes, and cerebral ischemic attacks may be associated with symptoms typically observed in anxiety disorders and may require appropriate evaluation.

## Substance-induced Anxiety Disorder

Anxiety disorders can occur frequently in association with intoxication and withdrawal from several classes of substances (see Table 53.1). Excessive use of caffeine, especially in children and adolescents, may cause significant anxiety. Cocaine intoxication may be associated with anxiety, agitation and hypervigilance. During cocaine withdrawal, patients may also present with prominent anxiety, irritability, insomnia, fatigue, depression and cocaine craving. Adverse reaction to marijuana includes extreme anxiety that usually lasts less than 24 hours. Mild opioid withdrawal presents with symptoms of anxiety and dysphoria. However, accompanying symptoms such as elevated blood pressure, tachycardia, pupillary dilatation, rhinorrhea, piloerection and lacrimation are rare in patients with GAD.

The clinical phenomenology observed both in alcohol and sedative-hypnotic drug withdrawal and in GAD, although variable, may be highly similar. In both conditions, nervousness, tachycardia, tremulousness, sweating, nausea and hyperventilation occur prominently. Additionally, the same drugs (i.e., benzodiazepines) can be used to treat anxiety symptoms, and some patients may use alcohol in an attempt to alleviate anxiety. Thus, the symptoms of an underlying anxiety disorder may be difficult to differentiate from the withdrawal symptoms associated with the use of benzodiazepines or alcohol.

The use of many commonly prescribed medications may produce side effects manifesting as anxiety (see Table 53.1). Such medications include sympathomimetics or other bronchodilators such as theophylline, anticholinergics, antiparkinsonian preparations, corticosteroids, thyroid supplements, oral contraceptives, antihypertensive, and cardiovascular medications such as digitalis, insulin (secondary to hypoglycemia), and antipsychotic and antidepressant medications. Finally, heavy metals and toxins such as organophosphates, paint and insecticides may also cause anxiety symptoms.

## Epidemiology and Comorbidity

Current data indicate that GAD is probably one of the more common psychiatric disorders. The National Comorbidity Survey (NCS) of psychiatric disorders (Kessler *et al.*, 1994) found prevalence rates of 1.6% for current GAD (defined as the most recent 6-month period of anxiety), 3.1% for 12-month GAD, and 5.1% for lifetime GAD, with lifetime prevalence higher in females (6.6%) than males (3.6%). The more recent National Comorbidity Survey replication (NCS-R) found a lifetime prevalence of 5.7% (Kessler *et al.*, 2005).

**Table 53.1** Medical Conditions and Drugs That May Cause Anxiety

Endocrine Disorders	Cardiovascular and Circulatory Disorders
Addison's disease	Anemia
Cushing's syndrome	Congestive heart failure
Hyperparathyroidism	Coronary insufficiency
Hyperthyroidism	Dysrhythmia
Hypothyroidism	Hypovolemia
Carcinoid	Myocardial infarction
Pheochromocytoma	
Drug Intoxication	Respiratory Disorders
Anticonvulsants	Asthma
Antidepressants	Chronic obstructive pulmonary disease
Antihistamines	Pulmonary embolism
Antihypertensive agents	Pulmonary edema
Antiinflammatory agents	
Antiparkinsonian agents	
Caffeine	
Digitalis	
Sympathomimetics	
Thyroid supplements	
Substance Use Related	Immunological, Collagen and Vascular Disorders
Cocaine	Systemic lupus erythematosus
Hallucinogens	Temporal arteritis
Amphetamines	
Withdrawal Syndromes	Metabolic Conditions
Alcohol	Acidosis
Narcotics	Acute intermittent porphyria
Sedatives-hypnotics	Electrolyte abnormalities
	Hypoglycemia
Gastrointestinal Disorders	Neurological Disorders
Peptic ulcer disease	Brain tumors
	Cerebral syphilis
	Cerebrovascular disorders
	Encephalopathies
	Epilepsy (especially temporal lobe epilepsy)
	Postconcussive syndrome
	Vertigo
	Akathisia
Infectious Diseases	
Miscellaneous viral and bacterial infections	

GAD appears at even higher rates in clinical settings, particularly in primary care settings. For example, Shear and colleagues (1994) found prevalence rates of GAD, using DSM-III-R criteria, reported by patients at four primary care centers, to be twice as high as those reported in community samples (i.e., 10 versus 5.1%). Similarly, a collaborative study by the World Health Organization (WHO) across 15 international sites reported prevalence rates of GAD at approximately 8% in primary care settings (Maier *et al.*, 2000).

Those with anxiety symptoms meeting criteria for GAD in the Epidemiological Catchment Area (ECA) study reported receiving more outpatient mental services during the previous year than those diagnosed with other psychiatric disorders (Blazer *et al.*, 1991). Many of those with GAD in the National Comorbidity Survey sought professional help for GAD (66% of participants) and used medications to reduce their symptoms of GAD (44% of participants). Over 80% of the GAD group in the Harvard/Brown Anxiety Disorders Research Program (HARP) data indicated that they received psychotherapy and/or pharmacotherapy (Yonkers *et al.*, 1996).

Rates of GAD appear similar in special populations such as children and the elderly. GAD appears to be less prevalent in children than in adults. Data from the NCS indicate that for both lifetime and 12-month prevalence rates, GAD occurs at the lowest rate in younger ages and at the highest rate in older adults. Epidemiological data on prevalence of GAD in childhood using DSM-IV criteria are currently lacking. In the elderly, GAD appears to account for the majority of anxiety disorders, with prevalence rates ranging from 0.7 to 7.3%.

Although it is unclear whether childhood GAD predisposes to the development of adult GAD or represents an early manifestation of adult GAD, these studies further suggest that generalized anxiety is highly prevalent both in the community and in the clinical population.

### GAD: Comorbidity with Other Disorders

Despite different methodological approaches in early studies, the available studies report a high prevalence of psychiatric comorbidity in patients with GAD. For example, in some studies more than 90% of GAD patients had additional symptoms that fulfilled criteria for at least one or more concurrent disorders (range of 45–91%). An examination of the relative frequencies of various comorbid diagnoses in patients with GAD obtained from the available studies reveals that other anxiety and mood disorders frequently complicate the course of GAD (see diagnostic decision tree for GAD: Figure 53.1).

The National Comorbidity Survey showed 90% of respondents with lifetime GAD had at least one other lifetime disorder and of those with current GAD, 66% had at least one other current disorder. The most common comorbidities (specifically that criteria for both disorders were met) were found for mood disorders (major depression and dysthymia), panic disorder and (for current comorbidity only) agoraphobia. High 12 month rates for comorbidity for GAD and major depression were reaffirmed in the NCS-R (Kessler *et al.*, 2005). Other studies have also found that the highest comorbidities were with depressive disorders and panic disorders. GAD usually has an earlier onset than other anxiety and depressive disorders when comorbid disorders are present. Brawman-Mintzer and associates (1993) found that GAD had an onset before dysthymia and panic disorder, and after simple and social phobia. Further, onset of major depression

seemed to follow the onset of anxiety. Similar findings have been reported by other investigators.

As in adult GAD, childhood GAD (or overanxious anxiety disorder as it was earlier labeled) is also characterized by an unusual degree of comorbidity. Kashani and coworkers (1990) observed that over 50% of children with overanxious disorder had symptoms that met criteria for at least one additional psychiatric diagnosis. Among the most prevalent current comorbid diagnoses are social phobia (16–59%), simple phobia (21–55%), panic disorder (3–27%) and depression (8–39%). Furthermore, Masi and coworkers (1999) found, in those children and adolescents they sampled, that 87% had a comorbid disorder. In particular, high rates of separation anxiety, social anxiety and depressive disorders were found.

Alcoholism also complicates the clinical course of GAD for some patients; however, the available literature suggests that the diagnosis of alcohol abuse is not as prevalent in GAD as in other anxiety disorders, and the pattern of abuse is often a brief and nonpersistent one. GAD onset is usually later than that of the alcohol use disorder. Personality disorders have been observed to co-occur in approximately 50% of patients with GAD. For example, rates of GAD and personality disorders in clinical populations have ranged from 31 to 46%. Cluster C personality disorders, specifically avoidant personality disorder, dependent personality disorder and obsessive–compulsive personality disorder are common. Interestingly, Cluster A personality traits, in particular suspiciousness and mistrust, may be prominent in GAD as well.

Comorbid GAD is associated with increased severity of comorbid disorders (Kessler, 2000; Kessler *et al.*, 2005). Additionally, the presence of comorbid disorders in GAD patients is related to increased rates of negative outcomes such as disability, impairment and cost of care. Rates of relapse for GAD patients with comorbid depression appear higher than in noncomorbid GAD patients. Further, comorbidity is also associated with greater treatment seeking. Unsurprisingly, data indicate that patients with comorbid GAD and depression may have poorer response to treatment than patients with either disorder only.

### Course

Retrospective and prospective reports indicate that the typical course of GAD is chronic, nonremitting, and that it often persists for a decade or longer. Rickels and colleagues (1986) reported that two-thirds of patients treated initially with diazepam relapsed within 1 year of discontinuation of treatment. Other studies utilizing criteria prior to the DSM-III-R for GAD found comparable levels of chronicity, with almost half the patients reporting moderate symptoms at follow-up (Yonkers *et al.*, 2000).

HARP, a prospective, naturalistic study of 711 adults with DSM-III-R anxiety disorders, recruited initially from psychiatric clinics and hospitals in the Boston Metropolitan area, indicated that only 15% of those with GAD at baseline experienced a full remission for 2 months or longer at any time during the first year after baseline, and only 25% had a full remission in the 2 years after baseline (Yonkers *et al.*, 1996). Further, among patients who experienced full or partial remission, 27 and 39% respectively, experienced a full relapse during a 3-year follow-up period (Yonkers *et al.*, 2000). Chronicity of GAD was also associated with cluster B and C personality disorders or a concurrent Axis I comorbidity. Wittchen and coworkers (1994) found that approximately 80% of subjects with GAD reported substantial interference with their life, a high degree of professional help-seeking, and a high prevalence of taking medications because of

### Clinical Vignette 1

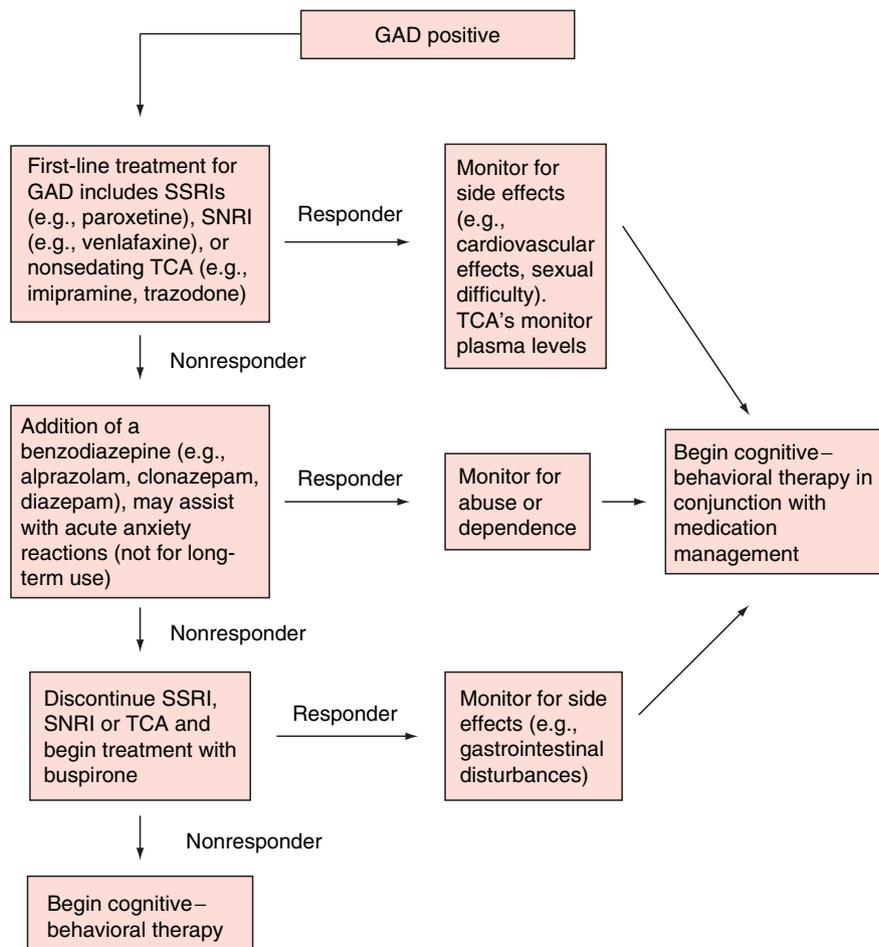

RJ is a 27-year-old graduate student who presented to his primary care physician with complaints of recurrent frontal headaches. He asked his physician to order a CT scan or an MRI because he feared that this may be a sign of a serious and a life-threatening illness. However, the headaches appeared to worsen during times of stress, and abated when the patient was on vacation with a friend. During the interview the patient admitted that he is very worried about the quality of his research at the university, even though he had received consistently positive evaluations. He attributed the perceived academic difficulties to his forgetfulness and diminished ability to concentrate during the last 6 months. He also described feeling fatigued, as well as significant indigestion, abdominal pain associated with bouts of changes in bowel movements (alternating diarrhea and constipation).

For the past 6 months he had few social contacts because of his symptoms and his girlfriend demanded that he seek professional help. Following complete physical evaluation, including consultation with a gastroenterologist, a diagnosis of generalized anxiety disorder and irritable bowel syndrome was made.

their GAD symptoms. The disability associated with GAD was found to be similar to that found in individuals with panic disorder or major depression.

### Treatment Approaches

GAD is a chronic, relapsing illness, which means that most treatments do not cure the patient. Furthermore, it also suggests that when treatments are discontinued, symptoms may return. It follows that a thorough understanding of the long-term benefits and risks associated with the different treatments available is important. Thus, each case must be considered individually according to the severity and chronicity of the disorder, the severity of somatic symptoms, the presence of stressors, and the presence of specific personality traits. The clinician may also need to work with the patient to determine how much improvement is sufficient. For example, a reduction in disability may occur without a marked change in symptoms. Symptoms may persist but occur less frequently, or their intensity may be reduced. All these variations have important treatment implications, including decisions regarding the need for long-term treatment. Patients with milder forms of GAD may respond well to simple psychological interventions, and require no medication treatment. In more severe forms of GAD, it may become necessary to see the patient regularly and to provide both more specific psychological and pharmacological interventions. Figure 53.2 can be used as a guide to the treatment of GAD.

**Figure 53.2** Generalized anxiety disorder treatment flowchart.

During the early (acute) phase of treatment, an attempt should be made to control the patient's symptomatology. It may take 3 to 6 months for an optimal response to be achieved. However, there may be a considerable variation in the length of the initial treatment phase. For example, clinical response to benzodiazepines occurs early in treatment. Response to other anxiolytic medications or to cognitive-behavioral treatment generally requires longer periods of time. During the maintenance phase, treatment gains are consolidated. Unfortunately, studies suggesting how long treatment should be continued are limited. Routinely, pharmacological treatment is continued for a total of 6 to 12 months before attempting to discontinue medications. Recent data indicate that "maintenance" psychotherapeutic treatments such as cognitive-behavioral therapy may be helpful in maintaining treatment gains in patients with anxiety disorders following the discontinuation of pharmacotherapy. It is clear that many patients may experience chronic and continuous symptoms that require years of long-term treatment.

### Doctor-Patient Relationship

The vast majority of patients with GAD who present for treatment have been ill for many years and frequently have received a variety of treatments. Some patients have been sent to psychiatrists for treatment as a "last resort" in order to learn how to cope with their various ill-defined somatic and emotional complaints. Patients may feel shame and guilt over their inability to control symptoms. They are often demoralized and angry, and feel that their symptoms are not taken seriously. Thus, it is important to help the patient understand their illness and to conceptualize it as a health problem rather than a "personal weakness". Once the burden of perceived responsibility is lifted from the patient, and they believe that effective treatment of their illness is possible, a working alliance with the treating physician can begin. The treatment plan should be outlined clearly, and the patient cautioned that recovery may have a gradual, variable course. Finally, during the critical early stages of treatment, the clinician should make a special effort to be available in person or by phone to answer questions and provide support.

### Pharmacotherapy

Below, we will discuss the use of various anxiolytic agents in the treatment of GAD. Table 53.2 provides a summarization of this information.

#### Benzodiazepines

Benzodiazepines are commonly used for the treatment of GAD and are still considered by some clinicians to be the first-line treatment for GAD. Several controlled studies have demonstrated the efficacy of different benzodiazepines such as diazepam, chlordiazepoxide and alprazolam in the treatment of GAD. The available placebo-controlled studies found that diazepam, alprazolam and lorazepam were effective in the treatment of GAD. The benzodiazepines have a broad spectrum of effects including sedation, muscle relaxation, anxiety reduction and decreased physiologic arousal (e.g. palpitations, tremulousness, etc.). Interestingly, available studies indicate that benzodiazepines have the most pronounced effect on hypervigilance and somatic symptoms of GAD, but exhibited fewer effects on psychic symptoms such as dysphoria, interpersonal sensitivity and obsessiveness (Hoehn-Saric *et al.*, 1988).

The main difference between individual benzodiazepines is potency and elimination half-life. These differences may have important treatment implications. For example, benzodiazepines with relatively short elimination half-lives such as alprazolam (range of 10–14 hours) may require dosing at least three to four times a day in order to avoid interdose symptom rebound. Conversely, the use of longer-acting compounds such as clonazepam (range of 20–50 hours) may minimize the risk of interdose symptom recurrence. In comparative studies of different benzodiazepines, alprazolam appeared to perform somewhat better than lorazepam. Data from the HARP study indicate that the most frequently reported medication used by GAD patients was alprazolam (31%), followed by clonazepam (23%) (Yonkers *et al.*, 1996).

Benzodiazepines exert their therapeutic effects quickly, often after a single dose. However, concern has emerged over the use of benzodiazepines, particularly long-term benzodiazepine use. Side effects of benzodiazepines, such as sedation, psychomotor impairment and memory disruption, were noted by treating clinicians, and confirmed in research studies. Further, although it was suggested that the use pattern of benzodiazepines by patients with anxiety disorders may not represent abuse, addiction, or drug dependence as typically understood, the chronic use of benzodiazepines in the treatment of GAD has been increasingly discouraged in recent years.

When initiating treatment with benzodiazepines, it is helpful for patients to take an initial dose at home in the evening to see how it affects them. Gradual titration to an effective dose allows for limiting unwanted adverse effects. A final daily dosage of alprazolam between 2 and 4 mg/day, 1 and 2 mg/day for clonazepam, or 15 and 20 mg/day of diazepam is usually sufficient for the majority of patients. Upon treatment discontinuation, it is important to consider appropriate taper in order to avoid withdrawal symptoms. Possible factors that may contribute to the severity of withdrawal and the ultimate outcome of benzodiazepine taper include the dosage, duration of treatment, the benzodiazepine elimination half-life and potency, and the rate of benzodiazepine taper (gradual versus abrupt). Additionally, patient factors such as premorbid personality features have been implicated. It appears that a taper rate of 25% per week is probably too rapid for many patients. We, therefore, recommend a slow benzodiazepine taper of at least 4 to 8 weeks, with the final 50% of the taper conducted even more gradually, with the patient decreasing by the lowest possible daily dose of the benzodiazepines during this period. We also recommend continuing to use divided doses of short to intermediate half-life benzodiazepines (alprazolam, lorazepam) during taper to minimize fluctuations in benzodiazepine levels over a 24-hour period, or using longer half-life benzodiazepines (such as clonazepam) which have the advantage of maintaining a once- or twice-daily dosing schedule.

#### Tricyclic Antidepressants

Clinical trials conducted in the early 1990s have confirmed that tricyclic antidepressants (TCAs) may also be effective in the treatment of GAD. These studies, as well as other trials, suggest that TCAs may be especially effective in the treatment of psychic symptoms of GAD (Brawman-Mintzer and Lydiard, 1994). The relationship between plasma levels of TCAs and their anxiolytic efficacy in patients with GAD has not been studied. Until this relationship is clarified, decisions regarding the total daily doses and the monitoring of plasma levels should be based on

**Table 53.2** Anxiolytic Agents

Drug	Daily Dosage Range (mg)	Advantages	Disadvantages
<i>Selective serotonin reuptake inhibitors</i>			
Paroxetine	20–40	Efficacy with GAD	Gastrointestinal side effects
Fluoxetine	20–60	Efficacy with comorbid depression	Delayed onset
Sertraline	50–200		Sexual side effects
Citalopram	20–40	Favorable side effects profile compared with TCAs	
Fluvoxamine	100–300	Easy dosing schedule	
<i>Serotonergic and noradrenergic reuptake inhibitors</i>			
Venlafaxine extended release (XR)	75–225	Efficacy with GAD Efficacy with comorbid depression	Gastrointestinal side effects Sexual side effects Potential for increased blood pressure
<i>Benzodiazepines</i>			
Alprazolam	2–6	Rapid onset of action	Sedation
Clonazepam	1–3	Favorable side-effects profile	Multiple doses for shorter acting agents
Lorazepam	4–10		Physical dependence
Diazepam	15–20		Limited antidepressant effects Sexual side effects
<i>Tricyclic antidepressants</i>			
Imipramine	75–300	Once-daily dosage Efficacy with comorbid depression	Delayed onset Need for titration Activation Anticholinergic effects Orthostatic hypotension Weight gain Toxicity in overdose Sexual side effects
<i>Atypical antidepressants</i>			
Trazodone	150–600	Once-daily dosage Efficacy with comorbid depression Low anticholinergic effects	Delayed onset Orthostatic hypotension Weight gain Sexual side effects Priapism (rare) Sedation
<i>Azapirones</i>			
Buspirone	30–60	No withdrawal symptoms No physical dependence Favorable side-effects profile	Multiple doses

the patient's treatment response and side-effects profile. Further, due to potential jitteriness, restlessness and agitation during the initial stages of treatment, we suggest that the initial dose of the TCAs in patients with GAD may need to be low (for example 10 mg/day of imipramine), and increased gradually.

Adverse effects commonly associated with the use of TCAs include anticholinergic effects (dry mouth, blurred vision,

constipation), cardiovascular effects (orthostatic hypotension, slightly increased heart rate), sexual side effects and weight gain. As mentioned, patients may also experience significant jitteriness, restlessness and agitation during the initial stages of treatment. These side-effects often limit the acceptability of TCAs by many patients. Potential toxicity in overdose has been of concern to clinicians as well. Due, in part, to the side-effect profile, need for dose titration and importantly the emergence of

new and effective agents (as described below), the use of TCAs in the treatment of GAD has been reserved for those resistant to these newer agents.

### Serotonin Reuptake Inhibitors

Selective serotonin reuptake inhibitors (SSRIs) are rapidly becoming a key tool in the treatment of GAD. SSRIs are generally well tolerated. The most problematic side effect associated with SSRI use is interference with sexual function (e.g., delayed orgasm or abnormal ejaculation) in women and men. A variety of treatment strategies have been suggested for the management of SSRI-induced sexual dysfunction. Such strategies include waiting for tolerance to develop, dosage reduction, drug holidays and various augmentation strategies with 5-hydroxytryptamine-2 (5-HT<sub>2</sub>), 5-HT<sub>3</sub> and alpha-2-adrenergic receptor antagonists, 5-HT<sub>1A</sub> and dopamine receptor agonists, and phosphodiesterase (PDE5) enzyme inhibitors.

### Serotonergic and Noradrenergic Reuptake Inhibitors

The antidepressant venlafaxine extended release (XR) is an inhibitor of both 5-HT and NE reuptake (SNRI). Several large, placebo-controlled trials have evaluated it in the treatment of patients with DSM-IV-diagnosed GAD. As a result, venlafaxine XR was the first antidepressant approved by the FDA for the treatment of GAD. Results from two short-term studies indicate that venlafaxine XR (75, 150 and 225 mg/day) was significantly more effective than placebo and superior to buspirone on certain anxiety measures and in the prevention of relapse (Sheehan, 2001). The adverse events for GAD patients treated with venlafaxine XR resembled those in depression trials. The most common adverse events included nausea, somnolence, dry mouth, dizziness, sweating, constipation and anorexia.

### Other Antidepressants

Both trazodone and imipramine have comparable efficacy to diazepam. In addition, trazodone and imipramine exhibit higher efficacy in the treatment of psychic symptoms such as tension, apprehension and worry. The alpha-2-adrenoreceptor antagonist mirtazapine, which is also a 5-HT<sub>2</sub>, 5-HT<sub>3</sub> and H(1) receptors antagonist, has been evaluated as a potential anxiolytic in the treatment of patients with major depressive disorder and comorbid GAD in an 8-week, open-label study (Goodnick *et al.*, 1999). Results suggest that this antidepressant may be useful in the treatment of anxiety symptoms.

### Azapirones

Buspirone hydrochloride, the only currently marketed azapirone, was the first nonbenzodiazepine anxiolytic agent approved for the treatment of persistent anxiety by FDA. Results have been mixed about the efficacy of buspirone over placebo. For example, in four placebo-controlled studies that compared buspirone with a standard benzodiazepine, two showed no benefit for diazepam and buspirone over placebo, and two showed no benefit for buspirone over placebo. Benzodiazepines may also be slightly more effective than buspirone in the treatment of somatic symptoms of anxiety but no significant differences appear to exist between buspirone and benzodiazepines in measures of psychic anxiety (Rickels *et al.*,

1997). Side effects most frequently associated with buspirone use included gastrointestinal system-related side effects, such as appetite disturbances and abdominal complaints, and dizziness. Prior use of benzodiazepines may adversely affect the therapeutic response to buspirone. DeMartinis and colleagues (2000) found that buspirone treatment was less effective for patients who had been taking benzodiazepines within 30 days of initiating buspirone treatment. Delle Chiaie and colleagues (1995) reported that a gradual 2-week taper of lorazepam with a simultaneous addition of buspirone for 6 weeks prevents the development of clinically significant rebound anxiety or benzodiazepine withdrawal. This approach was shown to provide clinically significant relief of anxiety symptoms in GAD patients previously treated with benzodiazepines for 8 to 14 weeks.

Perhaps the most significant problem with the use of buspirone has been that experts have advocated too low a dose to produce symptom reduction. In order to achieve optimal response, buspirone dosing in the range of at least 30 to 60 mg/day is currently recommended.

### Other Agents

Hydroxyzine is a histamine-1 receptor blocker and a muscarinic receptor blocker. Recent controlled trials with the antihistamine have suggested that this compound may be effective in the acute treatment of GAD symptoms. Finally, the potential use of the anticonvulsant gabapentin in the treatment of anxiety symptoms has also been suggested.

### Nonpharmacological Treatments

Numerous studies have shown that psychological interventions are beneficial in the comprehensive management of anxiety disorders. However, data suggesting that specific psychotherapeutic techniques yield better results in the treatment of patients with GAD are inconclusive and more evidence is needed on the comparative efficacy and long-term effects of different psychological treatments.

### Cognitive–Behavioral Therapy

In recent years specific cognitive–behavioral therapy (CBT) interventions for the treatment of patients with anxiety disorders have been developed. Components of CBT include teaching patients to identify and label irrational thoughts and to replace them with positive self-statements or modify them by challenging their veracity. The cognitive modification approaches are combined with behavioral treatments such as exposure or relaxation training. There is currently evidence suggesting that CBT may be more effective in the treatment of GAD than other psychotherapeutic interventions, such as behavioral therapy alone or nonspecific supportive therapy (Chambless and Gillis, 1993). Six additional studies confirmed the efficacy of CBT compared with waiting list or pill placebo and patients tend to maintain improvement following CBT over 6 to 12 months of follow-up.

CBT targeting intolerance of uncertainty, erroneous beliefs about worry, poor problem orientation and cognitive avoidance demonstrated effectiveness at post treatment (no change in the delayed treatment control group) 6- and 12-month follow-up, with 77% of the treatment group no longer having symptoms meeting criteria for a GAD diagnosis (Ladouceur *et al.*, 2000).

Cognitive therapy was also compared with analytic psychotherapy, and was found to be significantly more effective (Borkovec and Costello, 1993). Overall, two-thirds in the cognitive therapy group achieved clinically significant improvements and cognitive therapy was associated with significant reductions in medication usage.

A meta-analytic review of controlled trials examining CBT and pharmacotherapy for GAD, which included 35 studies, demonstrated the robustness of CBT in the treatment of GAD (Gould *et al.*, 1997). Overall, both modalities offered clear efficacy to patients, with the effect size for CBT not being statistically different from psychopharmacological approaches. CBT demonstrated greater effects in reducing depression and was associated with clear maintenance of treatment gains, whereas long-term efficacy of pharmacologic treatment was attenuated following medication discontinuation.

Barlow and colleagues (1986) developed a CBT approach to GAD which concentrates on the behavioral element of direct exposure to the contents of patients' worry and apprehension (i.e., a deconditioning strategy) in addition to relaxation techniques (progressive muscle relaxation) and cognitive restructuring. The authors found that this technique is effective in reducing anxiety symptoms in patients with GAD.

### Supportive Psychotherapy

Many patients with milder forms of GAD will benefit from simple psychological interventions such as supportive psychotherapy. They may experience lessening of anxiety when given the opportunity to discuss their difficulties with a supportive clinician and to become better informed about their illness. Thus, basic supportive techniques such as reassurance, clarification of patient concerns, direct suggestions and advice are often effective in reducing anxiety symptoms.

### Relaxation and Biofeedback

Relaxation techniques such as progressive muscle relaxation and biofeedback have also been utilized in the treatment of patients with anxiety symptoms. Few controlled studies have examined their effectiveness. In a recent controlled study, Borkovec and Costello (1993) compared a comprehensive relaxation treatment and cognitive-behavioral therapy in the treatment of patients with DSM-III-R-defined GAD. The authors found that both treatments were equally effective and superior to a nonspecific supportive treatment intervention.

### Psychodynamic Psychotherapy

Although there are no controlled studies evaluating the efficacy of psychodynamic psychotherapies in the treatment of patients with GAD, some of its important principles in understanding patients may be helpful. First, it is important to note that the psychoanalytic theories view anxiety as an indicator of certain unconscious conflicts, rather than as a primary target symptom to be alleviated. It is, therefore, the clinician's task to use various techniques to help the patient uncover these unconscious conflicts. It is believed that the newly gained understanding of the underlying reasons for symptoms will have a therapeutic effect, thereby reducing anxiety. Through interpretation of previously unconscious conflicts and unconscious origins of anxiety, the patient will be able to utilize new insights and find more adaptive outlets or solutions to problems. In Harry Stack Sullivan's theory, anxiety reflects the failure to develop secure interpersonal interactions, such as an emphatic and secure

mother-infant relationship. He believed that the child learns to identify anxiety states in himself and significant others and develops protective defensive strategies which enable him to avoid experiencing anxiety. However, the defenses employed (termed security operations) are generally restrictive and may result in limiting the subject's interpersonal interactions. Therefore, the task of the therapist, according to Sullivan's model, is to trace the patterns of interpersonal interactions throughout the patient's developmental stages (rather than to uncover the unconscious drives), thereby promoting a more accurate perception of self and others and subsequently better social adaptation.

Another therapeutic approach to the treatment of anxiety symptoms was offered by object relation and self-psychology theorists. They view anxiety as a result of the loss of or inadequate emotional relationships with significant others. Therefore, the primary focus of therapy shifts to emphasize the importance of the relationship to the therapist, who functions as an empathic object providing emotionally corrective experiences. For example, the patient may learn that an important person may be imperfect but still be trusted and nurturing.

Finally, most psychodynamically oriented therapists agree that the outcome of psychodynamic psychotherapy is determined by factors reflecting a patient's maturity and strength. Specifically factors such as the patient's capacity for introspection, intelligence, ability to relate to the therapist, and ability to bear painful feelings should be carefully evaluated.

### Long-term Management of Generalized Anxiety Disorder

As mentioned, GAD is a chronic, continuous condition in the majority of patients. Frequently beginning in adolescence or early adulthood, the course of GAD can persist for decades, with relatively low remission rates. The HARP data indicate that among the 164 GAD patients followed, only 15% had a full remission for 2 months or longer at any time during the first follow-up year, 25% had a full remission during the 2-year follow-up, and only 35% had a full remission after 5 years (Yonkers *et al.*, 1996). In a 5-year follow-up study of 64 GAD patients, only 18% of GAD subjects achieved a full remission compared with 45% of panic disorder subjects (Woodman *et al.*, 1999).

Despite these findings, less research has been conducted to assess the efficacy of chronic long-term anxiolytic therapy. To our knowledge, only three double-blind, controlled studies evaluating the long-term pharmacological treatment of GAD have been conducted. The first, a 1-year follow-up of patients who participated in a 6-month diazepam maintenance study, found that two-thirds of all patients relapsed within a 1-year period after diazepam discontinuation. In the second study, GAD patients were treated for 6 months with buspirone or clorazepate, and reevaluated them after discontinuation at 6 and 40 months. The authors found that the improvement achieved in both treatment groups was sustained during the 6-month maintenance phase, with no need for an increase in medication intake, and no evidence of tolerance or abuse. At follow-up, approximately 60% of patients treated initially with clorazepate compared with 30% of patients treated initially with buspirone were experiencing at least moderate anxiety symptoms. Finally, in a recent study, Stocchi and colleagues (2001) found that many patients with GAD are not able to remain symptom-free for long periods without treatment. Therefore, a long-term therapy may be needed in many patients.

Generally, the current recommendation for GAD treatment suggests a treatment period of approximately 1 year after response has been established prior to considering treatment discontinuation. Stress management and problem-solving techniques, along with specific psychotherapeutic approaches such as cognitive-behavioral therapy, should be attempted in addition to medication treatment.

### Comorbidity and the Treatment of GAD

GAD is often accompanied by other concurrent psychiatric disorders, specifically anxiety and mood disorders. The presence of these comorbid conditions may reflect more severe loading for psychopathology, and may have important implications on the course and treatment response of the primary disorder. In the National Comorbidity Survey, more patients with comorbidity experienced interference with daily activities than did patients with pure GAD (Wittchen *et al.*, 1994). The presence of a comorbid anxiety disorder and major depressive disorder is frequently associated with a poorer overall outcome than for patients with a single psychiatric disorder (Kessler *et al.*, 1999). Currently, there are treatment options that can target both GAD and major depressive disorder simultaneously. The use of SSRIs and the SNRI venlafaxine is recommended as the first-line treatment for comorbid GAD and depression.

Social anxiety disorder frequently complicates the course GAD takes. With the recent data indicating that the SSRIs such as sertraline and paroxetine are effective in the treatment of social anxiety, these agents may be useful in the treatment of comorbid social anxiety disorder and GAD. The benzodiazepines that have been established as effective in the treatment of patients with GAD also appear to be effective in the treatment of patients with social anxiety disorder. Thus, these agents (considering the caveats associated with their use described earlier) may have a therapeutic role in patients with GAD and coexisting social phobia. Finally, patients with GAD and concurrent panic disorder or panic attacks may be effectively treated with SSRIs, TCAs and benzodiazepines. However, buspirone is probably ineffective in the treatment of panic disorder.

Concurrent alcohol and substance abuse tend to confuse the clinical picture of GAD and can interfere with the therapeutic efforts. Additionally, symptoms associated with alcohol withdrawal or other sedative-hypnotics may mimic the underlying anxiety disorder. If a substance abuse problem exists, the clinician and the patient should take the necessary steps to discontinue the use of the abused substance. This may well include specific substance abuse treatment. Specifically, the need for detoxification should be assessed and discussed with the patient. Following cessation of substance abuse the patient's symptomatology should be reevaluated. The use of benzodiazepines in these patients may be contraindicated, and alternative treatments with SSRIs, SNRIs, TCAs, buspirone, or gabapentin may be needed.

### Treatment of GAD in the Elderly

Epidemiological data suggests that GAD is highly prevalent in the geriatric population (prevalence rates ranging from 0.7 to 7.1%), accounting for the majority of anxiety disorder cases in this group. GAD is the most common of the pervasive late-life anxiety disorders. In the elderly, anxiety symptoms are often associated with depression, medical conditions and cognitive

dysfunction. Thus, a careful differential diagnosis to eliminate exogenous causes of anxiety and identification of other coexisting conditions is necessary. For example, treatment of medical illness, depression, or underlying dementia may reduce anxiety symptoms. Dose reductions or elimination of anxiety-inducing medications as well as reducing stressful life circumstances may also reduce anxiety symptoms. However, if these interventions are not effective in reducing anxiety, pharmacotherapy may be necessary. Several factors influencing pharmacologic treatment in the elderly should be considered. These factors include alterations in pharmacokinetics and pharmacodynamics of psychotropic drugs, primarily because of reduced hepatic clearing efficiency, alterations in the response of the central nervous system to drugs, such as changes in receptor sensitivity, and concurrent medical conditions that may alter drug effect, side-effect profile, and toxicity.

Benzodiazepines can be effective in the treatment of anxiety symptoms. However, older patients are often sensitive to their effects. Adverse effects may include increased sedation, tendency to fall, psychomotor discoordination and cognitive impairment. Older patients may become disinhibited by benzodiazepines and experience agitation and aggression. The administration of long-acting benzodiazepines such as diazepam and chlorazepate may result in increased accumulation of the drug predisposing the patient to these side effects. Conversely, the use of short half-life high potency benzodiazepines such as alprazolam may be associated with more severe withdrawal symptoms following rapid discontinuation. Because of these factors, benzodiazepines should be prescribed for the briefest period of time, at the lowest therapeutic dose, giving preference for the short half-life, low-potency benzodiazepines such as oxazepam. We recommend initiating treatment with oxazepam at low doses (10 mg t.i.d.), to be increased gradually, while carefully monitoring for the emergence of side effects.

Buspirone has been extensively used in the treatment of GAD symptoms. The lack of associated sedation, discoordination and dependence with the use of buspirone makes its use in the elderly less problematic. However, additional research is needed to determine its long-term efficacy in the GAD elderly population. The average therapeutic doses of buspirone for elderly patients range from 5 to 20 mg/day.

The use of TCAs in the anxious elderly patient should be viewed in light of the side-effect profile of TCAs. Side effects commonly associated with the use of TCAs, such as the anticholinergic effects and orthostatic hypotension, may be especially troublesome in these patients. We therefore recommend the use of TCAs with low anticholinergic and hypotensive effects such as desipramine and nortryptiline, starting at low doses (10 mg/day) that are raised slowly and gradually.

Finally, despite the widespread use of the newer antidepressant agents, specifically the SSRIs and the SNRIs, in the treatment of adult GAD patients, very limited data exist regarding their use in the anxious elderly population. However, preliminary evidence suggests that they can decrease symptoms, improve quality of life and potentially promote healthier outcomes in geriatric patients who have comorbid anxiety and depression and/or comorbid mental and physical illness. A potential drawback of venlafaxine in this population is the need to monitor for drug-induced blood pressure elevation in those taking the medication.

Most controlled studies examining CBT in older adults have focused on the treatment of GAD. This literature suggests that CBT is effective in the treatment of GAD in this population.

For example, group-administered CBT was found to be effective in reducing GAD and coexistent symptoms in older adults. In conclusion, several agents may play an important role in the treatment of anxiety in the elderly. However, until more studies in the elderly GAD population are available, treatment choices should be guided by clinical judgment and specific factors relevant to this patient population, such as medical comorbidity and age-associated changes in the drug metabolism.

### Treatment of GAD in Adolescents and Children

The treatment of GAD in adolescents and children should be multifaceted, including psychotherapy for the patient, psychoeducation for the parents, and pharmacotherapy when other psychotherapeutic interventions have not produced satisfactory outcome. CBT is successful in treating GAD in children. The addition of family anxiety management skills taught to parents appears to increase treatment success.

Pharmacotherapy in children and adolescents differs from that of the adult population primarily because of the difference in the hepatic biotransformation and elimination of many psychotropic drugs that may require some adjustments in treatment regimen. Hepatic metabolic rate is faster in children and adolescents than in adults, reaching adult values around 15 years of age. Thus a particular milligram per kilogram (mg/kg) dose will yield a lower blood level in a child than in an adult, and higher mg/kg doses than based on those for adults may be necessary. This applies for all liver-metabolized drugs, such as antidepressants, anxiolytics, anticonvulsants and neuroleptics. In addition, the higher clearance of these drugs requires more frequent administration of medications (i.e., small divided doses rather than one large dose).

Over the years, a number of medications have been used in the treatment of childhood GAD (previously classified as overanxious anxiety disorder). Unfortunately, only a few studies have been conducted in children with overanxious anxiety disorder. Given these limited findings and the reported occurrence of significant behavioral activation, other side effects, and their addictive potential, the use of benzodiazepines to treat children with GAD is suspect.

The use of SSRIs in the treatment of GAD in children and adolescents appears promising; however, no controlled trials with large samples have been conducted. Buspirone may also be effective in the treatment of GAD in children and adolescents. No controlled studies have been completed for the treatment of GAD with buspirone in children to date. TCAs have not been studied in overanxious anxiety disorder. It should be noted that cardiovascular side effects may occur more frequently in children and adolescents than in adults, and preexisting conduction abnormalities may be associated with significant TCA effect on cardiac conduction. However, the clinical significance of TCA-induced changes in cardiac conduction is not clear. Given this lack of efficacy data for GAD and the concern of significant cardiovascular side effects in children, TCAs should not be a first-line treatment in children and adolescents with GAD.

### Treatment Resistance

The clinician is frequently faced with a patient whose anxiety symptomatology is not responding satisfactorily to the standard treatment. Different factors, such as inadequate length of treatment, low dose and noncompliance, may contribute to treatment

failure in the management of patients with GAD. Pharmacologic treatment is often complicated by the occurrence of side effects, which may impair quality of life, deter clinicians from prescribing adequate doses and contribute to noncompliance. For example, some antidepressants, including SSRIs, TCAs and venlafaxine, are associated with activation, overstimulation, or “jitters” primarily during the initial stage of treatment. When evaluating noncompliance, clinicians should also assess for akathisia and worsening of anxiety and hypomania or mania. Further, the presence of comorbid general medical and psychiatric conditions in GAD patients may be associated with nonresponse or lower response rates and should be carefully assessed during patient evaluation. Finally, the use of concurrent medications that can precipitate anxiety symptoms may affect the response to treatment.

The clinician should always evaluate whether an adequate treatment trial was complete. We believe that an attempt should be made to maintain the patient on medication for at least 6 weeks. Although there are no data suggesting that certain doses may be particularly effective in the treatment of GAD, it is advisable to titrate the medication up to maximally tolerated doses prior to discontinuing the medication for nonresponse. It is important to inquire about the presence of side effects such as sedation, anticholinergic effects, or sexual side effects, which may limit the attainment of a therapeutic dosage and reduce compliance. Additionally, many patients with GAD fear that they may become “drug-dependent” and thus avoid dose increases. Some estimate of the patient’s compliance may be helpful in determining whether a treatment was adequate, as indicated by blood plasma levels or pill counts. Drug plasma levels may also be useful to identify patients who are rapid metabolizers. A careful evaluation for the presence of psychiatric comorbid conditions that may contribute to treatment refractoriness should follow. As mentioned, comorbidity which may reflect more severe loading for psychopathology is often associated with increased severity of illness and poorer response to treatment in comparison to patients with an uncomplicated (i.e., single) disorder. Thus, treatment strategies in GAD patients with a concurrent disorder may differ from those in an uncomplicated disorder, often requiring multiple drug therapy. The clinician should also be alert to the presence of underlying general medical conditions such as hyperthyroidism which may present with refractory anxiety, or conditions/medications which may alter the effects of treatment such as hepatic disease or medications (e.g., steroids) that affect hepatic clearance.

The use of psychotherapy, such as cognitive-behavioral therapy, in conjunction with pharmacotherapy may also enhance response in the treatment-resistant patient. Finally, education and psychological support for patients and their families may help them better to understand and deal with their illness, especially during periods of increased stress, and consequently improve treatment outcome.

### Summary

In conclusion, GAD appears to be a chronic, frequently comorbid condition, often requiring long-term management. Benzodiazepines were, at one time, the first-line treatment choice for GAD. However, newer medication may offer more hope for those with GAD. SSRIs and SNRIs are promising new pharmacotherapies for GAD. Additionally, these treatments may be especially effective for patients presenting with depressive symptomatology. Further, buspirone and TCAs have been shown to be an important

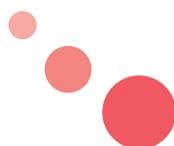

treatment alternative to benzodiazepines, and the TCAs may be especially effective in patients presenting with depressive symptomatology. Finally psychotherapy, specifically cognitive-behavioral therapy, is an additional treatment strategy, potentially effective in maintaining treatment gains. Further information is needed on long-term treatment, medication discontinuation and comparative efficacy of pharmacotherapies, psychotherapies and combination in the treatment of uncomplicated and comorbid GAD.

## Comparison of DSM-IV/ICD-10 Diagnostic Criteria

The ICD-10 Diagnostic Criteria for Research specify that four symptoms from a list of 22 be present. In contrast, DSM-IV-TR requires three out of a list of six (of which five are included among the ICD-10 list of 22).

### Definition

The somatoform disorders are a major diagnostic class in the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR) (American Psychiatric Association, 2000) that groups together conditions characterized by physical symptoms suggestive of but not fully explained by a general medical condition or the direct effects of a substance. In this class, symptoms are not intentionally produced and are not attributable to another mental disorder. To warrant a diagnosis, symptoms must be clinically significant in terms of causing distress or impairment in important areas of functioning. As summarized in Table 54.1, the disorders included in this class are somatization disorder, undifferentiated somatoform disorder, conversion disorder, pain disorder, hypochondriasis, body dysmorphic disorder and somatoform disorder not otherwise specified (NOS).

The somatoform disorders class was created for clinical utility, not on the basis of an assumed common etiology or mechanism. In DSM-IV-TR terms, it was designed to facilitate the differential diagnosis of conditions in which the first diagnostic concern is the need to “exclude occult general medical conditions or substance-induced etiologies for the bodily symptoms”. As shown in Figure 54.1, only after such explanations are reasonably excluded should somatoform disorders be considered.

Many criticisms of the somatoform disorder category have been raised and they include contentions that because the category is delineated on the basis of presenting symptoms, it is “superficial”; that the individual disorders are not qualitatively distinct from one another or from “normality” and hence would be better described dimensionally rather than differentiated categorically; that the disorders are derived from hospital rather than community- or primary care-based populations; and, perhaps the most serious challenge, that the grouping “gives the spurious impression of understanding”. On the other hand, proponents maintain that the somatoform grouping represents a major advance over previous systems and that segregation of such disorders into a class has helped clarify the conceptualization of the “mind–body” distinction, promoted greater consistency in terminology, and led to better descriptive distinctions between specific disorders. Supporters contend that maintaining this diagnostic class will foster more generalizable and thereby more clinically applicable research.

The somatoform disorder concept should be distinguished from traditional concepts of “psychosomatic illness” and “somatization”. The psychosomatic illnesses involved structural or physiological changes hypothesized as deriving from psychological factors. In the DSM-IV somatoform disorders, such objective changes are generally not evident. The “classic” psychosomatic illnesses of Alexander (1950) included bronchial asthma, ulcerative

colitis, thyrotoxicosis, essential hypertension, rheumatoid arthritis, neurodermatitis and peptic ulcer. In DSM-IV, most of these illnesses would be diagnosed as a general medical condition on Axis III, and in some cases with an additional designation of psychological factors affecting medical condition on Axis I. By definition, the diagnosis of “psychological factors affecting medical condition” is not a psychiatric disorder, but it is included in DSM-IV in the section for other conditions that may be a focus of clinical attention; it involves the presence of one or more specific psychological or behavioral factors that adversely affect a general medical condition.

The descriptive use of the term “somatization” in somatization disorder is not to be confused with theories that generally postulate a somatic expression of psychological distress. Empirical studies suggest that there is no single theory that can adequately explain somatization, which is not only multifactorially determined but is an exceedingly complex phenomenon. Furthermore, treatment strategies derived from somatization theories have not proven effective. For example, the postulation that patients with somatoform disorders are alexithymic, that is, are unable to process emotions and psychological conflicts verbally and therefore do so somatically, suggested that teaching such patients to “appreciate” and “verbalize” their emotions would circumvent the need to “somatize” them. Such treatment approaches have been ineffective.

### Diagnosis and Differential Diagnosis

As shown in Figure 54.1, after it is determined that physical symptoms are not fully explained by a general medical condition or the direct effect of a substance, somatoform disorders must be differentiated from other mental conditions with physical symptoms.

In contrast to malingering and factitious disorder, symptoms in somatoform disorders are not under voluntary control, that is, they are not intentionally produced or feigned. Determination of intentionality may be difficult and must be inferred from the context in which symptoms present. Somatic symptoms may also be involved in disorders in other diagnostic classes. However, in such instances, the overriding focus is on the primary symptom complex (i.e., anxiety, mood, or psychotic symptoms) rather than the physical symptoms. In panic disorder and in generalized anxiety disorder, physical symptoms such as chest pain, shortness of breath, palpitations, sweating and tremulousness may occur. However, such somatic symptoms occur only in the context of fear or anxious foreboding. In general, there is a lack of a consistent physical focus. In mood disorders (particularly major depressive disorder) and in schizophrenia and other psychotic disorders, somatic preoccupations, fears, and even

delusions and false perceptions may be evident. In the mood disorders, these are generally mood congruent (e.g., “I’m so worthless not even my organs work anymore”), whereas in the psychoses, bizarre and mood-incongruent beliefs are typical (e.g., “Half of my brain was removed by psychic neurosurgery”).

### Differentiation Among the Various Somatoform Disorders

Whereas it is assumed that the specific disorders in the somatoform grouping are heterogeneous in terms of pathogenesis and pathophysiology, they are also phenomenologically diverse. In somatization disorder, undifferentiated somatoform disorder, conversion disorder and pain disorder, the focus is on the physical

complaints themselves, and thus on perceptions. In hypochondriasis and body dysmorphic disorder, emphasis is on physically related preoccupations or fears, and thus on cognitions. Somatization disorder and, to a lesser extent, undifferentiated somatoform disorder are characterized by multiple symptoms of different types; conversion disorder, pain disorder, hypochondriasis and body dysmorphic disorder are defined on the basis of a single symptom or a few symptoms of a certain type (see Figure 54.1). Whereas somatization disorder, undifferentiated somatoform disorder and hypochondriasis are, by definition, at least 6 months in duration, conversion disorder, pain disorder, body dysmorphic disorder and somatoform disorder NOS may be of short duration as long as they are associated with clinically significant distress or impairment.

**Figure 54.1** Somatic symptom diagnostic exploration and treatment algorithm. Differential diagnosis of clinically significant physical symptoms. Shaded boxes represent diagnostic categories; GMC, General medical condition.

## Epidemiology

In view of the vicissitudes of diagnostic approaches and the re-ency of the current somatoform disorder grouping, it is not surprising that estimates of the frequency of this group of disorders in the general population as well as in clinical settings are inconsistent if not nonexistent. Yet, existing data seem to indicate that such problems are indeed common and account for a major proportion of clinical services, especially in primary care settings.

Table 54.2 summarizes what is known about the epidemiology of these disorders.

In consideration of the substantial frequency of somatoform disorders in nonpsychiatric settings, instruments have been designed to aid primary care physicians in diagnosing psychiatric conditions. The Primary Care Evaluation of Mental Disorders (PRIME-MD) (Spitzer *et al.*, 1994) includes somatoform items in its screening questionnaire and in its physician education guide. The DSM-IV Primary Care Edition (DSM-IV-PC) includes an “unexplained physical symptoms” algorithm among the nine it included to address the most common psychiatric symptom groups presenting in primary care settings (American Psychiatric Association, 1995).

**Table 54.2 Epidemiology and Natural History of the Somatoform Disorders**

Somatoform Disorder	Prevalence and Incidence	Age at Onset	Course and Progress
Somatization disorder	US women 0.2–2%; women/men = 10:1	First symptoms by adolescence, full criteria met by mid-20s, not after 30 yr by definition	Chronic with fluctuations in severity Most active in early adulthood Full remissions rare
Undifferentiated somatoform disorder	“Abridged somatization disorder” type estimated as 11–15% of US adults, 20% in Puerto Rico Preponderance of women in US but not Puerto Rico	Variable	Variable conversion disorder
Conversion disorder	Conversion symptoms common, as high as 25% Treated conversion symptoms: 11–500 per 100 000 5–14% of general hospital admissions 5–24% of psychiatric outpatients 1–3% of psychiatric outpatient referrals 4% of neurological outpatient referrals 1% of neurological admissions	Late childhood to early adulthood, most before age 35 yr medical neurological or general If onset in middle or late life, condition more likely	Individual conversion symptoms generally remit within days to weeks Relapse within 1 yr in 20–25%
Pain disorder	10–15% of US adults with work disability owing to back pain yearly more A predominant symptom in hospital admissions than half of general psychiatric Present in as many as 38% of psychiatric outpatients admissions, 18%	Any age	Good if less than 6 mo in duration disorder Unemployment, personality drugs habituation to addictive compensation, and potential for prognosis associated with poorer
Hypochondriasis	Perhaps 4–9% in general medical settings, but unclear whether full syndrome criteria are met Equal in both sexes	Early adulthood typical	10% recovery, two-thirds a chronic but fluctuating course, 25% do poorly absence Better prognosis if acute onset, secondary gain disorder, absence of personality
Body dysmorphic disorder	Not routinely screened for in psychiatric or general population studies corrective Perhaps 2% of patients seeking cosmetic surgery	Adolescence or early adulthood Perhaps in women at menopause	Generally chronic, fluctuating severity perceived In a lifetime, multiple defects Incapacitating: one-third house-bound
Somatoform disorder NOS	Unknown	Variable	Variable

The epidemiology of the specific somatoform disorders is discussed individually in following sections.

## Treatment

Whereas specific somatoform disorders indicate specific treatment approaches, some general guidelines apply to the somatoform disorders as a whole (Figure 54.2 and Table 54.2). Therapeutic goals include 1) as an overriding goal, prevention of the adoption of the sick role and chronic invalidism; 2) minimization of unnecessary costs and complications by avoiding unwarranted hospitalizations, diagnostic and treatment procedures, and medications (especially those of an addictive potential); and 3) effective treatment of comorbid psychiatric disorders, such as depressive and anxiety syndromes. The three general treatment strategies include 1) consistent treatment, generally by the same physician, with careful coordination if multiple physicians are involved; 2) supportive office visits, scheduled at regular intervals rather than in response to symptoms; and 3) a gradual shift in focus from symptoms to an emphasis on personal and interpersonal problems.

## Somatization Disorder

### Definition

As defined in DSM-IV, somatization disorder is a polysymptomatic somatoform disorder characterized by multiple recurring pains and gastrointestinal, sexual and pseudoneurological symptoms occurring for a period of years with onset before age 30 years. The physical complaints are not intentionally produced and are not fully explained by a general medical condition or the direct effects of a substance. To warrant diagnosis, they must result in medical attention or significant impairment in social, occupational, or other important areas of functioning. Table 54.1 summarizes the criteria for this disorder.

Despite efforts to simplify it, the somatization disorder construct has remained somewhat cumbersome.

It remains to be seen whether the DSM-IV diagnosis of somatization disorder will be used broadly and appropriately. Unresolved problems include that the term somatization disorder has acquired a pejorative connotation; a tendency to diagnose more readily treatable symptoms such as anxiety and depressive syndromes without considering the underlying illness; and that authorization and reimbursement for treatment of this chronic condition are often challenged or denied. It is relatively easier to obtain approval for an intervention on the basis of major depressive disorder, for example, than on the basis of a disorder that is much more likely to be poorly understood by case reviewers.

### Epidemiology

In the USA, somatization disorder is found predominantly in women, with a female/male ratio of approximately 10:1 (see Table 54.1). This ratio is not as large in some other cultures (e.g., in Greeks and Puerto Ricans). Thus, gender- and culture-specific rates are more meaningful than generalized figures. The lifetime prevalence of somatization disorder in US women has been estimated to be between 0.2 and 2%. The magnitude of this discrepancy is attributable, at least in part, to methodological differences. The Epidemiological Catchment Area study (Robins *et al.*, 1984), the most recent large-scale general population study in the

USA to include an assessment for somatization disorder, found a lifetime risk of somatization disorder of only 0.2 to 0.3% in US women. However, this study may have underestimated the prevalence of somatization disorder because nonphysician interviewers were used. It is argued that it is difficult for lay interviewers critically to assess whether somatic symptoms are fully explained by physical conditions. As a result, they may more readily accept patients' general medical explanations of symptoms, resulting in fewer diagnoses of somatization disorder. With age and method of assessment taken into account, the lifetime risk for somatization disorder was estimated to be 2% in US women.

### Etiology and Pathophysiology

Many theories on the cause of somatization disorder have been proposed, however, the etiology remains unknown. Psychodynamic hypotheses regarding the physical expression of unconscious conflict by conversion or somatization have been influential. Even Freud assumed a "constitutional diathesis", as had Charcot before him. Evidence exists for both biological and psychosocial contributions.

Somatization disorder has been shown to be familial. It is observed that in 10 to 20% of female relatives of patients affected by somatization disorder there is a lifetime risk in US women 10 to 20 times greater than that of the general population. Yet, aggregation in families may be attributable to both genetic and environmental factors. A cross-fostering study of a Swedish population demonstrated that genetic background and postnatal influences contribute to the risk of somatization disorder independently (Bohman *et al.*, 1984). Of additional interest are observations that male relatives of patients with somatization disorder show increased rates of antisocial personality and alcoholism, suggesting an etiological link.

Certain promising theories have focused on learning principles with possible organic underpinnings. Some have postulated a social communication model based on learning theory to explain somatization disorder. This theory hypothesizes that individuals learn to somatize as a means of expressing their wants and needs and evoking care, nurturance and support from family and caregivers. That different sex ratios may exist in different cultures suggests that such learning differs from culture to culture.

In the 1970s, impaired information-processing problems involving attention and memory were identified in experimental neuropsychological testing. Such deficits may result in vague, nonspecific and impressionistic description for experience. These may underlie a tendency for excessive somatic complaints and, together with tendencies for impulsiveness and monotony intolerance, may contribute to the often associated multiple personal and social problems. Early studies also reported that the pattern of neuropsychological defects found in subjects with somatization disorder differed from that in normal control, schizophrenic and psychotic depression comparison groups. Subjects with somatization disorder had greater bilateral, symmetrical patterns of frontal lobe dysfunction in comparison with normal control subjects and greater dominant hemisphere impairment than control and depressive subjects. Nondominant hemisphere dysfunction was also identified, with greater impairment in the anterior as opposed to posterior regions. However, subjects with somatization disorder had less nondominant hemisphere disorganization than schizophrenic subjects. Of interest, these findings were similar to findings in male patients with antisocial personality disorder, giving further support to an etiological link with this disorder.

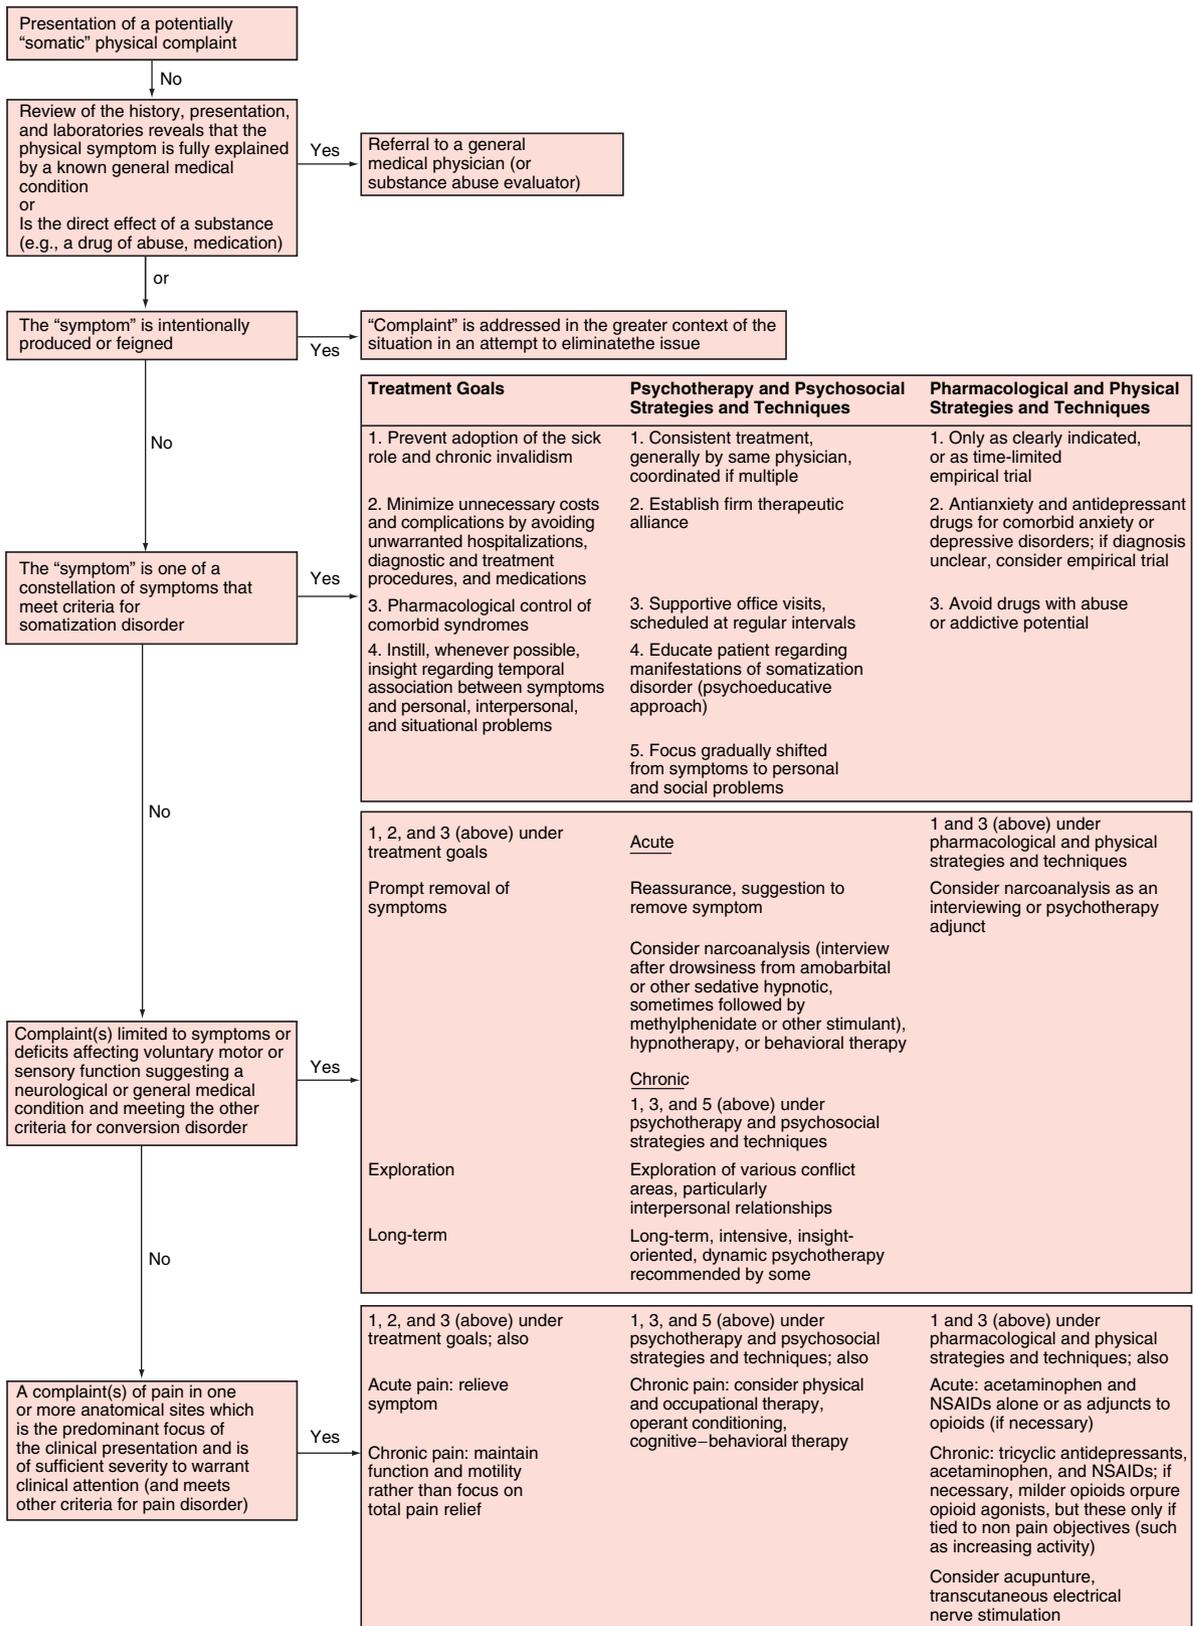

Figure 54.2 Diagnostic decision tree and treatment algorithm for Somatoform Disorders.

## Diagnosis and Differential Diagnosis

As defined in DSM-IV, somatization disorder is characterized by multiple recurring physical symptoms and, as will be described, often multiple psychiatric complaints. Thus, it is not surprising that somatization disorder may present in a manner suggestive of multiple general medical and, although too often forgotten, psychiatric disorders (Table 54.3). Indeed, it can be said that an essential aspect of somatization disorder is its simulation of other syndromes. As described by Preskorn (1995), “Somatization disorder is fundamentally a syndrome of apparent syndromes” (see Table 54.4). Thus, the first task in the diagnosis of somatization disorder is the exclusion of other suggested medical and psychiatric conditions.

To help in this, Cloninger (1986) identified three features that generally characterize somatization disorder but rarely general medical disorders and these are described in Table 54.5. Another way of characterizing the distinction is the “reverse funnel effect”. With most general medical conditions, the process of investigation “funnels down” to fewer and fewer specific diagnostic possibilities; in somatization disorder, the more extensive the investigation, the greater the number of suggested disorders.

Several general medical disorders may also fit this pattern and may be confused with somatization disorder. These include multiple sclerosis, other neuropathies, systemic lupus erythematosus, acute intermittent porphyria, other hepatic and hematopoietic porphyrias, hypercalcemia, certain chronic systemic

Somatoform disorder NOS	1, 2 and 3; also <ul style="list-style-type: none"> <li>• Evaluate carefully for alternative general medical or other psychiatric disorder to which the symptoms can be attributed</li> </ul>	1, 2 and 3	1 and 2

\*NSAIDs, Nonsteroidal antiinflammatory drugs; SSRIs, selective serotonin reuptake inhibitors.

infections such as brucellosis and trypanosomiasis, myopathies and vasculitides. In general, such conditions begin with disseminated, nonspecific subjective symptoms and transient or equivocal physical signs or laboratory abnormalities.

Somatization disorder is characterized by excessive psychiatric as well as physical complaints. Thus, other psychiatric disorders, including anxiety and mood disorders and schizophrenia, may be suggested. Although no specific exclusion criteria regarding other psychiatric disorders are given, one must be careful in accepting “comorbidity” and critically evaluate whether suggested syndromes are truly additional syndromes or simply manifestations of somatization disorder.

The overlap between somatization disorder and anxiety disorders may be a particular problem. Patients with somatization disorder frequently complain of many of the same somatic symptoms as patients with anxiety disorders, such as increased muscle tension, features of autonomic hyperactivity and even discrete panic attacks. Likewise, anxiety disorder patients may

report irrational disease concerns and such somatic complaints as those involving gastrointestinal function that are commonly seen in somatization disorder. However, patients with anxiety disorders neither typically report sexual and menstrual complaints or conversion or dissociative symptoms as in somatization disorder, nor do they have the associated histrionic presentation and personal, marital and social maladjustment common in patients with somatization disorder.

It must be remembered that an anxiety disorder may be comorbid with somatization disorder. Here, objective observation of the patient rather than reliance on the patient’s report may facilitate an additional diagnosis. For example, patients with somatization disorder may report that they are presently overwhelmed by anxiety while speaking calmly or even cheerfully about their symptoms, or they may be redirectable while in the midst of a reported panic attack.

Mood disorders (in particular depression) frequently present with multiple somatic complaints, especially in cer-

Gastrointestinal (nonpain)			
Difficulty swallowing	Myasthenia gravis	Esophageal motility disorder	Eating disorder
Nausea	Raised intracranial pressure	Meniere’s disease	Eating disorder
Bloating		Galactase deficiency	Eating disorder
Vomiting (nonpregnancy)	Raised intracranial pressure		Eating disorder
Diarrhea		Irritable bowel syndrome	Eating disorder
Intolerance to several foods		Food allergy	Eating disorder
Sexual (nonpain)			
Loss of interest			Major depressive episode
Erectile–ejaculatory dysfunction	Diabetic neuropathy	Antihypertensive drug effect	
Menorrhagia		Leiomyofibroma	
Vomiting throughout pregnancy		Preeclampsia, eclampsia	
Pseudoneurological			
Conversion			
Sensory	Stroke (hemianesthesia)		Schizophrenia/(hallucinations)
Motor	Huntington’s disease	Myopathy	Catatonia
Seizures	Epilepsy	Electrolyte imbalance	Catatonia
Mixed	Multiple sclerosis	Electrolyte imbalance	Catatonia
Dissociative			
Amnesia	Amnesic disorder	Anticholinergic drug effects	Dissociative identity disorder
Loss of consciousness (nonfainting)	Coma	Metabolic encephalopathy	Catatonia
Symptoms* often associated with somatization disorder			
Anxiety, panic		Pheochromocytoma	Generalized anxiety and panic disorders
Dysphoria, affective lability	Frontal lobe syndrome	Endocrinopathy	Major mood disorders
Cluster B personality features	Frontal lobe syndrome	Acute intermittent porphyria	Brief psychotic disorder

\*All of these symptoms may be reported by patients with somatization disorder, without the clinical consistency and pathological findings to support the diagnosis of neurological, general medical, or psychiatric conditions separate from somatization disorder.

Developed in conjunction with Sheldon H. Preskorn.

tain cultures such as in India, where somatic but not mental complaints are acceptable. A longitudinal history identifying age at onset and course of illness may facilitate discrimination of a mood disorder from somatization disorder. In mood disorders, the age at onset of the somatic symptoms is generally later than in somatization disorder; their first appearance generally correlates discretely with the onset of mood symptoms, and a lengthy pattern of multiple recurring somatic complaints is not seen. Also, resolution of the underlying

mood disorder will generally result in disappearance of the somatic complaints.

From the other perspective, patients with somatization disorder often present with depressive complaints. In somatization disorder, a thorough investigation will reveal a multitude of somatic as well as “depressive” symptoms. Interestingly, somatization disorder patients complaining of depression have been found to proffer greater depressive symptoms than individuals with major depression. As in anxiety disorders, major depressive

**Table 54.5 Discrimination of Somatization Disorder from General Medical Conditions**

Features Suggesting Somatization Disorder	Features Suggesting a General Medical Condition
Involvement of multiple organ systems	Involvement of single or few organ systems
Early onset and chronic course without development of physical signs or structural abnormalities	If early onset and chronic course, development of physical signs and structural abnormalities
Absence of laboratory abnormalities characteristic of the suggested general medical condition	Laboratory abnormalities evident

episodes may occur in patients with somatization disorder and must be differentiated from the tendency to have multiple complaints, which is characteristic of somatization disorder. As with anxiety disorders, in considering comorbidity with a depressive disorder, the patient's reports should be corroborated by collateral information or by direct observation. Thus, the veracity of the self-report of overwhelming depression and suicidal ideation should be doubted if the patient appears cheerful and charming, at least at times, when interviewed, or if the patient is reported to be actively involved in social activities on an inpatient psychiatric service.

Schizophrenia may present with generally single but occasionally multiple unexplained somatic complaints. Interview usually uncovers psychotic symptoms such as delusions, hallucinations, or disorganized thought. In some cases, the underlying psychosis cannot be identified initially but, in time, schizophrenia will become manifest. Hallucinations are included as examples of conversion symptoms in DSM-IV. As discussed in the conversion disorder section, careful analysis of this symptom is warranted so that a misdiagnosis is not made, relegating a patient to long-term neuroleptic treatment on the basis of conversion hallucinations.

Patients with histrionic, borderline and antisocial personality disorders frequently have an excess of somatic complaints, at times presenting with somatization disorder. Antisocial personality disorder and somatization disorder cluster in individuals and within families and may share common causes. Dissociative phenomena, in particular dissociative identity disorder, are commonly associated with somatization disorder. Because dissociative symptoms are included in the diagnostic criteria for somatization, a separate diagnosis of a dissociative disorder is not made if such symptoms occur only in the course of somatization disorder.

Unlike in hypochondriasis and body dysmorphic disorder, in which preoccupations and fears concerning the interpretation of symptoms predominate, the focus in somatization

disorder is on the physical complaints themselves. Unlike in pain disorder and conversion disorder, multiple complaints of different types are reported; by definition in DSM-IV, the history is of pain in at least four sites or functions (e.g., pain with intercourse, pain in swallowing), at least two nonpain gastrointestinal symptoms, at least one nonpain sexual or reproductive symptom, and at least one conversion or dissociative (i.e., pseudoneurological) symptom.

Whereas criteria require the onset of symptoms before the age of 30 years, most patients will have had some symptoms at least by adolescence or early adulthood. Symptoms are often described in a dramatic yet imprecise way and may be reported inconsistently from interview to interview. The medical history is usually complicated with multiple medical investigations, procedures and medication trials. If there have been symptoms for at least 6 months but the onset is later than at age 30 years, or if the required number and distribution of symptoms are not evident, undifferentiated somatoform disorder is diagnosed. If the duration has been less than 6 months, somatoform disorder NOS applies. In general, the greater the number and diversity of symptoms, and the longer they have been present without development of signs of an underlying general medical condition, the greater can be the confidence that a diagnosis of somatization disorder is correct.

### Course, Natural History and Prognosis

Somatization disorder is rare in children younger than 9 years of age. Characteristic symptoms of somatization disorder usually begin during adolescence, and the criteria are met by the mid-twenties. Somatization disorder is a chronic illness characterized by fluctuations in the frequency and diversity of symptoms. Full remissions occur rarely, if ever. Whereas the most active symptomatic phase is in early adulthood, aging does not appear to lead to total remission. Pribor and colleagues (1994) found that women with somatization disorder older than 55 years did not differ from younger somatization patients in the number of somatic symptoms. Longitudinal follow-up studies have confirmed that 80 to 90% of patients initially diagnosed with somatization disorder will maintain a consistent clinical picture and be rediagnosed similarly after 6 to 8 years. Women with somatization disorder seen in psychiatric settings are at increased risk for attempted suicide, although such attempts are usually unsuccessful and may reflect manipulative gestures more than intent to die. It is not clear whether such risk is true for patients with somatization disorder seen only in general medical settings.

### Treatment

First, a "management" rather than a "curative" strategy is recommended for somatization disorder. With the current absence of an identified definitive treatment, a modest, practical, empirical approach should be taken. This should include efforts to minimize distress and functional impairments associated with the multiple somatic complaints; to avoid unwarranted diagnostic and therapeutic procedures and medications; and to prevent potential complications including chronic invalidism and drug dependence.

In such regard, the general recommendations outlined for somatoform disorders should be followed (see Table 54.3). The patient should be encouraged to see a single physician with an understanding of and, preferably, experience in treating

somatization disorder. This helps limit the number of unnecessary evaluations and treatments. Most clinicians advocate routine, brief, supportive office visits scheduled at regular intervals to provide reassurance and prevent patients from “needing to develop” symptoms to obtain care and attention. This “medical” management can well be provided by a primary care physician, perhaps with consultation with a psychiatrist. The study by Smith and colleagues (1986) demonstrated that such a regimen led to markedly decreased health care costs, with no apparent decrements in health or satisfaction of patients.

The foundations of treatment for this disorder are: 1) establishment of a strong physician–patient relationship or bond; 2) education of the patient regarding the nature of the psychiatric condition; and 3) provision of support and reassurance.

The first component, establishing a strong therapeutic bond, is important in the treatment of somatization disorder. Without it, it will be difficult for the patient to overcome skepticism deriving from past experience with many physicians and other therapists who “never seemed to help”. In addition, trust must be strong enough to withstand the stress of withholding unwarranted diagnostic and therapeutic procedures that the patient may feel are indicated. The cornerstone of establishing a therapeutic relationship is laid when the psychiatrist indicates an understanding of the patient’s pain and suffering, legitimizing the symptoms as real. This demonstrates a willingness to provide direct compassionate assistance. A full investigation of the medical and psychosocial histories, including extensive record review, will illustrate to patients the willingness of the psychiatrist to gain the fullest understanding of them and their plight. This also provides another opportunity to evaluate for the presence of an underlying medical disorder and to obtain a fuller picture of psychosocial difficulties that may relate temporally to somatic symptoms.

Only after the diagnosis has been clearly established and the therapeutic alliance is firmly in place can the psychiatrist confidently limit diagnostic evaluations and therapies to those performed on the basis of objective findings as opposed to merely subjective complaints. Of course, the psychiatrist should remain aware that patients with somatization disorder are still at risk for development of general medical illnesses so that a vigilant perspective should always be maintained.

The second component is education. This involves advising patients that they suffer from a “medically sanctioned illness”, that is, a condition recognized by the medical community and one about which a good deal is known. Ultimately, it may be possible to introduce the concept of somatization disorder, which can be described in a positive light (i.e., the patient does not have a progressive, deteriorating, or potentially fatal medical disorder, and the patient is not “going crazy” but has a condition by which many symptoms will be experienced). A realistic discussion of prognosis and treatment options can then follow.

The third component is reassurance. Patients with somatization disorder often have control and insecurity issues, which often come to the forefront when they perceive that a particular physical complaint is not being adequately addressed. Explicit reassurance should be given that the appropriate inquiries and investigations are being performed and that the possibility of an underlying physical disorder as the explanation for symptoms is being reasonably considered.

In time, it may be appropriate gradually to shift emphasis away from somatic symptoms to consideration of personal and interpersonal issues. In some patients, it may be appropriate to

posit a causal theory between somatic symptoms and “stress”, that is, that there may be a temporal association between symptoms and personal, interpersonal and even occupational problems. In patients for whom such “insight” is difficult, behavioral techniques may be useful.

Even following such therapeutic guidelines, patients with somatization disorder are often difficult to treat. Attention-seeking behavior, demands and manipulation are common, necessitating firm limits and careful attention to boundary issues. This, again, is a management rather than a curative approach. Thus, such behaviors should generally be dealt with directly rather than interpreted to the patient.

## Pharmacological and Other Somatic Treatments

No effective somatic treatments for somatization disorder itself have been identified.

Patients with somatization disorder may complain of anxiety and depression, suggesting readily treatable comorbid psychiatric disorders. As previously discussed, it is often difficult to distinguish actual comorbid conditions from aspects of somatoform disorder itself. Pharmacological interventions are likely to be helpful in the former but not in the latter. At times, such discrimination will be impossible, and an empirical trial of such treatments may be indicated. Patients with somatization disorder are often inconsistent and erratic in their use of medications. They will often report unusual side effects that may not be explained pharmacologically. This makes evaluation of treatment response difficult. In addition, drug dependence and suicide gestures and attempts are not uncommon.

## Undifferentiated Somatoform Disorder

### Definition

As defined in DSM-IV, this category includes disturbances of at least 6 months’ duration, with one or more unintentional, clinically significant, medically unexplained physical complaints (see Table 54.1). In a sense, it is a residual category, subsuming syndromes with somatic complaints that do not meet criteria for any of the “differentiated” somatoform disorders yet are not better accounted for by any other mental disorder. On the other hand, it is a less residual category than somatoform disorder NOS, in that the disturbance must last at least 6 months (see Figure 54.1). Virtually any unintentional, medically unexplained physical symptoms causing clinically significant distress or impairment can be considered. In effect, this category serves to capture syndromes that resemble somatization disorder but do not meet full criteria.

### Epidemiology

Some have argued that undifferentiated somatoform disorder is the most common somatoform disorder. Escobar and coworkers (1991), using an abridged somatization disorder construct requiring six somatic symptoms for women and four for men, reported that 11% of nonHispanic US whites and Hispanics, 15% of US blacks and 20% of Puerto Ricans in Puerto Rico fulfilled criteria. A preponderance of women was evident in all groups except the Puerto Rican sample (see Table 54.1). According to Escobar, such an abridged somatoform syndrome is 100 times more prevalent than a full somatoform syndrome.

## Diagnosis and Differential Diagnosis

In comparison to when the full criteria for the well-validated somatization disorder are met, exclusion of an as yet undiscovered general medical or substance-induced explanation for physical symptoms is far less certain when the less stringent criteria for undifferentiated somatoform disorder are met. Thus, the diagnosis of undifferentiated somatoform disorder should remain tentative, and new symptoms should be carefully investigated.

Because undifferentiated somatoform disorder represents somewhat of a residual category, the major diagnostic process, once occult general medical conditions and substance-induced explanations have been considered, is one of exclusion. As shown in Figure 54.1, whether the somatic symptoms are intentionally produced as in malingering and factitious disorder must be addressed. Here, motivation for external rewards (for malingering) and a pervasive intent to assume the sick role (for factitious disorder) must be assessed. The next consideration is whether the somatic symptoms are the manifestation of another psychiatric disorder. Anxiety and mood disorders commonly present with somatic symptoms; high rates of anxiety and major depressive disorders are reported in patients with somatic complaints attending family medicine clinics. Of course, undifferentiated somatoform disorder could be diagnosed in addition to one of these disorders, so long as the symptoms are not accounted for by the other psychiatric disorder. Crucial in this determination is whether the symptoms are present during periods in which the anxiety or mood disorders are not actively present.

Next, other somatoform disorders must be considered. In general, undifferentiated somatoform disorders are characterized by unexplained somatic complaints; the most common according to Escobar and coworkers (Escobar *et al.*, 1989) are female reproductive symptoms, excessive gas, abdominal pain, chest pain, joint pain, palpitations and fainting, rather than preoccupations or fears as in hypochondriasis or body dysmorphic disorder. However, a patient with some manifestations of these two disorders but not meeting full criteria could conceivably receive a diagnosis of undifferentiated somatoform disorder. An example is a patient with recurrent yet shifting hypochondriacal concerns that do respond to medical reassurance. If symptoms are restricted to those affecting the domains of sexual dysfunction, pain, or pseudoneurological symptoms, and the specific criteria for a sexual dysfunction, pain disorder and/or conversion disorder are met, the specific disorder or disorders should be diagnosed. If other types of symptoms or symptoms of more than one of these disorders have been present for at least 6 months, yet criteria for somatization disorder are not met, undifferentiated somatoform disorder should be diagnosed. By definition, undifferentiated somatoform disorder requires a duration of 6 months. If this criterion is not met, a diagnosis of somatoform disorder NOS should be considered.

Patients with an apparent undifferentiated somatoform disorder should be carefully evaluated for somatization disorder. Typically, patients with somatization disorder are inconsistent historians, at one evaluation reporting a large number of symptoms fulfilling criteria for the full syndrome, at another time endorsing fewer symptoms. In addition, with follow-up, additional symptoms may become evident, and criteria for somatization disorder will be satisfied. Patients with multiple somatic complaints not diagnosed with somatization disorder because of a reported onset later than 30 years of age may be inaccurately reporting a later age at onset. If the late age at onset is accurate, the patient should be carefully scrutinized for an occult general medical disorder.

In addition to the range of symptoms specified in the other somatoform disorders, patients complaining primarily of fatigue (chronic fatigue syndrome), bowel problems (irritable bowel syndrome), or multiple muscle aches/weakness (fibromyalgia) can be considered for undifferentiated somatoform disorder. Substantial controversy exists regarding the etiology of such syndromes. Even if an explanation on the basis of a known pathophysiological mechanism cannot be established, many argue that the syndromes should be considered general medical conditions. However, for the time being, these syndromes could be considered in a highly tentative manner under the undifferentiated somatoform disorder rubric. Careful reconsideration of the psychiatric label should be undertaken at regular intervals if the symptoms persist. The psychiatrist should remain ever vigilant to the emergence of another general medical or psychiatric condition. When patients are diagnosed with chronic fatigue syndrome, careful evaluation procedures are recommended.

## Course, Natural History and Prognosis

As shown in Table 54.1, it appears that the course and prognosis of undifferentiated somatoform disorder are highly variable. This is not surprising, because the definition of this disorder allows a great deal of heterogeneity.

## Treatment

In view of the broad inclusion and minimal exclusion criteria for undifferentiated somatoform disorder, it is difficult to make treatment recommendations beyond the generic guidelines outlined for the somatoform disorders in general. More definitive recommendations await a more extensive empirical database. A substantial proportion of patients with undifferentiated somatoform disorders improve or recover with no formal therapy. However, appropriate psychotherapy and pharmacological intervention may accelerate the process.

Some recommendations for patients with symptoms of headache, fibromyalgia, and chronic fatigue syndrome, conditions that some would include under undifferentiated somatoform disorder. Generally recommended are brief psychotherapy of a supportive and educative nature. As with somatization disorder, the physician–patient relationship is of great importance. Judicious use of pharmacotherapy may also be of benefit, particularly if the somatoform syndrome is intertwined with an anxiety or depressive syndrome. Here, usual antianxiety and antidepressant medications are recommended. Patients with unexplained pains may benefit from pain management strategies as outlined in the pain disorder section.

## Conversion Disorder

### Definition

As defined in DSM-IV, conversion disorders are characterized by symptoms or deficits affecting voluntary motor or sensory function that suggest yet are not fully explained by a neurological or other general medical condition or the direct effects of a substance (see Table 54.1). The diagnosis is not made if the presentation is explained as a culturally sanctioned behavior or experience, such as bizarre behaviors resembling a seizure during a religious ceremony. Symptoms are not intentionally produced or feigned, that is, the person does not consciously contrive a symptom for external rewards, as in malingering, or for the intrapsychic rewards of assuming the sick role, as in factitious disorder.

Four subtypes with specific examples of symptoms are defined: with motor symptom or deficit (e.g., impaired coordination or balance, paralysis or localized weakness, difficulty swallowing or lump in throat, aphonia and urinary retention); with sensory symptom or deficit (e.g., loss of touch or pain sensation, double vision, blindness, deafness and hallucinations); with seizures or convulsions; and with mixed presentation (i.e., has symptoms of more than one of the other subtypes). The list of examples is also contained among the pseudoneurological symptoms listed in the diagnostic criteria for somatization disorder. Although determination is highly subjective and of questionable reliability and validity, association with psychological factors is required.

Whereas conversion symptoms are among the most dramatic symptoms, somatization disorder is characterized by multiple unexplained symptoms in many organ systems; in conversion disorder, even a single symptom affecting voluntary motor or sensory function may suffice. Such nosological inconsistencies have resulted in a great deal of confusion, both in research and in clinical practice.

The relationship of conversion disorder to the dissociative disorders warrants comment. Long recognized as related, they were subsumed as subtypes of hysterical neurosis in DSM-II: conversion involving voluntary motor and sensory functioning, and dissociation affecting memory and identity. DSM-IV-TR text acknowledges the symptomatic, epidemiological and probable pathogenetic similarities between conversion and dissociative symptoms. Such symptoms have been attributed to similar psychological mechanisms, and they often occur in the same individual, sometimes during the same episode of illness. DSM-IV-TR does suggest that patients with conversion disorder be carefully scrutinized for dissociative symptoms.

Hallucinations are included among the sensory nervous symptoms in DSM-IV. The concept of conversion hallucinations has a long tradition and its inclusion as a conversion symptom was supported by the somatization disorder field trial, in which one-third of a large sample of nonpsychotic women with evidence of unexplained somatic complaints reported a history of hallucinations. Among the 40% who had symptoms that met criteria for somatization disorder, more than half reported hallucinations. Women with other conversion symptoms were more likely to report hallucinations than were those with no other conversion symptoms.

In general, conversion hallucinations (referred to by some as pseudohallucinations) differ in several ways from those in psychotic conditions. Conversion hallucinations typically occur in the absence of other psychotic symptoms, insight that the hallucinations are not real may be retained, and they often involve more than one sensory modality, whereas hallucinations in psychoses generally involve a single sensory modality, usually auditory. Conversion hallucinations also often have a naive, fantastic, or childish content, as if they are part of a fairy tale, and are described eagerly, sometimes even provocatively, as an interesting story (e.g., "I was driving downtown and a flying saucer flew over my car and I saw you [the psychiatrist] in a window and I heard your voice calling to me"). They often bear some understandable psychological purpose, although the patient may not be aware of intent. In the example given, the "sighting" was reported at the time that no further sessions were scheduled.

## Epidemiology

Vastly different estimates of the incidence and prevalence of conversion disorder have been reported. Much of this difference

may be attributable to methodological differences from study to study, including the changing definition of conversion disorder, ascertainment procedures and populations studied. General population estimates have generally been derived indirectly, extrapolating from clinic or hospital samples.

Conversion symptoms themselves may be common; it was reported that 25% of normal postpartum and medically ill women had a history of conversion symptoms at some time during their life (Cloninger, 1993), yet in some instances, there may have been no resulting clinically significant distress or impairment. Lifetime prevalence rates of treated conversion symptoms in general populations are much more modest, ranging from 11 to 500 per 100 000 (see Table 54.1). About 5 to 24% of psychiatric outpatients, 5 to 14% of general hospital patients and 1 to 3% of outpatient psychiatric referrals reported a history of conversion symptoms, although their current treatment was not necessarily for conversion symptoms. A rate of nearly 4% of outpatient neurological referrals and 1% of neurological admissions (Ziegler and Paul, 1954) involved conversion disorder. In virtually all studies, an excess (to the extent of 2:1 to 10:1) of women reported conversion symptoms relative to men. In part, this may relate to the simple fact that women seek medical evaluation more often than men do, but it is unlikely that this fully accounts for the sex difference. There is a predilection for lower socioeconomic status; less educated, less psychologically sophisticated and rural populations are overrepresented. Consistent with this, higher rates (nearly 10%) of outpatient psychiatric referrals are for conversion symptoms in "developing" countries. As countries develop, there may be a declining incidence in time, which may relate to increasing levels of education, and medical and psychological sophistication.

## Etiology and Pathophysiology

The term conversion implies etiology because it is derived from a hypothesized mechanism of converting psychological conflicts into somatic symptoms, often symbolically (e.g., repressed rage is converted into paralysis of an arm that could be used to strike). A number of psychological factors have been promoted as part of such an etiological process, but evidence for their essential involvement is scanty at best. Theoretically, anxiety is reduced by keeping an internal conflict or need out of awareness by symbolic expression of an unconscious wish as a conversion symptom (primary gain). However, individuals with active conversion symptoms often continue to show marked anxiety, especially on psychological tests. Symbolism is infrequently evident, and its evaluation involves highly inferential and unreliable judgments. Overinterpretation of symbolism in persons with occult medical disorder may contribute to misdiagnosis. Secondary gain, whereby conversion symptoms allow avoidance of noxious activities or the procurement of otherwise unavailable support, may also occur in persons with medical conditions, who may take advantage of such benefits.

Individuals with conversion disorder may show a lack of concern out of keeping with the nature or implications of the symptom (the so-called *la belle indifférence*). However, indifference to symptoms is not invariably present in conversion disorder and is also seen in individuals with general medical conditions, on the basis of denial or stoicism. Conversion symptoms may present in a dramatic or histrionic fashion and may be highly suggestible. A dramatic presentation is also seen in distressed individuals with medical conditions. Even symptoms based on an underlying medical condition may respond to suggestion, at least

temporarily. In many instances, preexisting personality disorders (in particular histrionic personality disorder) are evident and may predispose to conversion disorder. Persons with conversion disorder may often have a history of disturbed sexuality many (one-third) report a history of sexual abuse, especially incestuous.

If not directly etiological, many psychosocial factors have been suggested as predisposing to conversion disorder. At a minimum, many persons with conversion disorder are in chaotic domestic and occupational situations. As previously mentioned, individuals from rural backgrounds and those who are psychologically and medically unsophisticated appear to be predisposed, as are those with existing neurological disorders. In the last case, a tendency to conversion symptoms has been attributed to “modeling”, that is, patients with neurological disorders are likely to have observed in others, as well as in themselves, various neurological symptoms, which they then may simulate as conversion symptoms.

Available data suggest a genetic contribution. Conversion symptoms are more frequent in relatives of individuals with conversion disorder. In a nonblinded study, rates of conversion disorder were found to be elevated tenfold in female (fivefold in male) relatives of patients with conversion disorder. Nongenetic familial factors, particularly incestuous childhood sexual abuse, may also be involved in some. Nearly one-third of individuals with medically unexplained seizures reported childhood sexual abuse, compared with less than 10% of those with complex partial epilepsy.

### Diagnosis and Differential Diagnosis

As shown in Figure 54.1, the first consideration is whether the conversion symptoms are explained on the basis of a general medical condition. Because conversion symptoms by definition affect voluntary motor or sensory function (thus pseudoneurological), neurological conditions are usually suggested, but other general medical conditions may be implicated as well. Neurologists are generally first consulted by primary care physicians for conversion symptoms; psychiatrists become involved only after neurological or general medical conditions have been reasonably excluded. Nonetheless, psychiatrists should have a good appreciation of the process of making such exclusions. More than 13% of actual neurological cases are diagnosed as functional before the elucidation of a neurological illness (Perkin, 1989). Even after referral, vigilance for an emerging general medical condition should continue. A significant percentage – 21 to 50% – of patients diagnosed with conversion symptoms are found to have neurological illness on follow-up.

Apparent conversion symptoms mandate a thorough evaluation for possible underlying physical explanation. This evaluation must include a thorough medical history; physical (especially neurological) examination; and radiographical, blood, urine and other tests as clinically indicated. Reliance should not be placed on determination of whether psychological factors explain the symptom. Such determinations are unreliable except, perhaps, in cases in which there is a clear and immediate temporal relationship between a psychosocial stressor and the symptom, or in cases in which similar situations led to conversion symptoms in the past. A history of previous conversion or other unexplained symptoms, particularly if somatization disorder is diagnosable, lessens the probability that an occult medical condition will be identified. Although conversion symptoms may occur at any age, symptoms are most often first manifested in late adolescence or early adulthood. Conversion symptoms first occurring in middle

age or later should increase suspicion of an occult physical illness.

Symptoms of many neurological illnesses may appear inconsistent with known neurophysiological or neuropathological processes, suggesting conversion and posing diagnostic problems. These illnesses include multiple sclerosis, in which blindness due to optic neuritis may initially present with normal fundi; myasthenia gravis, periodic paralysis, myoglobinuric myopathy, polymyositis and other acquired myopathies, in which marked weakness in the presence of normal deep tendon reflexes may occur; and Guillain-Barré syndrome, in which early extremity weakness may be inconsistent.

Complicating diagnosis is the fact that physical illness and conversion or other apparent psychiatric overlay are not mutually exclusive. Patients with physical illnesses that are incapacitating and frightening may appear to be exaggerating symptoms. Also, patients with actual neurological illness will also have “pseudo” symptoms. For example, patients with actual seizures may have pseudoseizures as well. Considering these observations, psychiatrists should avoid a rash and hasty diagnosis of conversion disorder when faced with symptoms that are difficult to interpret.

As with the other somatoform disorders, symptoms of conversion disorder are not intentionally produced, in distinction to malingering or factitious disorder. To a large part, this determination is based on assessment of the motivation for external rewards (as in malingering) or for the assumption of the sick role (as in factitious disorder). The setting is often an important consideration. For example, conversion-like symptoms are frequent in military or forensic settings, in which obvious potential rewards make malingering a serious consideration.

A diagnosis of conversion disorder should not be made if a conversion symptom is fully accounted for by a mood disorder or by schizophrenia (e.g., disordered motility as part of a catatonic syndrome of a psychotic mood disorder or schizophrenia). If the symptom is a hallucination, it must be remembered that the descriptors differentiating conversion from psychotic hallucinations should be seen only as rules of thumb. Differentiation should be based on a comprehensive assessment of the illness. In the case of hallucinations, post traumatic stress disorder and dissociative identity disorder (multiple personality disorder) must also be excluded. If the conversion symptom cannot be fully accounted for by the other psychiatric illness, conversion disorder should be diagnosed in addition to the other disorder if it meets criteria (e.g., an episode of unexplained blindness in a patient with a major depressive episode). In hypochondriasis, neurological illness may be feared (“I have strange feelings in my head; it must be a brain tumor”), but the focus here is on preoccupation with fear of having the illness rather than on the symptom itself as in conversion disorder.

By definition, if symptoms are limited to sexual dysfunction or pain, conversion disorder is not diagnosed. Criteria for somatization disorder require multiple symptoms in multiple organ systems and functions, including symptoms affecting motor or sensory function (conversion symptoms) or memory or identity (dissociative symptoms). Thus, it would be superfluous to make an additional diagnosis of conversion disorder in the context of a somatization disorder.

A last consideration is whether the symptom is a culturally sanctioned behavior or experience. Conversion disorder should not be diagnosed if symptoms are clearly sanctioned or even expected, are appropriate to the sociocultural context, and are not associated with distress or impairment. Seizure-like episodes,

such as those that occur in conjunction with certain religious ceremonies, and culturally expected responses, such as women “swooning” in response to excitement in Victorian times, qualify as examples of these symptoms.

### Course, Natural History and Prognosis

Age at onset is typically from late childhood to early adulthood. Onset is rare before the age of 10 years and after 35 years, but cases with an onset as late as the ninth decade have been reported. The likelihood of a neurological or other medical condition is increased when the age at onset is in middle or late life. Development is generally acute, but symptoms may develop gradually as well. The course of individual conversion symptoms is generally short; half to nearly all symptoms remit by the time of hospital discharge. However, symptoms relapse within 1 year in one-fifth to one-fourth of patients. Typically, one symptom is present in a single episode, but multiple symptoms are generally involved longitudinally. Factors associated with good prognosis include acute onset, clearly identifiable precipitants, a short interval between onset and institution of treatment, and good intelligence. Conversion blindness, aphonia and paralysis are associated with relatively good prognosis, whereas patients with seizures and tremor do more poorly. Some patients diagnosed initially with conversion disorder will have a presentation that meets criteria for somatization disorder when they are observed longitudinally.

Individual conversion symptoms are generally self-limited and do not lead to physical changes or disabilities. Rarely, physical sequelae such as atrophy may occur. Marital and occupational problems are not as frequent in patients with conversion disorder as they are in those with somatization disorder.

### Treatment

Reports of the treatment of conversion disorder date from those of Charcot, which generally involved symptom removal by suggestion or hypnosis. Breuer and Freud, using such psychoanalytic techniques as free association and abreaction of repressed affects, had more ambitious objectives in their treatment of Anna O, including the resolution of unconscious conflicts. To date, whereas some recommend long-term, intensive, insight-oriented psychodynamic psychotherapy in pursuit of such goals, most psychiatrists advocate a more pragmatic approach, especially for acute cases.

Therapeutic approaches vary according to whether the conversion symptom is acute or chronic. Whichever the case, direct confrontation is not recommended. Such a communication may cause a patient to feel even more isolated. An undiscovered physical illness may also underlie the presentation.

In acute cases, the most frequent initial aim is removal of the symptom. The pressure behind accomplishing this depends on the distress and disability associated with the symptom (Ford, 1995). If the patient is not in great distress and the need to regain function is not immediate, a conservative approach of reassurance, relaxation and suggestion is recommended. With this technique, the patient is reassured that on the basis of evaluation the symptom will disappear completely and, in fact, is already beginning to do so. The patient can then be encouraged to ventilate about recent events and feelings, without any causal relationships being suggested. This is in contrast to attempts at abreaction, by which repressed material, particularly regarding a painful experience or a conflict, is brought back to consciousness.

If symptoms do not resolve with such conservative approaches, a number of other techniques for symptom resolu-

tion may be instituted. It does appear that prompt resolution of conversion symptoms is important because the duration of conversion symptoms is associated with a greater risk of recurrence and chronic disability. The other techniques include narcoanalysis (e.g., amobarbital interview), hypnosis and behavioral therapy. In narcoanalysis, amobarbital or another sedative-hypnotic medication such as lorazepam is given intravenously to the point of drowsiness. Sometimes this is followed by administration of a stimulant medication, such as methamphetamine. The patient is then encouraged to discuss stressors and conflicts. This technique may be effective acutely, leading to at least temporary symptom relief as well as expansion of the information known about the patient. This technique has not been shown to be especially effective with more chronic conversion symptoms. In hypnotherapy, symptoms may be removed with the suggestion that the symptoms will gradually improve posthypnotically. Information regarding stressors and conflicts may be explored as well. Formal behavioral therapy, including relaxation training and even aversive therapy, has been proposed and reported by some to be effective. In addition, simply manipulating the environment to interrupt reinforcement of the conversion symptom is recommended.

Anecdotally, somatic treatments including phenothiazines, lithium and electroconvulsive therapy have been reported effective. However, in many cases, this may be attributable to simple suggestion. In other cases, resolution of another psychiatric disorder, such as a psychotic disorder or a mood disorder, may have led to the symptom's removal. It should be evident from the preceding discussion that in acute conversion disorders, it may be not the particular technique but the influence of suggestion that is specifically associated with symptom relief. It is likely that in various rituals, such as exorcism and other religious ceremonies, immediate “cures” are based on suggestion. Suggestion seems to play a major role in the resolution of “mass hysteria”, in which a group of individuals who believe that they have been exposed to some noxious influence such as a “toxin” or even a “spell” experience similar symptoms that do not appear to have any organic basis. Often, the epidemic can be contained if affected individuals are segregated. Simple announcements that no such factor has been identified and that symptoms experienced by the group have been linked to mass hysteria have been effective.

Thus far, this discussion has centered on acute treatment primarily for symptom removal. Longer-term approaches include strategies previously discussed for somatization disorder – a pragmatic, conservative approach involving support and exploration of various conflict areas, particularly of interpersonal relationships. A certain degree of insight may be attained, at least in terms of appreciating relationships between various conflicts and stressors and the development of symptoms. Others advocate long-term, intensive, insight-oriented dynamic psychotherapy.

## Pain Disorder

### Definition

As defined in DSM-IV, the essential feature of pain disorder is pain with which psychological factors “have an important role in the onset, severity, exacerbation, or maintenance” (see Table 54.1). Pain disorder is subtyped as pain disorder associated with psychological factors and pain disorder associated with both psychological factors and a general medical condition. The third possibility, pain disorder associated with a general medical condition, is not considered to be a mental disorder, because the requirement is not met

that psychological factors play an important role. Thus, the DSM-IV concept of pain disorder allows the psychiatrist greater specificity in considering etiological factors and a more useful schema for differential diagnosis. The focus is placed on the presence of psychological factors rather than the exasperating determination of whether the pain is attributable to organic disease.

In addition, DSM-IV requires that pain be the predominant focus of the clinical presentation and that it cause clinically significant distress or impairment. Specifiers of acute (duration of less than 6 months) and chronic (duration of 6 months or longer) are provided.

## Epidemiology

As to pain itself, some empirical studies suggest that it is common. Perhaps as indirect evidence of this is the proliferation of pain clinics nationally. Of course, many patients attending these clinics fall into the category of pain disorder associated with a general medical condition, but undoubtedly, some also have involvement of psychological factors as required for a diagnosis of pain disorder as a mental disorder. The same would apply to the 10 to 15% of adults in the USA in any given year who have work disability because of back pain. Pain has been found to be a predominant symptom in 75% of consecutive general medical patients, with 75% of these (thus 50% overall) judged as having no identifiable physical cause. No apparent physical basis is found in 40 to 50% of patients presenting with nonspecific abdominal pain. At least half of such patients show major personality problems in addition, with such aberrations associated with poor outcome. Whereas primary care and other nonpsychiatric physicians probably see most pain patients, 38% of psychiatric inpatient admissions and 18% attending a psychiatric outpatient clinic report pain as a significant problem.

## Etiology and Pathophysiology

In considering the etiology of pain disorder, possible mechanisms of pain itself must be considered. The definition of pain sanctioned by the International Association for the Study of Pain Subcommittee on Taxonomy is “an unpleasant sensory and emotional experience associated with actual or potential tissue damage”. It goes on to acknowledge that pain is not simply “activity induced in the nociceptor and nociceptive pathways by a noxious stimulus” but “is always a psychological state...”. Thus, it accepts the hypothesis that pain involves psychological as well as physical factors.

Many theories of the etiology and pathophysiology of pain involving both biological and psychological factors have been proposed. It is known that a neuropathway descends from the cerebral cortex and medulla, which inhibits the firing of pain transmission neurons when it is activated. This system is apparently mediated by the endogenous opiate-like compounds, endorphins and by serotonin. Indeed, metabolites of both of these neurotransmitters may be reduced in the cerebrospinal fluid of chronic pain patients.

The gate control theory links biological and psychological factors. It hypothesizes a gate-like mechanism involving the dorsal horn of the spinal cord by which large A-beta fibers as well as small A-delta and C fibers carry impulses from the periphery to the substantia gelatinosa and T-cells in the spinal cord. Activation of the large fibers inhibits, whereas activation of the small fibers facilitates transmission to the T-cells. In addition, impulses descending from the brain, influenced by cognitive processes, may either inhibit or facilitate transmission of pain impulses. Such a

mechanism may explain how psychological processes affect pain perception.

By definition, both pain disorder associated with psychological factors and pain disorder associated with both psychological factors and a general medical condition involve psychological factors. In the case of the former, it is presumed that there is little contribution from general medical conditions; in the latter, both physical and psychological factors contribute. A plethora of not necessarily mutually exclusive theories has been proposed to explain how this takes place.

Psychological constructs involving learning theories, both operant and classical conditioning, may apply. In operant paradigms, pain-related complaints are reinforced by increased attention, relief from obligations, monetary compensation and the pleasurable effects of analgesics. In classical conditioning, originally neutral settings such as a workplace or bedroom where pain was experienced come to evoke pain-related behavior. Social and cultural attitudes may also have effects. Patients with unexplained pain are more likely than others to have close relatives with chronic pain. Although findings have differed from study to study, ethnic differences may also have effects, such as greater pain tolerance in Irish and Anglo-Saxon groups in comparison to southern Mediterranean groups.

## Diagnosis and Differential Diagnosis

As shown in Figure 54.1, the diagnostic approach begins with assessment of whether the presentation is fully explained by a general medical condition. If not, it may be assumed that psychological factors play a major role. If it is judged that psychological factors do not play a major role, a diagnosis of pain disorder associated with a general medical condition may apply. As previously mentioned, this does not have a mental disorder code.

If psychological factors are involved, the first consideration is whether the pain is feigned. If so, either malingering or factitious disorder is diagnosed, depending on whether external incentives or assumption of the sick role is the motivation. Evidence of malingering includes consideration of external rewards relative to the chronology of the development and maintenance of the pain. In factitious disorder, a pattern of successive hospitalizations and medical evaluations is evident. Inconsistency in presentation, lack of correspondence to known anatomical pathways or disease patterns, and lack of associated sensory or motor function changes suggest malingering or factitious disorder, but pain disorder associated with psychological factors may show this pattern as well. The key question is whether the patient is experiencing rather than feigning the pain.

Determination of the relative contributions of psychological and general medical factors is difficult. Of course, careful assessment of the nature and severity of the potential underlying medical condition and the nature and degree of pain that would be expected should be made. Traditionally, the so-called conversion V or neurotic triad (consisting of elevation of the hypochondriasis and hysteria scales with a lower score on the depression scale) on the Minnesota Multiphasic Personality Inventory has been purported to indicate emotional indifference to the somatic concerns as might be expected if the symptom is attributable to psychological factors rather than organic disease. However, evidence indicates that this configuration may also occur as an adjustment to chronic illness.

A diagnosis of pain disorder requires that the pain be of sufficient severity to warrant clinical attention, that is, it causes clinically significant distress or impairment. A number of

instruments have been developed to assess the degree of distress associated with the pain. Such measures include the numerical rating scale and visual analog scale as described by Scott and Huskisson (1976), the McGill Pain Questionnaire and the West Haven-Yale Multidimensional Pain Inventory (Osterweis *et al.*, 1987).

DSM-IV includes a number of exclusionary conventions. By definition, if pain is restricted to pain with sexual intercourse, the sexual disorder, dyspareunia, not pain disorder, is diagnosed. If pain occurs in the context of a mood, anxiety, or psychotic disorder, pain disorder is diagnosed only if it is an independent focus of clinical attention and is not better accounted for by the other disorder, a highly subjective judgment.

If pain occurs exclusively during the course of somatization disorder, pain disorder is not diagnosed because pain symptoms are part of the criteria for somatization disorder and are thereby subsumed under the more comprehensive diagnosis. Because somatization disorder is virtually a lifelong condition, this exclusion generally applies in someone with somatization disorder by history. Important here is that, in addition to pain, somatization disorder involves multiple symptoms of the gastrointestinal system, the reproductive system, and the central and peripheral nervous systems; whereas in pain disorder, the focus is on pain symptoms only.

Specification of acute versus chronic pain disorder on the basis of whether the duration is less than or greater than 6 months is an important distinction. Whereas acute pain, in most cases, will be linked with physical disorders, when pain remains unexplained after 6 months, psychological factors are often involved (Cloninger, 1993). However, the psychiatrist must remember that a significant minority (in one study 19%) of patients with chronic pain of no apparent physical origin will ultimately be found to have occult organic disease (Cloninger, 1993).

In patients with unexplained pelvic pain, psychiatrists should be warned about cavalier conclusions regarding the absence of physical disease. With laparoscopy, a high frequency of occult organic disease has been identified in several studies. Thus, laparoscopy may be indicated in patients with pelvic pain. Electromyography may be helpful in distinguishing muscle contraction headaches. Failure to show coronary artery spasm with provocative procedures and failure to respond to nitroglycerin may be useful in distinguishing patients with pain disorder from those in whom the pain is attributable to coronary artery disease.

### Course, Natural History and Prognosis

Given the heterogeneity of conditions subsumed under the pain disorder rubric, course and prognosis vary widely. The subtyping at 6 months is of significance. The prognosis for total remission is good for pain disorders of less than 6 months' duration. However, for syndromes of greater than 6 months' duration, chronicity is common. The site of the pain may be another factor. Certain anatomically differentiated pain syndromes can be distinguished, and each has its own characteristic pattern. These include syndromes characterized primarily by headache, facial pain, chest pain, abdominal pain and pelvic pain. In such syndromes, symptoms tend to be recurrent, with relapses occurring in association with stress. A high rate of depression has been observed among patients with unexplained facial pain. Facial pain is often alleviated by antidepressant medication. This effect has been observed in both patients with depressive symptoms and those without.

Other factors affecting course and prognosis include associated psychiatric illness and external reinforcement. Employment at the outset of treatment predicts improvement. Chronicity is more likely in the presence of certain personality diagnoses or traits, such as pronounced passivity and dependency. External reinforcement includes litigation involving potential financial compensation or disability. Continuation of the pain disorder may prove more lucrative than its resolution and return to work. Level of activity, which is generally associated with improvement, is discouraged by fears of losing compensation. Thus, although outright malingering may be rare pain behaviors are often reinforced and maintained. Habituation with addictive drugs is associated with greater chronicity.

### Treatment

An overriding guideline is that the psychiatrist does not do anything that will actually perpetuate and even promote "pain-related behavior". Thus, a major goal is to encourage activity. Other guidelines include avoidance of sedative-antianxiety drugs, judicious use of analgesics on a fixed interval schedule so as not to reinforce pain-related behaviors, avoidance of opioids and consideration of alternative treatment approaches such as relaxation therapy. Depression should be treated with appropriate antidepressant drugs, not sedative-antianxiety medications. The difficulties in managing pain disorder patients have resulted in the establishment of many clinics and programs especially designed for pain. Referral to such a service may be indicated. Intervention should best be provided early in the course of the syndrome, before pain-related behaviors become entrenched. Once continuing disability compensation is established, therapeutic efforts become much more difficult.

The preceding general guidelines apply whether or not a general medical basis for the pain is involved. Of course, if only pain disorder associated with psychological factors is involved, psychological management will be the mainstay. For patients with pain associated with general medical factors (not a mental disorder) in which psychological factors do not play a major role, efforts should be made to prevent the development of psychological problems in response to the resulting distress, isolation and loss of function, and iatrogenic effects such as exposure to potentially addicting drugs.

In acute pain, the major goal is to relieve the pain. Thus, pharmacological agents generally play a more significant role than in chronic syndromes. Whereas the risk of developing opioid dependence appears to be surprisingly low (four per 12000) among patients without a prior history of dependence, nonopioid agents should be used whenever they can be expected to be effective. As discussed for chronic pain, these include particularly acetaminophen and the nonsteroidal antiinflammatory drugs (NSAIDs), of which aspirin is considered a member. Even if an opioid analgesic is employed, these drugs should be continued as adjuncts; often, they lessen the required dose of the opioid.

It is with the chronic syndromes that proper management is crucial to ease distress and prevent the development of additional problems. As advised by King (1994), the overriding goal is to maintain function, because total relief of the pain may not be possible. Physical and occupational therapy may play a major role. There may be resistance to the involvement of a psychiatrist as an indication that the pain is not seen as real. Such issues must first be resolved. An attempt should be made to ascertain the roles that psychological and general medical factors play in the maintenance of the pain.

A large variety of psychotherapies including individual, group and family strategies have been employed. Two techniques that warrant special attention are operant conditioning and cognitive-behavioral therapy. In operant conditioning, the pattern of reinforcement of pain behavior by medication, attention and excuse from responsibilities is to be interrupted and reinforcement shifted to usual daily activities. To assess the role of operant conditioning, it may be necessary to have patients keep a diary and to interview family members to identify any conditioning patterns. In cognitive-behavioral therapies, the goal is the identification and correction of attitudes, beliefs and expectations. Biofeedback and relaxation techniques may be used to minimize muscle tension that may aggravate if not cause pain. Hypnosis may also be used to achieve muscle relaxation and to help the patient “dissociate” from the pain.

Pharmacological intervention may also be useful in chronic syndromes. Effort should be made to avoid opioids if possible. Agents to be tried first include antidepressants, acetaminophen, NSAIDs (including aspirin) and anticonvulsants such as carbamazepine. Antidepressants seem particularly useful for neuropathic pain, headache, facial pain, fibrositis and arthritis (including rheumatoid arthritis). Analgesic action seems to be independent of antidepressant effects. Most work has been done with the tricyclic antidepressants; other classes, such as the monoamine oxidase inhibitors (MAOIs) and the selective serotonin reuptake inhibitors (SSRIs), may be effective as well. Although it was thought that the action is mediated by serotonergic effects, agents such as desipramine with predominantly noradrenergic activity seem to be effective as well. NSAIDs, of which aspirin, ibuprofen, naproxen and piroxicam are commonly used examples, may alleviate pain through inhibition of prostaglandin synthesis. Unfortunately, this effect may also contribute to side effects, such as aggravation of peptic or duodenal ulcers and interference with renal function. For patients unable to tolerate NSAIDs, acetaminophen should be tried.

If opioid analgesics are used, it is recommended that use be tied to objectives such as increasing level of activity rather than simply pain alleviation. Milder opioids, such as codeine, oxycodone and hydrocodone, should be implemented first. The once widely used propoxyphene has less analgesic effect than these drugs; it is not devoid of abuse potential as once thought and is not recommended. Pure opioid agonists such as morphine, methadone and hydromorphone should be tried next. Meperidine, also in this class, is contraindicated for prolonged use because accumulation of the toxic metabolite, normeperidine, a cerebral irritant, may result in anxiety, psychosis, or seizures. Meperidine may also have a lethal interaction with MAOIs. There are no advantages to mixed opioid agonist-antagonists. The commonly used pentazocine should be avoided because it has abuse potential and psychotomimetic effects in some patients. It remains to be seen whether newer agents (buprenorphine, butorphanol and nalbuphine) have lower abuse potential as claimed. Above all, psychiatrists should be judicious in the use of opioid analgesics, considering not only their abuse potential but their large number of side effects including constipation, nausea and vomiting, excessive sedation and, in higher doses, respiratory depression that may be fatal.

In addition to pharmacotherapy, a number of other “physical” techniques have been used, such as acupuncture and transcutaneous electrical nerve stimulation. These carry little risk of adverse effects or aggravation of the pain disorder. Other procedures such as trigger point injections, nerve blocks and surgical

ablation may be recommended if specifically indicated by an underlying general medical disorder.

As can be seen in the preceding discussion, the management of pain disorders is not monomodal. A great number of psychological and physical factors and interventions may be considered.

## Hypochondriasis

### Definition

The essential feature in hypochondriasis is preoccupation with fears or the idea of having a serious disease based on the “misinterpretation of bodily symptoms”. (see Table 54.1). This is in contrast to somatization disorder, conversion disorder and pain disorder, in which the symptoms themselves are the predominant focus. There was some debate in the development of DSM-IV as to whether it was necessary that a body complaint be present. On the basis of empirical data, however, it was determined that this requirement was a valid one and helped to distinguish the “disease conviction” of hypochondriasis from “disease fear” as in phobic disorder. Bodily symptoms may be interpreted broadly to include misinterpretation of normal body functions. In hypochondriasis, the preoccupation persists despite reassurance from physicians and the accumulation of evidence to the contrary. As in the other somatoform disorders, symptoms must result in clinically significant distress or impairment in important areas of functioning. The duration must be at least 6 months. Hypochondriasis is not diagnosed if the hypochondriacal concerns are better accounted for by another psychiatric disorder, such as major depressive episodes or various psychotic disorders with somatic delusions.

Throughout the modern period, there has been controversy as to whether hypochondriasis represented an independent, discrete disease entity. Some maintain that hypochondriasis is virtually always secondary to another psychiatric disorder, usually depression. A number of studies suggested that of the many patients with hypochondriacal complaints, few meet criteria for the full diagnosis. Moreover, the lack of bimodality to the complaints suggests a continuum rather than a discrete entity.

In the development of DSM-IV, owing to observations that the disease conviction resembled disease phobia or the incorrigible ideas of obsessive-compulsive disorder, placement of hypochondriasis with the anxiety disorders was considered. Similarly, a case can be made that disease conviction is on a continuum with somatic delusions of disease, suggesting inclusion with the delusional disorders. In the end, such considerations were resolved by keeping hypochondriasis with the somatoform disorders, defining it in terms of an idea that one already has a particular illness rather than fears of acquiring one to distinguish it from a disease phobia, and by excluding cases in which the idea was of delusional proportions to differentiate hypochondriasis from delusional disorder, somatic type.

### Epidemiology

Some degree of preoccupation with disease is apparently common. As reviewed by Kellner (1991), 10 to 20% of “normal” and 45% of “neurotic” persons have intermittent unfounded worries about illness, with 9% of patients doubting reassurances given by physicians. Kellner also estimated that 50% of all patients attending physicians’ offices “suffer either primary hypochondriacal symptoms or have minor somatic disorders with hypochondriacal

overlay”. How these relate to hypochondriasis as a disorder is difficult to assess because these estimates do not appear to distinguish between a focus on the symptoms themselves (as in somatization disorder) and preoccupation with the implications of the symptoms (as in hypochondriasis). The Epidemiological Catchment Area study (Robins *et al.*, 1984) did not consider hypochondriasis. A 1965 study reported prevalence figures ranging from 3 to 13% in different cultures, but it is not clear whether this represents a syndrome comparable to the current definition or just hypochondriacal symptoms. As already noted, many patients manifest some hypochondriacal symptoms as part of other psychiatric disorders, and others have transient hypochondriacal symptoms in response to stresses such as serious physical illness yet never fulfill the inclusion criteria for DSM-IV hypochondriasis. Assessment of the incidence and prevalence of hypochondriasis undoubtedly requires study of general or primary care rather than psychiatric populations, because patients with hypochondriasis are convinced that they suffer from some physical illness. To date, study of such populations suggests that 4 to 9% of patients in general medical settings suffer from hypochondriasis.

It does appear that hypochondriasis is equally common in males and females.

### Etiology and Pathophysiology

Until recently, psychoanalytic hypotheses of etiology predominated. Freud hypothesized that hypochondriasis represented “the return of object libido onto the ego with cathexis of the body” (Viederman, 1985). Subsequently, the cathexis to the body hypothesis was elaborated on to include interpretations involving disturbed object relations – displacement of repressed hostility to the body to communicate anger indirectly to others. Dynamic mechanisms involving masochism, guilt, conflicted dependency needs and a need to suffer and be loved at the same time have also been suggested (Stoudemire, 1988). The presence of such “narcissistic” mechanisms has been suggested as the reason that patients with hypochondriasis were “unanalyzable”. Other psychological theories involve defense against feelings of low self-esteem and inadequacy, perceptual and cognitive abnormalities, and operant conditioning involving reinforcement for assumption of the sick role.

Biological theories have been suggested as well. Hypochondriacal ideas have been attributed to a hypervigilance to insult, including overperception of physical problems. This has been posited in particular in reference to hypochondriasis as an aspect of depression or anxiety disorders. Hypochondriasis has been included by some in the posited obsessive–compulsive spectrum disorders along with obsessive–compulsive and body dysmorphic disorders, anorexia nervosa, Tourette’s disorder, trichotillomania, pathological gambling and other impulsive disorders. All these disorders involve repetitive thoughts or behaviors that patients are unable to delay or inhibit without great difficulty. Evidence for this clustering includes observations of clinical improvement with SSRIs such as fluoxetine even in nondepressed patients with hypochondriasis, body dysmorphic disorder, obsessive–compulsive disorder and anorexia nervosa. Because such a response is not evident with nonSSRI antidepressants, some type of common serotonin dysregulation is suggested for these disorders.

### Diagnosis and Differential Diagnosis

As shown in Figure 54.1, the first step in approaching patients with distressing or impairing preoccupation with or fears of having a

serious disease is to exclude the possibility of explanation on the basis of a general medical condition. Fears that may seem excessive may also occur in patients with general medical conditions with vague and subjective symptoms early in their disease course. These include neurological diseases, such as myasthenia gravis and multiple sclerosis; endocrine diseases; systemic diseases that affect several organ systems, such as systemic lupus erythematosus; and occult malignant neoplasms. The disease conviction of hypochondriasis may actually be less amenable to medical reassurance than the fears of patients, with general medical illnesses, who may at least temporally accept such encouragement. Hypochondriacal complaints are not often intentionally produced such that differentiation from malingering and factitious disorder is seldom a problem.

Exclusion is made if the preoccupation is better accounted for by another psychiatric disorder. DSM-IV lists generalized anxiety disorder, obsessive–compulsive disorder, panic disorder, a major depressive episode, separation anxiety, or another somatoform disorder as candidates. Chronology will be of utmost importance in such discriminations. Hypochondriacal concerns occurring exclusively during episodes of another disturbance, such as an anxiety or depressive disorder, do not warrant an additional diagnosis of hypochondriasis. The presence of other psychiatric symptoms will also be helpful. For example, a patient with hypochondriacal complaints as part of a major depressive episode will show other symptoms of depression, such as sleep and appetite disturbance, feelings of worthlessness and self-reproach, although depressed elderly patients may deny sadness or other expressions of depressed mood. A confounding factor is that patients with hypochondriasis often have comorbid anxiety or depressive syndromes. Again, characterizing the symptoms by chronology will be useful. Treatment trials may also have diagnostic significance. Depressed patients who are hypochondriacal may respond to nonSSRI antidepressant medications or electroconvulsive therapy (often necessary to reverse a depressive state of sufficient severity to lead to such profound symptoms), with resolution of the hypochondriacal as well as the depressive symptoms.

Hypochondriasis is differentiated from other somatoform disorders such as pain, conversion and somatization disorders by its predominant feature of preoccupation with and fears of having an underlying illness based on the misinterpretation of body symptoms, rather than the physical symptoms themselves. Patients with these other somatoform disorders at times are concerned with the possibility of underlying illness, but this will generally be overshadowed by a focus on the symptoms themselves.

The next consideration is whether the belief is of delusional proportions. Patients with hypochondriasis, although preoccupied, generally acknowledge the possibility that their concerns are unfounded. Delusional patients do not. Somatic delusions of serious illness are seen in some cases of schizophrenia and in delusional disorder, somatic type. In general, patients with schizophrenia that have such delusions also show other signs of schizophrenia, such as disorganized speech, peculiarities of thought and behavior, hallucinations and other delusions. Belief that an underlying illness is being caused by some bizarre process may also be seen (e.g., “I’m trying not to defecate because it will cause my brain to turn to jelly”). Schizophrenic patients may also show improvement with neuroleptic treatment, at least in the “active” symptoms of their illness, under which somatic delusions are included.

Differentiation from delusional disorder, somatic type, may be more difficult. It is often a thin line between preoccupation

and fear that is a conviction and that which is a delusion. Often, the distinction is made on the basis of whether the patient can consider the possibility that the conviction is erroneous. Yet, patients with hypochondriasis vary in the extent to which they can do this. DSM-IV acknowledges this by its inclusion of the specifier with poor insight. In the past, some argued that differentiation could be made on the basis of response to neuroleptics, especially pimozide; patients with delusional disorder, but not hypochondriasis, respond.

If it is concluded that the preoccupations are not delusional, the next consideration is whether the duration requirement of 6 months has been met (see Figure 54.1). Syndromes of less than 6 months' duration are diagnosed under either somatoform disorder NOS or adjustment disorder if the symptoms are an abnormal response to a stressful life event. The reason to make such a distinction is to distinguish hypochondriasis from transient syndromes, the longitudinal course of which have been shown to be more variable, suggesting heterogeneity.

Other diagnostic considerations include whether the preoccupations or fears are restricted to preoccupations with being overweight, as in anorexia nervosa; with the inappropriateness of one's sex characteristics, as in a gender identity disorder; or with defects in appearance, as in body dysmorphic disorder. The preoccupations of hypochondriasis resemble the obsessions, and the health checking and efforts to obtain reassurance resemble the compulsions of obsessive-compulsive disorder. However, if such manifestations are health centered only, obsessive-compulsive disorder is not diagnosed. If, on the other hand, nonhealth related obsessions and compulsions are present, obsessive-compulsive disorder may be diagnosed in addition to hypochondriasis.

### Course, Natural History and Prognosis

Data are conflicting, but it appears that the most common age at onset is in early adulthood. Available data suggest that approximately 25% of patients with a diagnosis of hypochondriasis do poorly, 65% show a chronic but fluctuating course and 10% recover. This pertains to the full syndrome. A much more variable course is seen in patients with just some hypochondriacal concerns. It appears that acute onset, absence of a personality disorder and absence of secondary gain are favorable prognostically.

### Treatment

Until recently, it appeared that patients with hypochondriasis as a primary condition benefited, but only modestly, from psychiatric intervention. Patients referred early for psychiatric evaluation and treatment showed a slightly better prognosis than those continuing with only medical evaluations and treatments. Of course, the first step in treatment is getting the patient to a psychiatrist. Patients with hypochondriasis generally present initially to nonpsychiatric physicians and are often reluctant to see a psychiatrist. Referral should be done sensitively, with the referring physician stressing to the patient that his or her distress is real and that psychiatric evaluation will be a supplement to, not a replacement for, continued medical care.

Initially, the generic techniques outlined for the somatoform disorders in general should be followed. However, it has not been demonstrated that a specific psychotherapy for hypochondriasis is available. Dynamic psychotherapy is of minimal effectiveness; supportive-educative psychotherapy is only somewhat helpful, and primarily for those with syndromes of less than 3 years' duration; and cognitive-behavioral therapy, especially response prevention of checking rituals and reassurance seeking,

is of only moderate effectiveness at best. All of these techniques seem to lack definitive effects on hypochondriasis itself.

Until recently, this could also be said of pharmacological approaches. Pharmacotherapy of comorbid depressive or anxiety syndromes was often effective, and control of such syndromes aided in general management, yet hypochondriasis itself was not ameliorated. Although controlled trials are lacking, anecdotal and open-label studies suggest that serotonergic agents such as clomipramine and the SSRI fluoxetine may be effective in ameliorating hypochondriasis. Similar effects are expected from the other SSRIs. Response to fluoxetine has been reported with doses recommended for obsessive-compulsive disorder, rather than usual antidepressant doses (i.e., 60–80 mg rather than 20–40 mg/day). Such pharmacotherapy is best combined with the generic psychotherapy recommendations for somatoform disorders, as well as with cognitive-behavioral techniques to disrupt the counterproductive checking and reassurance-seeking behaviors.

## Body Dysmorphic Disorder

### Definition

The essential feature of this disorder is preoccupation with an imagined defect in appearance or a markedly excessive concern with a minor anomaly (see Table 54.1). In body dysmorphic disorder, a person could be preoccupied with an imagined defect while she or he actually had some other anomaly and was not normal appearing. To exclude conditions with trivial or minor symptoms, the preoccupation must cause clinically significant distress or impairment. By definition, body dysmorphic disorder is not diagnosed if symptoms are limited to preoccupation with body weight, as in anorexia nervosa or bulimia nervosa, or to perceived inappropriateness of sex characteristics, as in gender identity disorder.

Preoccupations most often involve the nose, ears, face, or sexual organs. Common complaints include a diversity of imagined flaws of the face or head, including defects in the hair (e.g., too much or too little), skin (e.g., blemishes), and shape or symmetry of the face or facial features (e.g., nose is too large and deformed). However, any body part may be the focus, including genitals, breasts, buttocks, extremities, shoulders and even overall body size.

Body dysmorphic disorder has been well described in the European and Japanese literature, generally designated dysmorphophobia, often under the rubric of the monosymptomatic hypochondriacal psychoses. Until recently, it had been virtually ignored in the US literature as well as clinically.

The definition of the disorder was reexamined for DSM-IV on several counts, but especially as to its relationship to other psychiatric disorders (Phillips and Hollander, 1996). After much deliberation, it was determined that body dysmorphic disorder, although often comorbid with anxiety and mood disorders, was sufficiently discrete to be maintained as a separate disorder. As discussed in the differential diagnosis section, it can be distinguished from depressive disorders and from most anxiety disorders, although it resembles obsessive-compulsive disorder in phenomenology, course and even response to treatment. It was also decided to keep it with the somatoform disorders grouping, although it does not share much with the other disorders in this grouping (with the exception of hypochondriasis), beyond the fact that affected patients are generally referred to psychiatrists from other physicians and that they also present with medically

unexplained physical complaints (defects in appearance in body dysmorphic disorder).

As De Leon and colleagues (1989) pointed out, it is extremely difficult to determine whether a dysmorphic concern is delusional as in that with body dysmorphic disorder, for a continuum exists from clearly nondelusional preoccupations to unequivocal delusions such that defining a discrete boundary between the two ends of the spectrum would be artificial. Furthermore, individual patients seem to move back and forth along this continuum. Support for rejecting the exclusion is preliminary evidence that dysmorphic preoccupations may respond to the same pharmacotherapy (SSRIs), regardless of whether the concerns are delusional. Perhaps as a reflection of the state of knowledge at this point, both body dysmorphic disorder and delusional disorder, somatic type, can be diagnosed on the basis of the same symptoms, in the same individual, at the same time. Thus, the definition of body dysmorphic disorder differs from hypochondriasis, which is not diagnosed if hypochondriacal concerns are determined to be delusional.

### Epidemiology

Knowledge of such parameters is still incomplete. In general, patients with body dysmorphic disorder first present to nonpsychiatrists such as plastic surgeons, dermatologists and internists because of the nature of their complaints and are not seen psychiatrically until they are referred (De Leon *et al.*, 1989). Many resist or refuse referral because they do not see their problem as psychiatric; thus, study of psychiatric clinic populations may underestimate the prevalence of the disorder. It has been estimated that 2% of patients seeking corrective cosmetic surgery suffer from this disorder. Although women outnumber men in this population, it is not known whether this sex distribution holds true in the general population.

### Etiology and Pathophysiology

A number of sociological, psychological and neurobiological theories have been proposed. Body dysmorphic disorder has been explained, at least in part, as an exaggerated incorporation of societal ideals of physical perfection and acceptance of cosmetic plastic surgery to attain such goals. A high frequency of insecure, sensitive, obsessional, schizoid, anxious, narcissistic, introverted and hypochondriacal personality traits in body dysmorphic patients have been described (Phillips, 1991). Various psychodynamic mechanisms and symbolic meanings of dysmorphic symptoms have been suggested (Phillips, 1991), going back to Freud's case of the Wolfman who had dysmorphic preoccupations regarding his nose.

Some interesting neurobiological possibilities have emerged, particularly concerning observations that hypochondriasis, body dysmorphic disorder and a number of other conditions involving compelling repetitive thoughts or behaviors may respond preferentially to SSRIs, not to other antidepressant drugs. An obsessive-compulsive spectrum disorders grouping, the pathological process of which is mediated by serotonergic dysregulation, has been suggested. As further evidence, symptoms of body dysmorphic disorder as well as those of obsessive-compulsive disorder may be aggravated by the partial serotonin agonist *m*-chlorophenylpiperazine.

### Diagnosis and Differential Diagnosis

The preoccupations of body dysmorphic disorder must first be differentiated from usual concerns with grooming and appear-

ance. Attention to appearance and grooming is universal and socially sanctioned. However, diagnosis of body dysmorphic disorder requires that the preoccupation cause clinically significant distress or impairment. In addition, in body dysmorphic disorder, concerns focus on an imaginary or exaggerated defect, often of something, such as a small blemish, that would warrant scant attention even if it were present. Persons with histrionic personality disorder may be vain and excessively concerned with appearance. However, the focus in this disorder is on maintaining a good or even exceptional appearance, rather than preoccupation with a defect. Such concerns are probably unrelated to body dysmorphic disorder. In addition, by nature, the preoccupations in body dysmorphic disorder are essentially unamenable to reassurance from friends or family or consultation with physicians, cosmetologists, or other professionals.

Next, the possibility of an explanation by a general medical condition must be considered (see Figure 54.1). As mentioned, patients with this disorder often first present to plastic surgeons, oral surgeons and others, seeking correction of defects. By the time a mental health professional is consulted, it has generally been ascertained that there is no physical basis for the degree of concern. As with other syndromes involving somatic preoccupations (or delusions), such as olfactory reference syndrome and delusional parasitosis (both included under delusional disorder, somatic type), occult medical disorders, such as an endocrine disturbance or a brain tumor, must be excluded.

In terms of explanation on the basis of another psychiatric disorder, there is little likelihood that symptoms of body dysmorphic disorder will be intentionally produced as in malingering or factitious disorder. Unlike in other somatoform disorders, such as pain, conversion and somatization disorders, preoccupation with appearance predominates. Somatic preoccupations may occur as part of an anxiety or mood disorder. However, these preoccupations are generally not the predominant focus and lack the specificity of dysmorphic symptoms. Because patients with body dysmorphic disorder often become isolative, social phobia may be suspected. However, in social phobia, the person may feel self-conscious generally but will not focus on a specific imagined defect. Indeed, the two conditions may coexist, warranting both diagnoses. Diagnostic problems may present with the mood-congruent ruminations of major depression, which sometimes involve concern with an unattractive appearance in association with poor self-esteem. Such preoccupations generally lack the focus on a particular body part that is seen in body dysmorphic disorder. On the other hand, patients with body dysmorphic disorder commonly have dysphoric affects described by them variously as anxiety or depression. In some cases, these affects can be subsumed under body dysmorphic disorder; but in other instances, comorbid diagnoses of anxiety or mood disorders are warranted.

Differentiation from schizophrenia must also be made. At times, a dysmorphic concern will seem so unusual that such a psychosis may be considered. Furthermore, patients with this disorder may show ideas of reference in regard to defects in their appearance, which may lead to the consideration of schizophrenia. However, other bizarre delusions, particularly of persecution or grandiosity, and prominent hallucinations are not seen in body dysmorphic disorder. From the other perspective, schizophrenia with somatic delusions generally lacks the focus on a particular body part and defect. Also in schizophrenia, bizarre

interpretations and explanations for symptoms are often present, such as “this blemish was a sign from Jesus that I am to protect the world from Satan”. Other signs of schizophrenia, such as hallucinations and disorganization of thought, are also absent in body dysmorphic disorder. As previously mentioned, the preoccupations in body dysmorphic disorder appear to be on a continuum from full insight to delusional intensity whereby the patient cannot even consider the possibility that the preoccupation is groundless. In such instances, both body dysmorphic disorder and delusional disorder, somatic type, are to be diagnosed.

Body dysmorphic disorder is not to be diagnosed if the concern with appearance is better accounted for by another psychiatric disorder. Anorexia nervosa, in which there is dissatisfaction with body shape and size, is specifically mentioned in the criteria as an example of such an exclusion. Although not specifically mentioned in DSM-IV, if a preoccupation is limited to discomfort or a sense of inappropriateness of one’s primary and secondary sex characteristics, coupled with a strong and persistent cross-gender identification, body dysmorphic disorder is not diagnosed.

The preoccupations of body dysmorphic disorder may resemble obsessions and ruminations as seen in obsessive-compulsive disorder. Unlike the obsessions of obsessive-compulsive disorder, the preoccupations of body dysmorphic disorder focus on concerns with appearance. Compulsions are limited to checking and investigating the perceived physical defect and attempting to obtain reassurance from others regarding it. Still, the phenomenology is similar, and the two disorders are often comorbid. If additional obsessions and compulsions not related to the defect are present, obsessive-compulsive disorder can be diagnosed in addition to body dysmorphic disorder.

### Course, Natural History and Prognosis

Age at onset appears to peak in adolescence or early adulthood. Body dysmorphic disorder is generally a chronic condition, with a waxing and waning of intensity but rarely full remission. In a lifetime, multiple preoccupations are typical; in one study, the average was four (Phillips *et al.*, 1993). In some, the same preoccupation remains unchanged. In others, new perceived defects are added to the original ones. In others still, symptoms remit, only to be replaced by others. The disorder is often highly incapacitating, with many patients showing marked impairment in social and occupational activities. Perhaps a third becomes housebound. Most attribute their limitations to embarrassment concerning their perceived defect, but the attention and time-consuming nature of the preoccupations and attempts to investigate and rectify defects also contribute. The extent to which patients with body dysmorphic disorder receive surgery or medical treatments is unknown. Superimposed depressive episodes are common, as are suicidal ideation and suicide attempts. Actual suicide risk is unknown.

In view of the nature of the defects with which patients are preoccupied, it is not surprising that they are found most commonly among patients seeking cosmetic surgery. Preoccupations persist despite reassurance that there is no defect to correct surgically. Surgery or other corrective procedures rarely if ever lead to satisfaction and may even lead to greater distress with the perception of new defects attributed to the surgery.

### Treatment

First, the generic goals and treatments as outlined for the somatoform disorders overall should be instituted. These are

beneficial in interrupting an unending procession of repeated evaluations and the possibility of needless surgery, which may lead to additional perceptions that surgery has resulted in further disfigurement.

Traditional insight-oriented therapies have not generally proved to be effective. Results with traditional behavioral techniques, such as systematic desensitization and exposure therapy, have been mixed. At least without amelioration with effective pharmacotherapy, the preoccupations do not extinguish as would be expected with phobias. A cognitive-behavioral approach similar to what was recommended for hypochondriasis may be more effective. This includes response prevention techniques whereby the patient is not permitted repetitively to check the perceived defect in mirrors. In addition, patients are advised not to seek reassurance from family and friends, and these persons are instructed not to respond to such inquiries. Some patients adopt such behaviors spontaneously, avoiding mirrors and other reflecting surfaces, refusing even to allude to their perceived defects to others. Such “self-techniques” may be encouraged and refined.

Biological treatments have long been used but until recently were of limited benefit to patients with body dysmorphic disorder. Approaches have included electroconvulsive therapy, tricyclic and MAOI antidepressants, and neuroleptics, particularly pimozide. In most reports of positive response to tricyclic or MAOI antidepressant drugs, it is unclear whether response was truly in terms of the dysmorphic syndrome or simply represented improvement in comorbid depressive or anxiety syndromes. Response to neuroleptic treatment has been suggested as a diagnostic test to distinguish body dysmorphic disorder from delusional disorder, somatic type. The delusional syndromes often respond to neuroleptics; body dysmorphic disorders, even when the body preoccupations are psychotic, generally do not. Pimozide has been singled out as a neuroleptic with specific effectiveness for somatic delusions, but this specificity does not appear to apply to body dysmorphic disorder.

An exception to this uninspiring picture is the observation of a possible preferential response to antidepressant drugs with serotonin reuptake blocking effects, such as clomipramine, or SSRIs, such as fluoxetine and fluvoxamine (Hollander *et al.*, 1992). Phillips and coworkers (1993) reported that more than 50% of patients with body dysmorphic disorder showed a partial or complete remission with either clomipramine or fluoxetine, a response not predicted on the basis of coexisting major depressive or obsessive-compulsive disorder. As with hypochondriasis, effectiveness is generally achieved at levels recommended for obsessive-compulsive disorder rather than for depression (e.g., 60–80 mg rather than 20–40 mg/day of fluoxetine). The SSRIs appear to ameliorate delusional as well as nondelusional dysmorphic preoccupations. Successful augmentation of clomipramine or SSRI therapy has been suggested with buspirone, another drug with serotonergic effects. Neuroleptics, particularly pimozide, may also be helpful adjuncts, particularly if delusions of reference are present. Little seems to be gained with the addition of anticonvulsants, or benzodiazepines to the SSRI therapy.

As yet, rigorous studies have not been conducted, but anecdotal observations and open-label studies show promise for effective treatment with SSRIs and other serotonergic agents for this, until now, therapeutically exasperating disorder. If such approaches fulfill their initial promise, integrated

approaches using pharmacotherapy and other modalities such as cognitive-behavioral therapy may provide effective treatment options.

## Somatoform Disorder not Otherwise Specified

### Definition

Somatoform disorder NOS is the true residual category (see Table 54.1). Disorders considered under this category are characterized by somatic symptoms, but criteria for any of the specific somatoform disorders are not met. Several examples are given, but syndromes potentially included under this category are not limited to these. Unlike for undifferentiated somatoform disorder, no minimal duration is required. DSM-IV lists as examples pseudocyesis, disorders involving hypochondriacal complaints but of less than 6 months' duration, and disorders involving unexplained physical complaints such as fatigue or body weakness not due to another mental disorder and again of less than 6 months' duration. This last syndrome would seem to resemble neurasthenia of short duration, a syndrome with a long historical tradition.

Inclusion of pseudocyesis deserves special mention. With the restriction of conversion in DSM-IV to include only symptoms affecting voluntary motor and sensory function, pseudocyesis was excluded from the conversion disorder definition. In a sense, it is placed in the somatoform disorder NOS category for lack of a more appropriate place. Pseudocyesis is a reasonably discrete syndrome for which specific criteria as listed in DSM-IV can be delineated. However, given its rarity, it is not listed as a specified somatoform disorder.

### Diagnosis and Differential Diagnosis

As a residual category, somatoform disorder NOS is to be diagnosed after all other possibilities are excluded (see Figure 54.1). After it is determined that a syndrome with somatoform symptoms is not attributable to a nonsomatoform psychiatric disorder and does not meet criteria for any of the specific somatoform disorders (including, on the symptom-focused side, pain, conversion and somatization disorders and, on the preoccupation-focused side, hypochondriasis or body dysmorphic disorder), the two diagnostic possibilities that remain are undifferentiated somatoform disorder and somatoform disorder NOS. Except in the case of pseudocyesis, these two are differentiated on the basis of whether the disturbance is of 6 months' duration. If symptoms last more than 6 months, undifferentiated somatoform disorder is diagnosed; if less than 6 months, somatoform disorder NOS.

### Conclusion

As a group, the syndromes now subsumed under the rubric of somatoform disorders are relatively common and are associated with great direct and indirect costs to society. Yet, they have remained a "stepchild" of psychiatry, underdiagnosed and under-researched. Therapeutic direction is emerging, with some general guidelines for all of these disorders; some specific ways of managing patients with somatization disorder, undifferentiated somatoform disorder and conversion disorder; and a more utilitarian approach to management of patients with pain disorders.

It appears that pharmacological inroads are being made in the treatment of hypochondriasis and body dysmorphic disorder in terms of the possible efficacy of SSRIs. This pharmacological "probe" suggests that these disorders may be more closely linked with the so-called obsessive-compulsive spectrum disorders than with the other somatoform disorders, a linkage that may be reflected in future diagnostic systems. Even if this turns out to be the case, the somatoform disorder concept will have served its purpose in stimulating and making possible research leading to a better understanding and ultimately more effective treatments for these complex conditions.

Much work remains to be done before the knowledge concerning the somatoform disorders and their treatment catch up with the understanding of other groupings of psychiatric disorders.

### Comparison of DSM-IV/ICD-10 Diagnostic Criteria

The ICD-10 Diagnostic Criteria for Research for Somatization Disorder has both a different item set and algorithm. Six symptoms are required out of a list of 14 symptoms which are broken down into the following groups: six gastrointestinal symptoms, two cardiovascular symptoms, three genitourinary symptoms, and three "skin and pain" symptoms. It is specified that the symptoms occur in at least two groups. In contrast, DSM-IV-TR requires four pain symptoms, two gastrointestinal symptoms, one sexual symptom and one pseudoneurological symptom. Furthermore, the ICD-10 Diagnostic Criteria for Research specify that there must be "persistent refusal to accept medical reassurance that there is no adequate physical cause for the physical symptoms". DSM-IV-TR only requires that the symptoms result in treatment being sought or significant impairment in social, occupational, or other important areas of functioning and that the symptoms cannot be fully explained by a known general medical condition or substance. For Undifferentiated Somatoform Disorder, the ICD-10 Diagnostic Criteria for Research and the DSM-IV-TR criteria are almost identical.

Regarding conversion disorder, ICD-10 considers conversion a type of dissociative disorder and includes separate criteria sets for dissociative motor disorders, dissociative convulsions and dissociative anesthesia and sensory loss in a section that also includes dissociative amnesia and dissociative fugue.

For pain disorder, the ICD-10 Diagnostic Criteria for Research require that the pain last at least 6 months and that it not be "explained adequately by evidence of a physiological process or a physical disorder". In contrast, DSM-IV-TR does not force the clinician to make this inherently impossible judgment and instead requires the contribution of psychological factors. Furthermore, DSM-IV-TR includes both acute (duration less than 6 months) and chronic pain (more than 6 months). This disorder is referred to in ICD-10 as "Persistent Somatoform Pain Disorder".

ICD-10 provides a single criteria set that applies to both the DSM-IV-TR categories of hypochondriasis and body dysmorphic disorder. The ICD-10 Diagnostic Criteria for Research for Hypochondriasis specifies that the belief is of a "maximum of two serious physical diseases" and requires that at least one be specifically named by the individual with the disorder. The DSM-IV-TR has no such requirement.

## Introduction

A patient with factitious disorder consciously induces or feigns illness in order to obtain a psychological benefit by being in the sick role. It is the conscious awareness of the production of symptoms that differentiates factitious disorder from the somatoform disorders in which the patient unconsciously produces symptoms for an unconscious psychological benefit. It is the underlying motivation to produce symptoms that separates factitious disorders from malingering. Patients who malingering consciously feign or induce illness in order to obtain some external benefit such as money, narcotics, or excuse from duties. While the distinctions among these disorders appear satisfyingly clear, in practice, patients often blur the boundaries. Patients with somatoform disorders will sometimes consciously exaggerate symptoms which they have unconsciously produced, and it is a rare patient who consciously creates illness and yet receives no external gain at all, be it disability benefits, excuse from work, or even food and shelter.

Talcott Parsons described the “sick role” in 1951 and noted that in our society there are four aspects of this role. First, the patient is not able to will himself or herself back to health but instead must “be taken care of”. Secondly, the patient in the sick role must regard the sickness as undesirable and want to get better. Thirdly, the sick patient is obliged to seek medical care and cooperate with his or her medical treatment. Finally, the sick patient is exempted from the normal responsibilities of his or her social role (Parsons, 1951).

Patients with factitious disorder seek, often desperately, the sick role. They usually have little insight into the motivations of their behaviors but are still powerfully driven to appear ill to others. In many cases, they endanger their own health and life in search of this role. Patients with this disorder will often induce serious illness or undergo numerous unnecessary, invasive procedures. As most people avoid sickness, the actions of these patients appear to run counter to human nature. Also, since entry into the “sick role” requires that the sick person should try to get better, patients with factitious disorder must conceal the voluntary origin of their symptoms. The inexplicability of their actions combined with their deceptive behavior stir up both intense interest and intense (usually negative) countertransference in health care providers.

Patients have been known to create or feign numerous illnesses, both acute and chronic, in all of the medical specialties. These illnesses can be either physical or psychological. It appears that the only limit is the creativity and knowledge of a given patient. In fact, there is at least one case report of a patient who feigned factitious disorder itself (Gurwith and Langston, 1980). The patient claimed to have Munchausen’s syndrome, to have

## DSM-IV-TR Criteria

### Factitious Disorder

- A. Intentional production or feigning of physical or psychological signs or symptoms.
- B. The motivation for the behavior is to assume the sick role.
- C. External incentives for the behavior (such as economic gain, avoiding legal responsibility, or improving physical well-being, as in malingering) are absent.

### Code based on type

300.16 With Predominantly Psychological Signs and Symptoms: if psychological signs and symptoms predominate in the clinical presentation  
 300.19 With Predominantly Physical Signs and Symptoms: if physical signs and symptoms predominate in the clinical presentation  
 300.19 With Combined Psychological and Physical Signs and Symptoms: if both psychological and physical signs and symptoms are present and neither predominates in the clinical presentation

undergone numerous unnecessary procedures and operations and, as a result, to need immediate hospitalization. He displayed his abdomen, which appeared to have numerous surgical scars and hinted that searches of his hospital room would be fruitful. However, collateral information revealed that the physicians and hospitals he had reported had never treated the patient, and his “scars” washed off with soap and water. Patients with factitious disorder are often quite medically sophisticated. Even though acquired immune deficiency syndrome was not described until the early 1980s, the first factitious cases followed shortly thereafter, at least as early as 1986.

## Definition

For a diagnosis of factitious disorder (see DSM-IV-TR criteria for factitious disorder) to be justified, a person must be intentionally producing illness; his or her motivation is to occupy the sick role, and there must not be external incentives for the behavior. The diagnosis is further subclassified, depending on whether the factitious symptoms are predominantly physical, psychological, or a combination. The DSM also includes a category

(see DSM-IV-TR criteria for factitious disorder not otherwise specified) for patients with factitious symptoms who do not meet the listed criteria. The most common example of factitious disorder not otherwise specified is factitious disorder by proxy, in which the individual creates symptoms in another person, usually a dependent, in order to occupy the sick role. Patients who readily admit to inducing symptoms, such as self-mutilating patients, are not diagnosed with factitious disorder as they are not using their symptoms to occupy the sick role.

### Factitious Disorder with Predominantly Physical Signs and Symptoms

Patients with this subtype of factitious disorder present with physical signs and symptoms. The three main methods patients use to create illness are: 1) giving a false history, 2) faking clinical and laboratory findings, and 3) inducing illness (e.g., by surreptitious medication use, inducing infection, or preventing wound healing). There are reports of factitious illnesses in all of the medical specialties. Particularly common presentations include fever, self-induced infection, gastrointestinal symptoms, impaired wound healing, cancer, renal disease (especially hematuria and nephrolithiasis), endocrine diseases, anemia, bleeding disorders and epilepsy (Wise and Ford, 1999). True Munchausen's syndrome fits within this subclass and is the most severe form of the illness. According to the DSM-IV, patients with Munchausen's syndrome have chronic factitious disorder with physical signs and symptoms, and in addition, have a history of recurrent hospitalization, peregrination, and **pseudologia fantastica** – dramatic, untrue, and extremely improbable tales of their past experiences (American Psychiatric Association, 2000).

### Factitious Disorder with Predominantly Psychological Signs and Symptoms

Another subtype of factitious disorder includes patients who present feigning psychological illness. They both report and mimic psychiatric symptoms. These patients can be particularly difficult to diagnose as psychiatric diagnosis depends greatly on the patient's report. There are reports of factitious psychosis, post traumatic stress disorder and bereavement. In addition, there are reports of psychological distress due to false claims of being a victim of stalking, rape, or sexual harassment, and these cases are often diagnosed with a factitious psychological disorder such as post traumatic stress disorder. While patients with factitious psychological symptoms feign psychiatric illness, they also often suffer from true comorbid psychiatric disorders, particularly Axis II disorders and substance abuse. Case reports suggest that patients with psychological factitious disorder have a high rate of suicide and a poor prognosis. While Munchausen's syndrome is considered a subset of physical factitious disorder, there are case reports of patients presenting with psychological symptoms who also have some of the key features of Munchausen's (pathological lying, wandering and recurrent hospitalizations).

### Factitious Disorder with Combined Psychological and Physical Signs and Symptoms

DSM-III separated factitious disorder into two disorders, based on whether the symptoms were physical or psychological.

## Clinical Vignette 1

### Factitious Disorder with Psychological Features

A 46-year-old man presented complaining of symptoms of post traumatic stress disorder (PTSD). He reported intense flashbacks, numbing and avoidance, and irritability resulting from his experience as a combat veteran. He began intensive treatment for PTSD including support groups, individual therapy and medication management. He was an extremely active participant in the support groups and would recount detailed horrors of his time in combat. A staff member verifying the patient's history learned the patient had served in the military but was not a combat veteran. The patient was confronted in a supportive manner, and he admitted that he had fabricated his history. It was recommended that the patient continue in psychiatric treatment, and he agreed to do so.

However, case reports clarified that this distinction was often artificial (Merrin *et al.*, 1986; Parker, 1993). Some patients present with simultaneous psychological and physical factitious symptoms, and some patients move between physical and psychological presentations over time. For example, a patient who presented with factitious post traumatic stress disorder was confronted about the nature of his symptoms and then began complaining of physical symptoms. DSM-IV was revised to account for patients who present with both psychological signs and symptoms, though this category of patients is the least well-studied.

### Factitious Disorder not Otherwise Specified (Factitious Disorder by Proxy)

Some individuals pursue the sick role not by feigning illness in themselves, but instead by creating it in another person, usually someone dependent on the perpetrator. They seek the role of caring for an ill individual (the sick role by proxy). While the victim is usually a child, there are reports of victimization of elders and developmentally delayed adults. The veterinary literature even reports cases of factitious disorder by proxy in which the victim is a pet. Due to the unique characteristics of this disorder, it will be discussed in a separate section at the end of the chapter.

## Clinical Findings

Due to the inherently deceptive nature of patients with factitious disorder, the literature is largely confined to case reports and case series. It is likely that many patients with less severe forms of the disease escape detection and their clinical characteristics might be quite different. In addition, the literature on factitious disorder with physical symptoms is much more extensive than the literature on the other subtypes. As a result, we will discuss the features of the factitious disorders as a whole, referring to specific characteristics of patients with psychological symptoms (either alone or accompanying physical symptoms) when they are known.

Numerous reports in the literature describe two different subclasses of factitious patients. The first type fits with the classic Munchausen's syndrome diagnosis: they have chronic factitious symptoms associated with antisocial traits, pathological lying, minimal social supports, wandering from hospital to hospital, and very poor work and relationship functioning. They are often

very familiar with hospital procedure and use this knowledge to present dramatically during off-hours or at house officer transition times when the factitious nature of their symptoms is least likely to be discovered. Male patients comprise the majority of these cases. Patients with Munchausen's syndrome appear to have an extremely poor prognosis. Fortunately, this most severe class of patients makes up the minority of factitious patients, probably fewer than 10%.

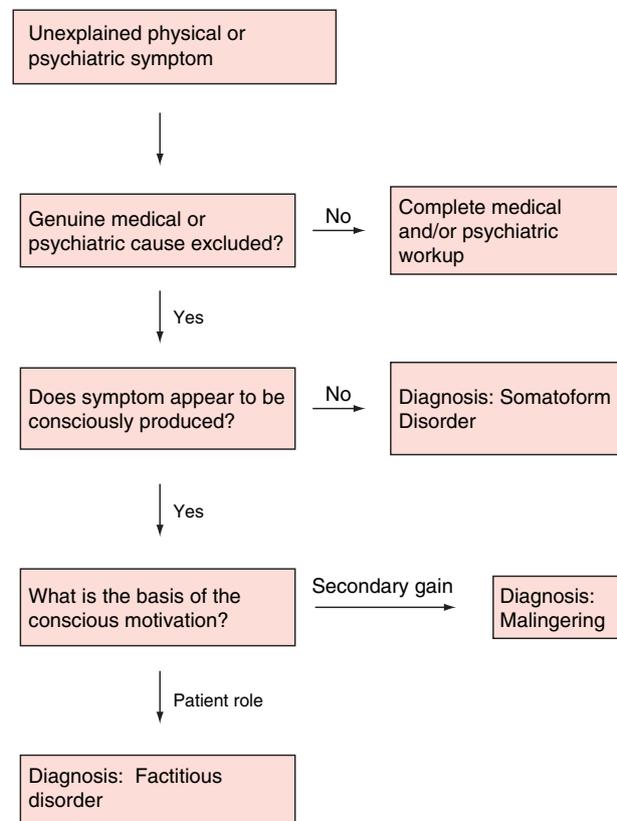

The second, and more typical, type of patient does not display pathological lying or wandering. Their recurrent presentations are usually within the same community, and they become well known within the local health care system. They often have stable social supports and employment, and a history of a medically related job. This larger class of factitious patients is mostly made up of women, and is more likely to accept psychiatric treatment and to show improvement. Plassmann (1994a) reviewed 1070 cases of patients with factitious, but not Munchausen's disorder. He found that 78% of the patients were women and 58% had a medically related job. Finally, there are individuals who may have an episode of factitious disorder in reaction to a life stressor, but may return to premorbid functioning after the stressor is resolved.

All types of factitious disease show a strong association with substance abuse as well as borderline and narcissistic personality disorders. In a case series by Ehlers and Plassman (1994), nine of 18 patients had personality features that met criteria for borderline personality disorder, and another six of 18 had personality features that met criteria for narcissistic personality disorder. Factitious patients span a broad age range. Reports in the literature show patients ranging from four to 85 years. Of note, a 4-year-old patient with factitious disorder reported that he had been coached by his mother and may be better diagnosed as a victim of factitious disorder by proxy. The next youngest case found was 8 years old. Ethnicity is frequently not reported in case studies and series, so it is difficult to determine if there are any ethnic differences in the prevalence or presentation of factitious disorder.

### Diagnosis and Differential Diagnosis

The diagnosis of factitious disorder is made in several ways. Factitious disorder is occasionally diagnosed accidentally when the patient is discovered in the act of creating symptoms. A history of inconsistent or unexplainable signs and symptoms or failure to respond to appropriate treatment can prompt health care providers to probe for evidence of the disorder, as can evidence of peregrination or pathological lying. In some cases, it is a diagnosis of exclusion in an otherwise inexplicable case. The differential diagnosis of factitious disorder includes rare or complex physical illness, somatoform disorders, malingering, other psychiatric disorders and substance abuse. It is especially important to rule out genuine physical illness since patients with factitious disorder often induce real physical illness. Furthermore, it is always important to remember the patients with factitious disorder are certainly not immune to the physical illnesses that plague the general population.

If there is suspicion of factitious disorder, confirmation can be difficult. Laboratory examination can confirm some factitious diagnoses such as exogenous insulin or thyroid hormone administration. Collateral information from family members or previous health care providers can also be extremely helpful. Factitious disorder with psychological signs and symptoms can

**Figure 55.1** Diagnostic decision tree for factitious disorder.

be particularly difficult to diagnose, as so much of psychiatric diagnosis relies on the patient's report. However, there is some evidence that neuropsychological testing may be helpful in making the diagnosis. There are conflicting reports about the ability to detect over 90% of cases of factitious post traumatic stress disorder using the MMPI. In addition, there is a report of MMPI test results being used to support a diagnosis of factitious disorder with psychological features in a woman thought to be feigning symptoms of multiple personality disorder (see Figure 55.1).

### Epidemiology

The nature of factitious disorder makes it difficult to determine how common it is within the population. Patients attempt to conceal themselves, thereby artificially lowering the prevalence. The tendency of patients to present several times at different facilities, however, may artificially raise the prevalence. Most estimates of the prevalence of the disease, therefore, rely on the number of factitious patients within a given inpatient population. Such attempts have generated estimates that 0.5 to 3% of medical and psychiatric inpatients suffer from factitious disorder. Of 1288 patients referred for psychiatric consultation at a Toronto general hospital, 10 (0.8%) were diagnosed with factitious disorder. A prospective examination of all 1538 patients hospitalized in a Berlin neurology department over 5 years found five (0.3%) cases of factitious disorder. An examination of 506 patients with fever of unknown origin (FUO) revealed that 2.2% of the fevers were of factitious origin, and a review of 199 Belgian patients with FUO found seven of 199 (3.5%) to be factitious. A similar study of patients with FUO at the National

Institutes of Health (NIH) revealed that 9.3% of the fevers were factitious. The increased prevalence found at the NIH may be due to the fact that the study was undertaken in a more tertiary setting, and it is a reminder that the prevalence of factitious disorder likely varies widely depending on the population and the setting. Gault and colleagues (1988) examined 3300 renal stones brought in by patients and found that 2.6% of these stones were mineral and felt to be submitted by factitious or malingering patients. There is much less data on the prevalence of factitious disorder with psychological features. A study of psychiatric inpatients showed a prevalence of 0.5% of admissions determined to be a result of a factitious psychological condition. There are few data about the prevalence of factitious disorder in an outpatient population. Because factitious patients do not readily identify themselves in large community surveys, it is not currently possible to determine the prevalence of the disorder in the general population.

## Etiology

Both psychological and biological factors have been postulated to play a role in the etiology of factitious disorder. Although numerous case reports have generated speculation that factitious disorder may run in families, this could be explained by environmental factors, genetic factors, or both. The presence of central nervous system (CNS) abnormalities in some patients with factitious disorders have led some to hypothesize that underlying brain dysfunction contributes to factitious disorder. One review of factitious patients with *pseudologia fantastica* found CNS abnormalities (such as EEG abnormality, head injury, imaging abnormalities, or neurological findings) in 40% of the patients (King and Ford, 1988). There have been case reports of MRI and SPECT abnormalities, but it is unknown if these abnormalities were related to the disorder.

In addition, childhood developmental disturbances are thought to contribute to factitious disorder. Predisposing factors are thought to include 1) serious childhood illness or illness in a family member during childhood, especially if the illness was associated with attention and nurturing in an otherwise distant family, 2) past anger with the medical profession, 3) past significant relationship with a health care provider, and 4) factitious disorder in a parent (McKane and Anderson, 1997).

Patients with factitious disorder create illness in pursuit of the sick role. For these patients, being in the sick role allows them to compensate for an underlying psychological deficit. Most authors identify several common psychodynamic motivations for factitious disorder. First, patients with little sense of self may seek the sick role in order to provide a well-defined identity around which to structure themselves. Others may seek the sick role in order to meet dependency needs which have gone unmet elsewhere. As a patient, they receive the attention, caring and nurturing of the health care environment and are relieved of many of their responsibilities. In addition, some patients may engage in factitious behaviors for masochistic reasons. They feel they deserve punishment for some forbidden feelings and thus they should suffer at the hands of their physicians. Other patients may be motivated by anger at physicians and dupe them in retaliation. Patients with a history of childhood illness or abuse may attempt to master past traumas by creating a situation over which they have control. Finally, some authors have speculated that some patients may be enacting suicidal wishes through their factitious behavior.

## Treatment and Prognosis

The goals in treating patients with factitious disorder are twofold; first to minimize the damage done by the disorder to both the patient's own health and the health care system. The second goal is to help patients recover, at least partially, from the disorder. These goals are furthered by treating comorbid medical illnesses, avoiding unnecessary procedures, encouraging patients to seek psychiatric treatment and providing support for health care clinicians. Because the literature is based exclusively on case reports and series, determining treatment effectiveness is difficult. As mentioned before, patients with true Munchausen's syndrome (including antisocial traits, pathological lying, wandering and poor social support) are felt to be refractory to treatment. While factitious disorder is extremely difficult to cure, effective techniques exist to minimize morbidity, and some patients are able to benefit greatly from psychiatric intervention.

The course of untreated factitious disorder is variable. While patients with factitious disorder commonly suffer a great deal of morbidity, fatal cases appear to be less common. One survey of 41 cases noted only one fatality, though many of the other cases were life-threatening (Reich and Gottfried, 1983). However, patients with psychological signs and symptoms are reported to have a high rate of suicide and a poor prognosis.

Soon after the widely noted publication of the first article on factitious disorders (Asher, 1951) many patients with factitious disorder were vigorously confronted once the nature of their illness was discovered. Unfortunately, most patients would deny their involvement and seek another provider who was unaware of their diagnosis (Eisendrath, 2001). In addition, the idea of "blacklists" was proposed in order to aid detection of these patients. However, issues regarding patient confidentiality as well as concerns about cursory medical evaluations that might miss genuine physical illness prevented this idea from being adopted. Although aggressive confrontation is usually unsuccessful, supportive, nonpunitive confrontation may be helpful for some. In one case series, 33 patients were confronted with the factitious nature of their illness. While only 13 admitted feigning illness, most of the patients' illnesses subsequently improved, at least in the short term (Reich and Gottfried, 1983).

Eisendrath suggested three alternatives to confrontation that he found effective. First is inexact interpretation, in which the psychiatrist interprets the psychodynamics thought to be underlying the patient's behavior without explicitly identifying the factitious behavior. He gave the example of a patient suspected of having factitious disorder who developed septicemia after her boyfriend proposed marriage. The consultant suggested that the patient might feel a need to punish herself when good things happened to her. She agreed and, soon after, admitted that she had injected a contaminant intravenously (Eisendrath, 2001). The second technique is the therapeutic double-blind. The physician presents the patient with a new medical intervention to treat his or her illness. The patient is told that one possibility is that the patient's illness has a factitious origin, and that, if so, the treatment would not be expected to work while, if the illness is biological, the treatment will work and the patient will improve. The patient must decide to give up the factitious illness or admit it. A third technique is to provide the patient with a face-saving way, such as hypnosis or biofeedback, of giving up his or her symptoms without admitting that they are not genuine. Eisendrath (2001) points out that in emergent situations, there may not be time for nonconfrontational techniques, and more directly confrontational means may be necessary.

Another important component in the treatment of patients with factitious disorder is the coordination of health care among

all providers. This allows for fewer unnecessary interventions, minimizes splitting among the health care team, and allows the health care team to vent and process the strong emotions that arise when caring for factitious patients. This decreases both the negative impact on the providers and the chance that anger will be acted out on the patient.

There are no clear data supporting the effectiveness of medications in treating factitious disorder. There is a case report of effective pimozide treatment in a patient thought to have delusional symptoms (Prior and Gordon, 1997), as well as a case report of a factitious patient with comorbid depression improving when treated with an antidepressant in addition to intensive psychotherapy.

While many patients with factitious disorder are hesitant to pursue psychiatric treatment, there are numerous case reports of successful treatment of the disorder with long-term psychotherapy. In many of these cases, the therapy lasted several years, including one patient who received treatment while imprisoned for over 10 years. Plassman reports a case series of 24 factitious patients. Twelve of these patients accepted psychotherapy and 10 continued with long-term treatment, lasting up to 4½ years. He reports “significant, or at least marked, improvement” in those 10 patients (Plassman, 1994b). These case reports support the idea that treatment of patients with factitious disorder is not impossible, and these patients can improve. However, expectations must be realistic as improvement in the disorder itself can take several years. Techniques that target short-term reduction in the production of factitious symptoms can be effective more quickly. See Figure 55.2 for a treatment flowchart for factitious disorder.

### Ethical Considerations

Treating patients with factitious disorder often raises ethical questions including those regarding confidentiality, privacy and medical decision-making, and it is important to be alert to these issues. Often, patients with factitious disorder will want to keep their diagnosis confidential, even when to do so may harm the patient or others. For example, although a consulting physician may diagnose a patient with factitious disorder, the patient may refuse consent to reveal this information to the referring physician. If the consultant does inform the referring physician, she has violated the patient’s confidentiality, but if she does not, the referring physician is likely to continue to treat the patient for the incorrect diagnosis. Dilemmas regarding patient privacy also arise with factitious patients. For example, hospital room searches could often help clarify the diagnosis or remove materials the patient is using to harm himself, but these searches also violate the patient’s privacy. Dilemmas surrounding medical decision-making can arise when a patient with factitious disorder refuses treatment or requests potentially harmful treatments. It can often be difficult to resolve these ethical dilemmas. In general, even though the factitious patient is deceptive within the doctor–patient relationship, the physician is not released from his or her responsibilities within that relationship, and the patient retains his or her rights of confidentiality, privacy and autonomy. As with all patients, emergency situations require different ethical guidelines. Often, an ethics consultation can be very helpful in sorting through the difficult issues of patient care in the setting of factitious disorder.

### Factitious Disorder by Proxy

In factitious disorder by proxy, one person creates or feigns illness in another person, usually a child, though occasionally the victim is an elder or developmentally delayed adult. Factitious

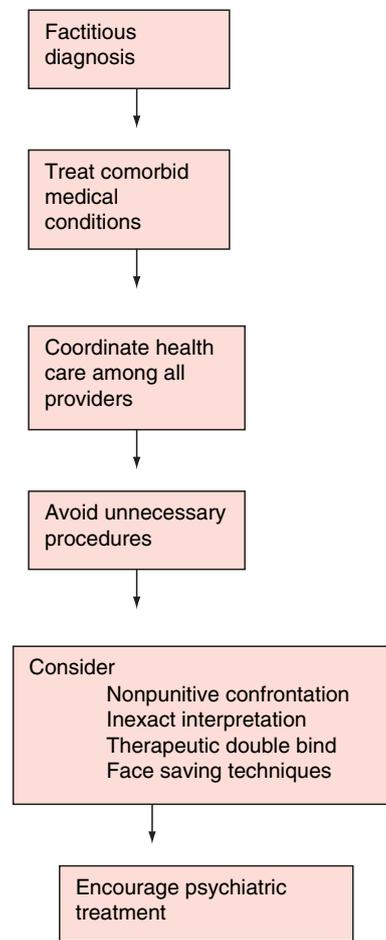

Figure 55.2 Treatment flowchart for factitious disorder.

disorder by proxy is not defined as a specific disorder in DSM-IV but instead is listed under the “not otherwise specified” heading with research criteria included. While rare instances of fathers perpetrating factitious disorder by proxy have been reported, the perpetrator is usually the mother. Usually the victim is a preverbal child. While numerous symptoms have been reported, common presentations include apnea, seizures and gastrointestinal problems. The mothers appear extremely caring and attentive

### DSM-IV-TR Criteria

#### Factitious Disorder by Proxy

- A. Intentional production of or feigning of physical or psychological signs or symptoms in another person who is under the individual’s care.
- B. The motivation for the perpetrator’s behavior is to assume the sick role by proxy.
- C. External incentives for the behavior (such as economic gain) are absent.
- D. The behavior is no better accounted for by another mental disorder.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

when observed, but appear indifferent to the child when they are not aware of being observed (Eisendrath, 2001).

As in factitious disorder, the exact prevalence of factitious disorder by proxy is unknown. There have been studies of the annual incidence of factitious disorder by proxy in the general population in both the UK and New Zealand. In the former, the annual incidence of factitious disorder by proxy in children less than 16 years was found to be 2.0/100 000 (18 total cases) and in the latter, the annual incidence in children under 16 was 0.5/100 000 (128 total cases). As for the incidence within clinical populations, an Argentinean survey of 113 children with FUI found four (3.5%) cases of factitious fever. A survey of 20 090 children brought in with apnea found 54 (0.27%) to be victims of factitious disorder by proxy (Kravitz and Willmott, 1990). Finally, a review of children brought in for treatment of acute, life threatening episodes of diverse etiologies ranging from seizure disorders to electrolyte abnormalities found 1.5% to be factitious (Rahilly, 1991). Factitious disorder by proxy appears to have a much higher mortality rate than self-inflicted factitious disorder. In Rosenberg's survey of 117 victims, there was a 9% mortality rate (Rosenberg, 1987), and of the 54 victims of the disorder in the apnea survey, three index cases and five siblings were dead at follow-up (Kravitz and Willmott, 1990). More recently, McClure found that eight of 128 index cases in the UK were fatal (6.25%) (McClure *et al.*, 1996) while Denny reported no fatalities in 18 index cases (Denny *et al.*, 2001).

The diagnosis of factitious disorder by proxy is usually made by having an index of suspicion in a child with unexplained illnesses. The diagnosis is supported if symptoms occur only in the parent's presence and resolve with separation. Covert video surveillance has been used to diagnose this condition, though it raises questions of invasion of privacy. In general, it has been felt that the welfare of the child overrides the parent's right to privacy.

As counterintuitive as it is to comprehend why anyone would induce illness in oneself, it can be even more difficult to understand inducing illness in one's own child. The perpetrator in factitious disorder by proxy appears to seek not the "sick role" but the "parent to the sick child" role. This role is similar to the sick role in that it provides structure, attention from others, caring and relief from usual responsibilities. The parent also receives some psychological benefit from inducing illness in his or her child. Based on case reports, the parent often has a comorbid personality disorder and a history of family dysfunction.

## Treatment

Due to the high morbidity and mortality, treatment requires at least temporary separation from the parent and notification of local child protective agencies. The perpetrators often face criminal charges of child abuse. There is high psychiatric morbidity in the children: many go on to develop factitious disorder or other psychiatric illnesses themselves. Psychiatric intervention is necessary to ameliorate this morbidity as much as possible in these children. There are some case reports of successful psychotherapeutic treatments of the parents in this disorder.

## Summary

Patients with factitious disorder seek, often desperately, the sick role. Due to the nature of the disorder, the literature on factitious disorder is largely confined to case reports and case series, limiting the information available. Patients with factitious disorder present

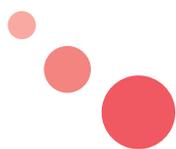

with a broad spectrum of signs and symptoms, and effective diagnosis often requires a high index of suspicion. The differential diagnosis of factitious disorder includes physical illness, somatoform disorders, malingering, psychiatric illness and substance abuse. While factitious disorder is extremely difficult to cure, effective techniques exist to minimize morbidity, and some patients are able to benefit greatly from psychiatric intervention.

## Comparison of DSM-IV/ICD-10 Diagnostic Criteria

The ICD-10 Diagnostic Criteria for Research and the DSM-IV criteria sets are almost identical.

Dissociative phenomena are best understood through the term *désagrégation* (disaggregation) originally given by Janet (1920). Events normally experienced as connected to one another on a smooth continuum are isolated from the other mental processes with which they would ordinarily be associated. The dissociative disorders are a disturbance in the organization of identity, memory, perception, or consciousness. When memories are separated from access to consciousness, the disorder is dissociative amnesia. Fragmentation of identity results in dissociative fugue or dissociative identity disorder (DID; formerly multiple personality disorder). Disintegrated perception is characteristic of depersonalization disorder. Dissociation of aspects of consciousness produces acute stress disorder and various dissociative trance and possession states. Numbing and amnesia are diagnostic components of post traumatic stress disorder (PTSD). These dissociative and related disorders are more a disturbance in the organization or structure of mental contents than in the contents themselves. Memories in dissociative amnesia are not so much distorted or bizarre as they are segregated from one another. The identities lost in dissociative fugue or fragmented in DID are two-dimensional aspects of an overall personality structure. In this sense, patients with DID suffer not from having more than one personality but rather from having less than one personality. The problem involves information processing: the failure of integration of elements rather than the contents of the fragments.

The dissociative disorders have a long history in classical psychopathology, being the foundation on which Freud began his explorations of the unconscious and Janet developed dissociation theory. Although much attention in psychiatry has shifted to diagnosis and treatment of mood, anxiety and thought disorders, dissociative phenomena are sufficiently persistent and interesting that they have elicited growing attention from both professionals and the public. There are at least four reasons for this:

1. They are fascinating phenomena in and of themselves, involving the loss of or change in identity, or memory, or a feeling of detachment from extreme and traumatic physical events.
2. Dissociative disorders seem to arise in response to traumatic stress.
3. Dissociative disorders remain an area of psychopathology for which the best treatment is psychotherapy, although adjunctive pharmacological interventions can be helpful.
4. Dissociation as a phenomenon has much to teach us about information processing in the brain.

### Development of the Concept

The dissociative disorders might have been studied more intensively during the 20th century had not Janet's and Charcot's work

been so thoroughly eclipsed by Freud's psychoanalytic theory, emphasizing as it did repression rather than dissociation.

Hilgard (1977) developed a neodissociation theory that revived interest in Janetian psychology and dissociative psychopathology. He postulated divisions in mental structure that were horizontal rather than vertical, as was the case in Freud's archeological model. This model allowed for immediate access to consciousness of any of a variety of warded-off memories, which is not the case in Freud's system. In the dynamic unconscious model, repressed memories must first go through a process of transformation as they are accessed and lifted from the depths of the unconscious, for example, through the interpretation of dreams or slips of the tongue. In Hilgard's model, amnesia is a crucial mediating mechanism that creates barriers dividing one set of mental contents from another. Thus, flexible use of amnesia is conceptualized as a key defensive strategy. Therefore, reversal of amnesia is an important therapeutic tool.

Repression as a general model for keeping information out of conscious awareness differs from dissociation in four important ways:

1. In repression, information is disguised as well as hidden. Dissociated information is stored in a discrete and untransformed manner, for example, as a memory of some element of a traumatic experience, whereas repressed information is usually disguised and fragmented. Even when repressed information becomes available to consciousness, its meaning is hidden, for example, in dreams or slips of the tongue.
2. Retrieval of repressed information requires translation. Retrieval of dissociated information can often be direct. Techniques such as hypnosis can be used to access warded-off memories. By contrast, uncovering of repressed information often requires repeated recall trials through intense questioning, psychotherapy, or psychoanalysis with subsequent interpretation (i.e., of dreams).
3. Repressed information is not discretely organized temporally. The information kept out of awareness in dissociation is often for a discrete and sharply delimited time, whereas repressed information may be for a type of encounter or experience scattered across times.
4. Repression is less specifically tied to trauma. Dissociation seems to be elicited as a defense most commonly after episodes of physical trauma, whereas repression is in response to warded-off fears, wishes and other dynamic conflicts.

Whether dissociation is a subtype of repression or vice versa, both are important methods for managing complex and affectively charged information. Given the complexity of human information processing, the synthesis of perception, cognition and

**Table 56.1** Models of Mental Experience

Mental Function	Dissociation	Repression
Organization	Horizontal	Vertical
Barriers	Amnesia	Dynamic conflict
Etiology	Trauma	Developmental conflict over unacceptable wishes
Nature of contents	Untransformed: traumatic memories	Disguised, primary process: dreams, slips
Means of access	Hypnosis	Interpretation
Treatment	Psychotherapy emphasizing access, control, and working through traumatic memories	Psychotherapy emphasizing interpretation, transference

affect is a major task. Mental function is composed of a variety of reasonably autonomous subsystems involving a perception, memory storage and retrieval, intention and action. Indeed, the accomplishment of a sense of mental unity is an achievement, not a given. It is remarkable not that dissociative disorders occur at all, but rather that they do not occur more often. Models of mental experience are presented in Table 56.1.

## Epidemiology

Dissociative disorders are not among the more common psychiatric illnesses but are not rare. Few good epidemiological studies have been performed. Some estimate the prevalence at only 1 per 10 000 in the population, but far higher proportions are reported among psychiatric populations. In fact, the prevalence of the disorder seems to be associated to the specific population under study. For example, data from the general population suggest that the numbers are as high as 1%. On the other hand, the data seem to indicate that the numbers are even higher in specialized inpatient populations, as high as 3%.

There has been a rise in reported cases, which may be attributed to greater awareness of the diagnosis among mental health professionals, to the availability of specific criteria, and to previous misdiagnosis of DID as schizophrenia or borderline personality disorder. Some experts attribute possible underdiagnosis to family disavowal of sexual and physical abuse. However, there is also controversy about possible overdiagnosis of the syndrome, while others propose that the increase is the result of hypnotic suggestion and inadequate handling by therapists. Individuals who most commonly have the disorder are highly hypnotizable and therefore especially sensitive to suggestion or cultural influences. Although psychiatrists' expectations amplified with hypnosis may account for some cases, they cannot account for many patients diagnosed without benefit of hypnosis or by "skeptical" psychiatrists.

Women make-up the majority of cases, accounting for 90% of the cases or more, in some studies. Strangely, the most

## DSM-IV-TR Criteria 308.12

### Dissociative

- A. The predominant disturbance is one or more episodes of inability to recall important personal information, usually of a traumatic or stressful nature, that is too extensive to be explained by ordinary forgetfulness.
- B. The disturbance does not occur exclusively during the course of dissociative identity disorder, dissociative fugue, posttraumatic stress disorder, acute stress disorder, or somatization disorder and is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a neurological or other general medical condition (e.g., amnesic disorder due to head trauma).
- C. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

common dissociative disorder diagnosis falls into the "not otherwise specified" category, both in the USA and in nonWestern countries, where dissociative trance and possession trance are the most common dissociative disorder diagnoses. Dissociative disorders are ubiquitous around the world, although the structure of the symptoms varies across cultures. Indeed, the symptomatology reflects cultural biases. In Western cultures, which emphasize the importance of the individual, dissociation often takes the form of dissociated elements of individual personality, while in Eastern cultures, which are more sociocentric, possession trance, in which patients feel themselves to be taken over by an outside entity or entities, is more common.

## Diagnostic Criteria and Treatment

### Dissociative Amnesia

This is the classical functional disorder of episodic memory. It does not involve procedural memory or problems in memory storage, as in Wernicke–Korsakoff syndrome. Furthermore, unlike dementing illnesses, dissociative amnesia is reversible for example, by using hypnosis or narcoanalysis. It has three primary characteristics:

1. Type of memory lost: The memory loss is episodic. The first-person recollection of certain events, rather than knowledge of procedures, is lost.
2. Temporal structure: The memory loss is for one or more discrete time periods, ranging from minutes to years. It is not vagueness or inefficient retrieval of memories but rather a dense unavailability of memories that were encoded and stored. Unlike the situation in amnesic disorders, for example, resulting from damage to the medial temporal lobe in surgery (the case of H.M. [Milner, 1959]), in Wernicke–Korsakoff syndrome, or in Alzheimer's dementia, there is usually no difficulty in learning new episodic information. Thus, the amnesia

of dissociative disorders is typically retrograde rather than anterograde. However, a dissociative syndrome of continuous difficulty in incorporating new information that mimics organic amnesic syndromes has been observed.

3. Type of events forgotten: The memory loss is usually for events of a traumatic or stressful nature. This fact has been noted in the language of the DSM-IV diagnostic criteria. In one study (Coons and Milstein, 1986), the majority of cases involved child abuse (60%) but disavowed behaviors such as marital problems, sexual activity, suicide attempts, criminal activity, and the death of a relative have also been reported as precipitants.

Dissociative amnesia most frequently occurs after an episode of trauma, and its onset may be gradual or sudden.

Dissociative amnesia occurs most often in the third and fourth decades of life. It usually involves one episode, but multiple periods of lost memory are not uncommon. Comorbidity with conversion disorder, bulimia nervosa, alcohol abuse and depression are common, and Axis II diagnoses of histrionic, dependent, or borderline personality disorders occur in a substantial minority of such patients.

Such individuals typically demonstrate not vagueness or spotty memory but rather a loss of any episodic memory for a finite period. They may not initially be aware of the memory loss; that is, they do not remember that they do not remember. They often report being told that they have done or said things that they cannot remember.

Some individuals do suffer from episodes of selective amnesia, usually for specific traumatic incidents, which may be interwoven with periods of intact memory. In these cases, the amnesia is for a type of material remembered rather than for a discrete time period.

### Implicit Effects of Dissociated Memories

Although information is kept out of consciousness in dissociative amnesia, it may well exert an influence on consciousness: out of sight does not mean out of mind. For example, a rape victim with no conscious recollection of an assault nonetheless behaves like someone who has been sexually victimized. Such individuals often suffer detachment and demoralization, are unable to enjoy intimate relationships, and show hyperarousal to stimuli reminiscent of the trauma. This loss of explicit memory with retention of implicit knowledge is similar to priming in memory research. Individuals who have read a word in a list complete a word stem (a partial word such as “pre” for “present”) more quickly if they have seen that word minutes or even hours earlier. This priming effect occurs despite the fact that they cannot consciously recall having read the word, or even the list in which it occurred. When asked in a free recall format to list the word they have seen, they cannot name it, yet they act as though they have seen it and do remember it. Similarly, individuals instructed in hypnosis to forget having seen a list of words nonetheless demonstrate priming effects of the hypnotically suppressed list. It is the essence of dissociative amnesia that material kept out of conscious awareness is nonetheless active and may influence consciousness indirectly.

Individuals with dissociative amnesia generally do not suffer disturbances of identity, except to the extent that their identity is influenced by the warded-off memory. It is not uncommon for such individuals to develop depressive symptoms as

well, especially when the amnesia occurs in the wake of a traumatic stressor.

## Treatment

### Psychotherapy

Often, patients suffering from dissociative amnesia experience spontaneous recovery when they are removed from the stressful or threatening situation, when they feel safe, and/or when exposed to personal cues from their past (i.e., home, pets, family members). In cases where exposure to a safe environment is not enough to restore normal memory functioning, pharmacologically-facilitated interviews may prove useful.

### Hypnosis

Most patients with dissociative disorder are highly hypnotizable on formal testing and are therefore easily able to make use of hypnotic techniques such as age regression. Hypnosis can enable such patients to reorient temporally and therefore achieve access to otherwise dissociated and unavailable memories.

### Abreaction

If there is traumatic content to the warded-off memory, patients may abreact, that is, express strong emotion as these memories are elicited. Such abreactions are rarely damaging in themselves but are not intrinsically therapeutic either. They may be experienced by the patient as a reinflicting of the traumatic stressor. Such patients need psychotherapeutic help in integrating these warded-off memories and the associated affect into consciousness, thereby gaining a sense of mastery over them.

### Screen Technique

One technique that can help bring such memories into consciousness while modulating the affective response to them is a projective technique known as “the screen technique” (Spiegel, 1981). While using hypnosis, such patients are taught to recall the traumatic event as if they were watching it on an imaginary movie or television screen. This technique is often helpful for individuals who are unable to remember the event as if it were occurring in the present, either because for some highly hypnotizable individuals that approach is too emotionally taxing or because others are not sufficiently hypnotizable to be able to engage in such hypnotic age regression. The screen can be employed to facilitate cognitive restructuring of the traumatic memory, for example, by picturing on the left side of the screen some component of the traumatic experience, and on the right side something they did to protect themselves or someone else during it. This makes the memory both more complex and more bearable.

A particularly useful feature of this technique is that it allows for the recollection of traumatic events without triggering an uncontrolled reliving of the trauma, as is the case of traumatic flashbacks. The screen technique provides a “controlled dissociation” between the psychological and somatic aspects of memory retrieval. Individuals can be put into self-hypnosis and instructed to get their body into a state of floating comfort and safety. They can do this by imagining that they are somewhere safe and comfortable: “Imagine that you are floating in a bath, a lake, a hot tub, or just floating in space”. They are reminded that no matter what they see on the screen their bodies are safe and comfortable: “Do the work on your imaginary screen, not in your body”. In this way the tendency for physiological arousal to accompany

and intensify the working through of traumatic memories can be controlled, facilitating the psychotherapeutic work.

The psychotherapy of dissociative amnesia involves accessing the dissociated memories, working through affectively loaded aspects of these memories, and supporting the patient through the process of integrating these memories into consciousness.

### Dissociative Fugue

Dissociative fugue combines failure of integration of certain aspects of personal memory with loss of customary identity and automatism of motor behavior. It involves one or more episodes of sudden, unexpected, purposeful travel away from home, coupled with an inability to recall portions or all of one's past, and a loss of identity or the assumption of a new identity. The onset is usually sudden, and it frequently occurs after a traumatic experience or bereavement. A single episode is not uncommon, and spontaneous remission of symptoms can occur without treatment. Dissociative fugue has the identical DSM-IV TR criteria as that of dissociative amnesia with the exception that it involves travel.

It was originally thought that the assumption of a new identity, as in the classical case of the Reverend Ansel Bourne (James, 1984), was typical of dissociative fugue. However, a review of the literature shows that in the majority of cases there is loss of personal identity but no clear assumption of a new identity.

Many cases of dissociative fugue remit spontaneously. Again, hypnosis can be useful in accessing dissociated material. Not infrequently, fugue episodes represent dissociated but purposeful activity.

Hypnosis can be helpful in treating dissociative fugue by accessing otherwise unavailable components of memory and identity. The approach used is similar to that for dissociative amnesia. Hypnotic age regression can be used as the framework for accessing information available at a previous time. Demonstrating to patients that such information can be made available to consciousness enhances their sense of control over this material and facilitates therapeutic working through of emotionally laden aspects of it.

Once reorientation is established and the overt identity and memory loss of the fugue have been resolved, it is important to work through interpersonal or intrapsychic issues that underlie the dissociative defenses. Such individuals are often relatively unaware of their reactions to stress because they can so effectively dissociate them. Thus, effective psychotherapy is anticipatory, helping patients to recognize and modify their tendency to set aside their own feelings in favor of those of others.

Patients with dissociative fugue may be helped with a psychotherapeutic approach that facilitates conscious integration of dissociated memories and motivations for behavior previously experienced as automatic and unwilling. It is often helpful to address current psychosocial stressors, such as marital conflict, with the involved individuals, as in the case of the woman found on the army base. To the extent that current psychosocial stress triggers fugue, resolution of that stress can help resolve it and reduce the likelihood of recurrence. Highly hypnotizable individuals prone to these extreme dissociative symptoms often have great difficulty in asserting their own point of view in a personal relationship. Rather, they interact with others as though they were undergoing a spontaneous trance experience. One such individual described herself as a "disciple in search of a teacher". Psychotherapy can help such individuals recognize and modify

their tendency to unthinking compliance with others and extreme sensitivity to rejection and disapproval.

In the past, medication facilitated interviews were used to reverse dissociative amnesia or fugue. However, such techniques offer no advantage over hypnosis and are not especially effective. Not infrequently, the ceremony of injecting the drug elicits spontaneous hypnotic phenomena before the pharmacological effect is felt, and sedation, respiratory depression and other side effects can be troublesome. It also promotes dependency on the therapist. On the contrary, when hypnosis is used, patients are trained on self-hypnotic techniques, promoting the use of hypnosis instead of spontaneous dissociation. This enhances the patients' level of control while enhancing a sense of mastery and self-control.

---

#### Clinical Vignette 1

A woman who appeared dazed but physically unharmed was brought into an army hospital emergency department by the base guards because she had been found wandering nearby. She said that she did not know who she was, where she lived, or how she happened to be there. Initially, plans were made to admit her to the hospital for a full neurological and psychiatric evaluation. She proved to be highly hypnotizable, and hypnosis age regression was used to take her back to an earlier year. She then reported her name and that she lived some 500 miles away. The time was changed again to a period just before this apparent fugue episode. She reported having received unsigned letters from someone at that army base, where, it turned out, her husband was stationed. These letters suggested that her husband was having an affair. This had deeply upset her. She and her husband were reunited and reconciled, and the fugue episode ended.

### Depersonalization Disorder

This dissociative disorder involves lack of integration of one or more components of perception. The essential feature of depersonalization disorder is the occurrence of persistent feelings of unreality, detachment, or estrangement from oneself or one's body, usually with the feeling that one is an outside observer of one's own mental processes (American Psychiatric Association, 2000). Individuals suffering depersonalization are distressed by it. They are aware of some distortion in their perceptual experience and therefore are not hallucinating or delusional. Affected individuals often fear that they are "going crazy". The symptom is not infrequently transient.

Derealization, in which affected individuals notice an altered perception of their surroundings, resulting in the world seeming unreal or dream-like, frequently occurs as well. Such individuals often ruminate anxiously about this symptom and are preoccupied with their own somatic and mental functioning.

Depersonalization frequently cooccurs with a variety of other symptoms, especially anxiety, panic, or phobic symptoms. It is often a symptom of PTSD and also occurs as a symptom of alcohol and drug abuse, as a side effect of the use of prescription medication, and during stress and sensory deprivation. The symptom of depersonalization is also commonly seen in the course of a number of other neurological and psychiatric disorders. It is considered a disorder when it is a persistent and predominant symptom. The phenomenology of the disorder involves both the

initial symptoms themselves and the reactive anxiety caused by them.

## Treatment

Depersonalization is most often transient and may remit without formal treatment. Recurrent or persistent depersonalization should be thought of both as a symptom in itself and as a component of other syndromes requiring treatment, such as anxiety disorders and schizophrenia.

### DSM-IV-TR Criteria 300.6

#### Depersonalization Disorder

- A. Persistent or recurrent experiences of feeling detached from, and as if one is an outside observer of, one's mental processes or body (e.g., feeling like one is in a dream).
- B. During the depersonalization experience, reality testing remains intact.
- C. The depersonalization causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- D. The depersonalization experience does not occur exclusively during the course of another mental disorder, such as schizophrenia, panic disorder, acute stress disorder, or another dissociative disorder, and is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., temporal lobe epilepsy).

The symptom itself may respond to training in self-hypnosis. Paradoxically, induction or deliberate worsening of symptoms may provide relief by teaching a method of controlling them. For example, a hypnotic induction may induce transient depersonalization symptoms, such as a sense of detachment from part of the body, in such individuals. This is a useful exercise, in that by having a structure for inducing the symptoms, one provides the patient with a context for understanding and controlling them. They are presented as a spontaneous form of hypnotic dissociation that can be modified. Such individuals can be taught to induce a pleasant sense of floating lightness or heaviness in place of the anxiety-related somatic detachment. The use of an imaginary screen to picture problems in a way that detaches them from the typical somatic response is also helpful. Other relaxation techniques such as systematic desensitization, progressive muscle relaxation and biofeedback may also be of help. Psychotherapy aimed at working through emotional responses to any traumatic or other stressors that tend to elicit the depersonalization is also helpful.

Pharmacological approaches involve balancing therapeutic benefit and risk. Antianxiety medications are most commonly used and may be helpful in reducing the amplification of depersonalization caused by anxiety. However, depersonalization and derealization are also side effects of antianxiety drugs, so their use should be carefully monitored. Increasing dosage, a standard

technique when there is lack of therapeutic response, may also increase symptoms, leading to a spiral of increasing symptoms and drug dosage but without therapeutic benefit.

However, appropriate pharmacological treatment for comorbid disorders is an important part of treatment. Use of antianxiety medications for generalized anxiety or phobic disorders or of antipsychotic medications for psychotic disorders is often beneficial in conditions in which there is contributory comorbidity.

## Dissociative Identity Disorder (Multiple Personality Disorder)

Dissociative identity disorder is a rare but real disorder that is the most widely discussed of the dissociative disorders. It involves the “presence of two or more distinct identities or personality states (each with its own relatively enduring pattern of perceiving, relating to, and thinking about the environment and self)” (American Psychiatric Association, 2000). The diagnostic criteria also require that “At least two of these identities or personality states recurrently take control of the person's behavior” (American Psychiatric Association, 2000), and that there be amnesia: “Inability to recall important personal information that is too extensive to be explained by ordinary forgetfulness” (American Psychiatric Association, 2000). It is a failure of integration of various aspects of identity and personality structure. Often different relationship styles (dependent versus assertive/aggressive) and mood states (depressed versus hostile) segregate with different identities and personal memories. Such patients may be mystified by events that occurred in another “state”, or by responses of others to them for behavior that occurred in a different “state”. This fragmentation of personality often occurs in response to trauma in childhood, and is perceived by the patient as protective, allowing him or her to tolerate and partially evade chronic abuse. These patients thus view treatment ambivalently as an attempt to deprive them of a defense against attack. They also tend to see others as irrational

### DSM-IV-TR Criteria 308.14

#### Dissociative Identity Disorder

- A. The presence of two or more distinct identities or personality states (each with its own relatively enduring pattern of perceiving, relating to, and thinking about the environment and self).
- B. At least two of these identities or personality states recurrently take control of the person's behavior.
- C. Inability to recall important personal information that is too extensive to be explained by ordinary forgetfulness.
- D. The disturbance is not due to the direct physiological effects of a substance (e.g., blackouts or chaotic behavior during alcohol intoxication) or a general medical condition (e.g., complex partial seizures). **Note:** In children, the symptoms are not attributable to imaginary playmates or other fantasy play.

and unfair, since response to one aspect of their personality frequently reflects experience with other aspects. One DID patient (prior to diagnosis) reported puzzlement about accusations by friends and acquaintances that she had made hostile comments for which she had no memory. She would find people angry at her for no reason. Thus their personality fragmentation renders them vulnerable to interpersonal problems yet gives them the belief that they are relatively protected from them.

## Prevalence

There are no convincing studies of the absolute prevalence of DID, although there is widespread agreement that the number of diagnosed cases has increased considerably in the USA and some European countries in the past two decades. Two studies have estimated the prevalence as approximately 1% of psychiatric inpatients (Saxe *et al.*, 1993; Ross *et al.*, 1991). Factors that may account for the increase in the number of true reported cases include 1) more general awareness of the diagnosis among mental health professionals, 2) the availability of specific diagnostic criteria starting with DSM-III and 3) reduced misdiagnosis of DID as schizophrenia or borderline personality disorder.

Other authors attribute the increase in reported cases to social contagion, hypnotic suggestion and misdiagnosis. Proponents of this point of view argue that these individuals are highly hypnotizable and therefore quite suggestible. They would therefore be especially vulnerable to direct or implicit hypnotic suggestion. They note that not infrequently a few specialist psychiatrists make the vast majority of diagnoses. However, it has been observed that the symptoms of patients diagnosed by specialists in dissociation do not differ from those of patients diagnosed by psychiatrists, psychologists and physicians in more general practice who diagnose one or two cases a year. Furthermore, such patients have been noted to persist in presenting symptoms for an average of 6.5 years before attaining the diagnosis. They encounter many psychiatrists who are convinced that they do not have DID and that they have some other disorder, such as schizophrenia. Were they so easily suggestible, it seems likely that they would accept a suggestion that they have other disorders as well, such as schizophrenia or borderline personality disorder.

Nonetheless, because these patients are indeed highly hypnotizable and therefore suggestible, care must be taken in the manner in which the illness is presented to them. However, it is unlikely that the increased number of cases currently reported is accounted for by suggestion alone. Reduction in previous misdiagnosis and increased recognition of the prevalence and sequelae of physical and sexual abuse in childhood are also reasonable explanations.

## Course

The disorder is more frequently recognized during childhood but typically emerges between adolescence and the third decade of life; it rarely presents as a new disorder after age 40 years, but there is often considerable delay between initial symptom presentation and diagnosis.

Untreated, it is a chronic and recurrent disorder. It rarely remits spontaneously, but the symptoms may not be evident for certain time periods. DID has been called “a disease of hiddenness” (Schacter, 1995). The dissociation itself hampers self-monitoring and accurate reporting of symptoms and history. Many patients with the disorder are not fully aware of the extent of their dissociative symptoms. They may be reluctant to bring up symptoms because of confusion or shame about the illness

or because they encountered previous skepticism. Furthermore, because the majority of patients report histories of sexual and physical abuse, the shame associated with that and fear of retribution may inhibit reporting of symptoms as well.

## Comorbidity

The major comorbid psychiatric illnesses are the depressive disorders, substance use disorders and borderline personality disorder. Sexual, eating, and sleep disorders cooccur less commonly. Such patients frequently display self-mutilative behavior, impulsiveness, and overvaluing and devaluing of relationships. Indeed, approximately a third of patients with DID have symptoms that fit criteria for borderline personality disorder as well. Such individuals are also more frequently depressed. Conversely, research shows dissociative symptoms in many patients with borderline personality disorder, especially those who report histories of physical and sexual abuse. Indeed, the impulsiveness, splitting, hostility and fear of abandonment, frequently seen in certain personality states, are similar to the presentation of many patients with borderline personality disorder. Many such patients also have symptoms that meet criteria for PTSD, with intrusive flashbacks, recurrent dreams of physical and sexual abuse, avoidance of and loss of pleasure in usually pleasurable activities, and symptoms of hyperarousal, especially when exposed to reminders of childhood trauma.

Thus, comorbidity is a complex issue. In addition, these patients are not infrequently misdiagnosed as having schizophrenia (Kluft, 1987). This diagnostic confusion is understandable in that they have an apparent delusion that their bodies are occupied by more than one person. In addition, they frequently have auditory hallucinations when one personality state speaks to or comments on the activities of another. When misdiagnosed as schizophrenic, patients with DID are frequently given neuroleptics, which results in a poor therapeutic response and a flattening of affect, which tends to confirm the misdiagnosis (since flat affect is characteristic of schizophrenia).

Individuals with DID commonly report somatic or conversion symptoms and other psychosomatic symptoms, such as migraine headaches. Studies have shown that approximately a third of these patients have complex partial seizures (Schenk and Bear, 1981), although later studies did not show seizure rates that high. Furthermore, the studies did not show substantial elevations in scores on Dissociative Experiences Scale in patients with complex partial seizures as compared with those of other neurological patients (Loewenstein and Putnam, 1988). However, there is sufficient comorbidity that patients recently diagnosed with DID should be evaluated for the possibility of a seizure disorder.

## Psychological Testing

The diagnosis can be facilitated by psychological testing. Scales of trait dissociation have been developed (Bernstein and Putnam, 1986; Ross, 1989; Carlson *et al.*, 1993), and patients with DID score extremely high on these scales, in contrast to normal populations and other groups of patients. Those with DID score far higher than normal individuals on standard measures of hypnotizability, whereas schizophrenic patients tend to have lower than normal scores or the absence of high hypnotizability. Thus, there is comparatively little overlap in the hypnotizability scores of patients with schizophrenia and those with DID. Form level on the Rorschach test is usually within the normal range, but there are frequent emotionally dramatic responses, often involving mutilation (especially with the color cards) of a type that is often seen

in histrionic personality disorder as well. Form level is an assessment of the match between the percept (what the subject reports seeing) and the inkblot structure. Good form level involves relatively little distortion of the image to match percept to inkblot. Good form level is useful in distinguishing patients with DID from those with schizophrenia, who have poor form level.

## Treatment

### Psychotherapy

#### Therapeutic Direction

It is possible to help patients with DID gain control over the dissociative process underlying their symptoms in several ways. The fundamental psychotherapeutic stance should involve meeting patients halfway, a form of structured empathy in which their experience of themselves as fragmented is acknowledged while the reality that the fundamental problem is a failure of integration of disparate memories and aspects of the self is kept in view. In this sense, such individuals suffer from having less than one personality rather than more than one. Therefore, the goal in therapy is to facilitate integration of disparate elements. This can be done in a variety of ways.

Secrets are frequently a problem with such patients, who attempt to use the psychiatrist to reinforce a dissociative strategy of withholding relevant information from certain personality states. Such patients often like to confide in the psychiatrist with the idea that the information is to be kept from other parts of the self, for example, traumatic memories or plans for self-destructive activities.

Clear limit setting and commitment on the part of the psychiatrist to helping all portions of the patient's personality structure learn about warded-off information are important. It is wise to clarify explicitly that the psychiatrist will not become involved in secret collusion. Furthermore, when important agreements are negotiated, such as commitments on the part of patients to seek medical help before acting on a thought to harm themselves or others, it is useful to discuss with the patients that this is an "all-points bulletin", requiring attention from all the relevant personality states. The excuse that certain personality states were "not aware" of the agreement should not be accepted.

#### Hypnosis

Hypnosis can be helpful in facilitating psychotherapy as well as establishing the diagnosis. First of all, the simple structure of hypnotic induction may elicit dissociative phenomena. Hypnosis can be helpful in facilitating access to dissociated personalities. They may simply occur spontaneously during hypnotic induction. An alternative strategy is to hypnotize the patient and use age regression to reorient to a time when a different personality state was manifest. An instruction later to change times back to the present usually elicits a return to the other personality state. This then becomes a means of teaching such an individual how to control the dissociative process.

Alternatively, entering the state of hypnosis may make it possible simply to address and elicit different identities or personality states. Patients can be taught a simple self-hypnosis exercise for this purpose. For example, the patient can be told to count to herself or himself from one to three. After some formal exercises such as this, it is often possible to ask the patient to speak with a given alter personality, without the formal use of

hypnosis. Merely asking to talk with a given identity usually suffices after a while.

#### Memory Retrieval

Because the loss of memory in DID is complex and chronic, its retrieval is likewise a more extended and integral part of the psychotherapeutic process. The therapy becomes an integrating experience of information sharing among disparate personality elements. Conceptualizing DID as a chronic PTSD, the psychotherapeutic strategy involves a focus on working through traumatic memories in addition to controlling the dissociation.

Controlled access to memories greatly facilitates psychotherapy. As with dissociative amnesia, a variety of strategies can be employed to help patients with DID break down amnesic barriers. Eliciting various identities or personality states can facilitate access to memories previously unavailable to consciousness. While so-called "pseudomemories" can occur, previously dissociated traumatic memories are often accurate.

Once these memories of earlier traumatic experience have been brought into consciousness, it is crucial to help the patient work through the painful affect, inappropriate self-blame and other reactions to these memories. It may be useful to have patients visualize the memories rather than relive them as a means of making their intensity more manageable. It can also be useful to have patients divide the memories, for example, picturing on one side of an imaginary screen something an abuser did to them and on the other side how they tried to protect themselves from the abuse.

Such techniques can help make the traumatic memories more bearable by placing them in a broader perspective, one in which trauma victims can also identify adaptive aspects of their response to the trauma.

This and similar approaches can help these individuals work through traumatic memories, enabling them to bear them in consciousness and therefore reducing the need for dissociation as a means of keeping such memories and associated painful affect out of consciousness. Although these techniques can be helpful and often result in reduced fragmentation and integration, a number of complications can occur in the psychotherapy of these patients.

The therapeutic process can be thought of as a kind of grief work in which information retrieved from memory is reviewed, traumatic memories are put into perspective, and emotional expression is encouraged and worked through, thereby making it more possible to endure and disseminate the information as widely as possible among various parts of the patient's personality structure. Instructions to other alter personalities to "listen" while a given one is talking and reviewing previously dissociated material can be helpful.

#### The Rule of Thirds

The psychotherapy of DID can be a time-consuming and emotionally taxing process. The rule of thirds (Kluft, 1991; Schacter, 1995) is a helpful guideline. Spend the first third of the psychotherapy session assessing the patient's current mental state and life problems and defining a problem area that might benefit from retrieval into conscious memory and working through. Spend the second third of the session accessing and working through this memory. Allow a final third for helping the patient assimilate the information, regulate and modulate emotional responses, and discuss any responses to the psychiatrist and plans for the immediate future. The psychiatrist may resist doing this because

the intense abreactive materials are often so compelling and interesting. The patient may also resist sharing information across personalities. Nonetheless, the psychiatrist can be helpful in imposing structure on often chaotic memories and identity states.

Given the intensity of the material that often emerges involving memories of sexual and physical abuse and sudden shifts in mental state accompanied by amnesia, the psychiatrist is called on to take a clear and structured role in managing the psychotherapy. Appropriate limits must be set concerning self-destructive or threatening behavior, agreements must be made regarding physical safety and treatment compliance, and other matters must be presented to the patient in such a way that dissociative ignorance is not an acceptable explanation for failure to live up to the agreements.

### Traumatic Transference

Transference applies with special meaning to patients who have been physically and sexually abused, especially in childhood. They have experienced individuals who are presumed to be caretakers acting instead in an exploitative and sometimes sadistic fashion. They thus expect similar betrayal from psychiatrists. Although their reality testing is good enough that they can perceive genuine caring, they often unconsciously expect psychiatrists to exploit them. They may experience working through of traumatic memories as a reinflicting of the trauma, with the psychiatrist taking sadistic pleasure in their suffering. They may expect excessive passivity on the part of the psychiatrist, identifying the psychiatrist with some uncaring family figure who knew that abuse was occurring but did little or nothing to stop it. It is important in managing the therapy to keep these issues in mind and make them frequent topics of discussion. This can diffuse, if not eliminate, such traumatic transference distortions of the therapeutic relationship.

### Integration

The ultimate goal of psychotherapy is integration of these multiple ego states. It is often the case that one or more of the personality states may exert considerable resistance to the process of integration, particularly early in the process of therapy. Also patients may experience efforts of integration as an attempt on the part of the therapist to “kill” personalities. These fears must be worked through and the patient needs to understand that the goal is to learn how to control the episodes of dissociation. This gives patients a sense of gradually being able to control their dissociative processes in order to work through the traumatic memories. In order to enhance mastery and control, the process of the psychotherapy must help patients minimize rather than reinforce the content of traumatic memories, which often involves reexperiencing a sense of helplessness in a symbolic reenactment of the trauma.

At the same time, the dissociative defense represents an internalization of the abusive people in the patient’s past, a kind of identification with the aggressor, which makes the patient feel powerful rather than helpless. Setting aside the defense also means acknowledging and bearing the helplessness of having been victimized and working through the irrational self-blame that gave such individuals a fantasy of control over events during which they were helpless. Yet, difficult as it is, ultimately the goal of psychotherapy is mastery over the dissociative process, controlled access to dissociative states, integration of warded-off painful memories and material, and a more integrated continuum of identity, memory and consciousness. Although there have been no controlled trials of the outcome of psychotherapy

**Table 56.2 Stages of Therapy**

Stage	Technique
Establishing treatment	Education, atmosphere of safety, instill confidence
Preliminary interventions	Confirm diagnosis, set limits, access dissociation with hypnosis
History gathering	Explore components of dissociative structure
Working through trauma	Grief work
Move toward integration	Enhance communication across dissociative states
Integration–resolution	Encourage development of integrated self
Learning coping skills	Help with life decisions and relationships
Solidification of gains	Transference examination
Follow-up	Maintenance

for this disorder, case series reports indicate a positive outcome in a majority of cases (Kluft, 1984, 1986, 1991).

The stages of therapy are presented in Table 56.2.

### Psychopharmacology

As with other dissociative disorders, there is little evidence that psychoactive drugs are of great help in reversing dissociative symptoms (Maldonado *et al.*, 2000). In the past, short-acting barbiturates such as sodium amobarbital were used intravenously to reverse functional amnesia, but this technique is no longer employed, largely because of poor results. Research data provide no evidence suggesting that any medication regimen has any significant therapeutic effect on the dissociative process manifested by DID patients. To date, pharmacological treatment has been limited to symptom control or the management of comorbid conditions (e.g., depression).

Of all available classes of psychotropic agents, antidepressants are the most useful class for the treatment of patients with DID. That is because patients suffering from dissociation frequently experience comorbid dysthymic or major depressive disorder. The newer agents – selective serotonin reuptake inhibitors (SSRIs) – are particularly useful, given their high level of effectiveness, low side-effect profile, and even lower danger in overdose, compared with tricyclic antidepressants and monoamine oxidase inhibitors. Nevertheless, medication compliance may be a problem with dissociative patients because dissociated personality states may interfere with medication taking or may take the medication in an overdose attempt.

Benzodiazepines have mostly been used to facilitate recall by controlling secondary anxiety associated with retrieval of traumatic memories (i.e., medication facilitated interviews). Nevertheless, despite their short-term usefulness, CNS-depressant agents may cause sudden mental state transitions, which may in

turn increase rather than decrease amnesic barriers. Therefore, as useful as they could be on short-term basis (i.e., acute management of a panic attack), the long term of these agents may, in fact, contribute rather than treat dissociative episodes.

There are several uses for anticonvulsant agents. We know that seizures disorders have a high rate of comorbidity with DID. Thus, anticonvulsant agents may help control the dissociation associated with epileptogenic activity. On the other hand, anticonvulsant agents have proven to be effective in the management of mood disorders, as well as the impulsiveness associated with personality disorders and brain injury. Also despite their effectiveness, these agents produce less amnesic side effects than the benzodiazepines and thus may be preferred. On the other hand, the need for closer monitoring due to potential toxicity, particularly in overdoses, makes their use less desirable than the newer SSRIs.

Of all pharmacological agents available, antipsychotics may be the less desirable. First, they are rarely useful in reducing dissociative symptoms. In fact, there have been reports of increased levels of dissociation and an increased incidence of side effects when used in patients suffering from dissociative disorders.

## Dissociative Trance Disorder

### Dissociative Trance

Dissociative trance disorder has been divided into two broad categories, dissociative trance and possession trance (American Psychiatric Association, 2000). Dissociative trance phenomena are characterized by a sudden alteration in consciousness, not accompanied by distinct alternative identities. In this form the dissociative symptom involves an alteration in consciousness rather than identity. Also, in dissociative trance, the activities performed are rather simple, usually involving sudden collapse, immobilization, dizziness, shrieking, screaming, or crying. Memory is rarely affected, and if there is amnesia, it is fragmented.

Dissociative trance phenomena frequently involve sudden, extreme changes in sensory and motor control. A classic example is the *ataque de nervios*, prevalent in Latin American countries. For example, this phenomenon is estimated to have a 12% lifetime prevalence rate in Puerto Rico (Lewis-Fernandez, 1994). A typical episode involves a sudden feeling of anxiety, followed by total body shakes, which may mimic convulsions. This is then followed by hyperventilation, unintelligible screaming, agitation and often violent bodily movements. Often, this is followed by collapse and probably transient loss of consciousness. After the episode is over, subjects complain of fatigue and having been confused, although this behavior is dramatically different from classic postictal states. Some subjects may experience amnesia at least to some aspects of the event (Lewis-Fernandez, 1994).

Other examples include **lata** and “falling out”. **Lata** represents the Malay version of trance disorder. In these episodes, afflicted individuals usually experience a sudden vision, mostly of a threatening spirit. The observable behavior includes screaming or crying and physical manifestation of overtly violent behavior which often requires the sufferer to be physically restrained. Patients often report episodes of amnesia, but there is no clear possession by the offending spirit. On the other hand, “falling out” more commonly occurs among African-Americans in the southern USA. Similarly to other trance episodes, the affected individual may enter a trance state, followed by bodily collapse, the

## DSM-IV-TR Criteria

### Dissociative Trance Disorder

A. Either (1) or (2):

- (1) trance, i.e., temporary marked alteration in the state of consciousness or loss of customary sense of personal identity without replacement by an alternate identity, associated with at least one of the following:
  - (a) narrowing of awareness of immediate surroundings, or unusually narrow and selective focusing on environmental stimuli
  - (b) stereotyped behaviors or movements that are experienced as being beyond one's control
- (2) possession trance, a single or episodic alteration in the state of consciousness characterized by the replacement of customary sense of personal identity by a new identity. This is attributed to the influence of a spirit, power, deity, or other person, as evidenced by one (or more) of the following:
  - (a) stereotyped and culturally determined behaviors or movements that are experienced as being controlled by the possessing agent
  - (b) full or partial amnesia for the event

B. The trance or possession trance state is not accepted as a normal part of a collective cultural or religious practice.

C. The trance or possession trance state causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

D. The trance or possession trance state does not occur exclusively during the course of a psychotic disorder (including mood disorder with psychotic features and brief psychotic disorder) or dissociative identity disorder, and is not due to the direct physiological effects of a substance or a general medical condition.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

inability to see or speak, despite the fact that they are fully conscious. Temporary confusion may be observed, although subjects are not usually amnesic to what occurred during the episode.

### Possession Trance

In contrast to dissociative trance episodes, possession trance involves the assumption of a distinct alternative identity. The new identity is presumed to be that of a deity, ancestor, or spirit who has transiently taken possession of the subject's mind and body. Different from dissociative trance episodes, which are characterized by rather crude, simplistic, regressive-like behaviors, possession trance victims often exhibit rather complex behavior. During these episodes, subjects may, for example, express otherwise forbidden thoughts or needs, engage in unusually and uncharacteristic aggressive behavior (e.g., verbal or physical expressions of aggression), or may attempt to negotiate for change in family or social status. Also, in contrast to dissociative trance

episodes, possession trance episodes often are followed by dense amnesia for a large portion of the episode during which the spirit identity was in control of the subject's behavior.

### Cultural Context

Dissociative-like phenomena have been described in virtually every culture. Yet they appear to be more prevalent in the less heavily industrialized Second and Third World countries. Studies on the prevalence of dissociative disorders in India have suggested that the 1-year prevalence of dissociative trance disorder is approximately 3.5%; of all psychiatric hospitalizations, making it a highly frequent mental disorder. Trance and possession syndromes are by far the most common type of dissociative disorders seen around the world. On the other hand, DID, which is relatively more common in the USA, is virtually never diagnosed in underdeveloped countries. This difference in prevalence and distribution of dissociative disorder across different populations may be mediated by cultural as well as biological factors. For example, Eastern culture is far more sociocentric than Western culture. Thus, being "possessed" by an outside entity would be more culturally comprehensible and acceptable in the East. On the other hand, an apparent proliferation of individual identities would fit better with the Western preoccupation with individualism. Nonetheless, the underlying dissociative mechanism inhibiting integration of perception, memory and identity may suggest a common underlying mechanism amongst these dissociative syndromes.

Trance and possession episodes are usually understood as an idiom of distress and yet they are not viewed as normal. That is, they are not a generally accepted part of cultural and religious practice, which often does involve normal trance phenomena, such as trance dancing in the Balinese Hindu culture. Trance dancers enjoy the remarkable privilege of being the only portion of this socially rigid society able to elevate their social status. The way they are able to do that is by developing the ability to enter trance states. During these altered states of consciousness, which usually occur within the context of a socially acceptable ceremony setting, they dance over hot coals, hold a sword at their throat, or in other ways exhibit supernormal powers of concentration and physical prowess. The mechanism mediating these phenomena is not fully understood, but there is evidence of elevations in plasma noradrenaline, dopamine and beta-endorphin among Balinese trance dancers during trance states. This form of trance is considered socially normal and even exalted.

By contrast, disordered trance and possession trance are viewed by the local community as an aberrant form of behavior that requires intervention. Such symptoms often arise in the context of family or social distress, for example, discomfort in a new family environment. Thus, cultural informants make it clear that people with dissociative trance disorder are abnormal.

## Treatment

### Dissociation and Trauma

One of the important developments in the modern understanding of dissociative disorders is the establishment of a clearer link between trauma and dissociation. Trauma can be understood as the experience of being made into an object, a thing, the victim of someone else's rage or of nature's indifference. Trauma represents the ultimate experience of helplessness: loss of control over one's own body. There is growing clinical evidence that dissociation occurs as a defense during traumatic experiences, constituting

an attempt to maintain mental control at the moment when physical control has been lost. Assault victims report floating above their body, feeling sorry for the person being assaulted beneath them. Patients, victims of childhood abuse, have reported "taking themselves elsewhere" where they could "safely play" by themselves or with imaginary friends, while their bodies were brutally abused by a perpetrator. In fact, there is evidence (Terr, 1991) that children exposed to multiple traumas as opposed to single-blow traumas are more likely to use dissociative defense mechanisms, which include spontaneous trance episodes and amnesia.

As noted in the section on DID, there is an accumulating literature suggesting a connection between a history of childhood physical and sexual abuse and the development of dissociative symptoms. Similarly, dissociative symptoms have been found to be more prevalent in patients with Axis II disorders, such as borderline personality disorder, when there has been a history of childhood abuse. Another means of examining the putative connection between dissociation and trauma is to look at the prevalence of dissociative symptoms after recent trauma. If it is indeed the case that trauma seems to elicit dissociative symptoms, they should be observable in the immediate aftermath of trauma. In the early literature examining responses to trauma, Lindemann (1944), studying the aftermath of the Coconut Grove fire, observed that the individuals who acted as though little or nothing had happened had an extremely poor long-term prognosis. These were individuals who had been injured or had lost loved ones. Indeed, it was the absence of post traumatic symptoms in this group, compared with the agitation, dysphoria, and restlessness that typified the majority of survivors, that led him to formulate the normal process of acute grief. Several subsequent researchers have observed that psychic numbing is a predictor of later PTSD symptoms.

Research on survivors of other life-threatening events, including hostage taking, indicated that more than half have experienced a sense of detachment, feelings of unreality (i.e., depersonalization), lack of emotions, hyperalertness, and automatic movements. Although these dissociative responses to traumatic stressors have been conceptualized as adaptive defenses to overwhelming situations, the thrust of the literature indicates that the presence of dissociative symptoms in the immediate aftermath of trauma is a strong predictor of the development of later PTSD. Physical trauma seems to elicit dissociation, perhaps in individuals who are prone to the use of this defense by virtue of either previous traumatic experience or a constitutional tendency to dissociate. This dissociative reaction may, in some cases, resolve quickly. However, in others it may become the matrix for later post traumatic symptoms, such as dissociative amnesia for the traumatic episode. Indeed, more extreme dissociative disorders, such as DID, have been conceptualized as chronic PTSDs (Kluft, 1984, 1991; Spiegel, 1985, 1986b). Recollection of trauma tends to have an off-on quality involving either intrusion or avoidance (Horowitz, 1976), in which victims either intensively relive the trauma as though it were recurring or have difficulty remembering it. Thus, physical trauma seems to elicit dissociative responses, which, in turn, predispose to the development of later PTSD, perhaps by reducing the likelihood of working through the traumatic experiences afterward.

### Acute Stress Disorder

Although acute stress disorder is classified among the anxiety disorders in DSM-IV-TR (American Psychiatric Association, 2000)

(see acute stress disorder criteria on p. 635) mention is made of it in this chapter because half of the symptoms of this disorder are dissociative in nature. These diagnostic criteria would designate approximately a third of individuals exposed to serious trauma as symptomatic. As noted, dissociative symptoms occurring at the time of the trauma are strongly predictive of later development of PTSD and are associated with higher cortisol levels during exposure to uncontrollable stress. Similarly, the occurrence of PTSD is predicted by intrusion, avoidance and hyperarousal symptoms in the immediate aftermath of rape and combat trauma. Although most individuals experiencing serious trauma are initially symptomatic, the majority recover without developing PTSD. Most studies demonstrate that 25% or less of those who experience serious trauma later become symptomatic.

This diagnostic category is useful not only for research on the normal and abnormal processes of adjusting to trauma, but also as a means of providing an important opportunity for early intervention and thus prevention of later psychopathology. Even though dissociation has a role at the time of trauma, if the defense persists too long it may interfere with the working through of traumatic material. Lindemann (1944) described the term **grief work**, referring to process needed to put traumatic experience into perspective and reduce the likelihood of later symptoms. In this context, psychotherapy, aimed at helping individuals acknowledge, bear and put into perspective a traumatic experience shortly after the trauma, should be helpful in reducing the incidence of later PTSD.

## Theoretical and Research Issues: Models and Mechanisms of Dissociation

### Dissociation and Information Processing

Dissociation may seem like a historical aberration, a throwback to earlier and more primitive models of the mind. Yet these disorders are surprisingly congruent with information processing-based theories of mental function. For example, connectionist and parallel distributed processing models (Rumelhart and McClelland, 1986) take a bottom-up rather than a top-down approach to cognitive organization. Traditional models emphasize a supraordinate structure in which broad categories of information structure the processing of specific examples of those categories, that is, the category “sweet” must exist to make sense of “sugar”, “candy” and “jelly”. In the parallel distributed processing models, subunits or neural nets process information through patterns of cooccurrence of input stimuli that lead to activation patterns in these neural nets, which produce pattern recognition. The output of one neuronal system becomes the input to another, thereby gradually building up integrated and complex patterns of activation and inhibition. A bottom-up processing model system has the advantage of accounting for the processing of vast amounts of information and the ability to recognize patterns with approximate information. Nevertheless, such models make the classification and integration of information problematical.

Information seems to be processed on the basis of the cooccurrence of patterns of activation rather than its appearance in a predefined category. Therefore, in parallel distributed processing system models, failures in integration of mental contents are theoretically likely to occur. Inappropriate but apparent similarities may appear when activation patterns are similar and, conversely, no two pieces of information are necessarily connected. There have been models created to explain psychotic, dissociative and

mood disorders, based on abnormal or defective neuronal association network patterns. These neural models assumed that when there are problems with the processing of input information (a model for traumatic input), the brain is more likely to have difficulty achieving a coherent and balanced output. This could then lead to the development of dissociation of information and data manifested in the subject’s inability to process smoothly all of the incoming information.

### Dissociation and Memory Systems

There are two broad categories of memory known as explicit and implicit, declarative and procedural, or episodic and semantic. These two basic memory systems serve different functions. Explicit or episodic memory involves recall of personal experience identified with the self, for example, “I went dancing last night”. The second type is known as implicit or procedural memory. This involves the execution of routine operations, such as driving a car, or typing on a keyboard. Most of these rather automatic operations could be carried out with little conscious awareness, but yet with a high degree of proficiency. These two types of memory seem to reside in different cerebral anatomical localizations. Episodic memory seems to be primarily associated with limbic system function, primarily involving the hippocampal formation and mamillary bodies. On the other hand, procedural memory appears to be a function of basal ganglia and cortical functioning.

The fact that there are separate memory systems may account for certain types of dissociative phenomena. For example, the automaticity observed in certain types of dissociative disorders reflect the separation of self-identification associated with explicit memory from routine activity in implicit or procedural memory. It is thus not at all foreign to our mental processing to act in an automatic way devoid of explicit self-identification. Future research on the neurobiology of memory may well provide insights into the functional disintegration of memory, perception, identity and consciousness seen in dissociative disorders.

### Comparison of DSM-IV/ICD-10 Diagnostic Criteria

The ICD-10 Diagnostic Criteria for Research for dissociative amnesia specify that there be a “convincing association in time between the onset of symptoms of the disorder and stressful events, problems, or needs”. In DSM-IV-TR, the criteria set notes that the forgotten information is usually of a stressful or traumatic nature.

For dissociative fugue, in contrast to DSM-IV-TR, the ICD-10 Diagnostic Criteria for Research specify “amnesia for the journey”. Furthermore, in contrast to DSM-IV-TR, the ICD-10 Diagnostic Criteria for Research do not indicate that there is an inability to recall one’s past during the fugue or that there be confusion about personal identity.

Dissociative identity disorder is included in ICD-10 as an example of an “other dissociative (conversion) disorder” under the rubric “multiple personality disorder”. The ICD-10 Diagnostic Criteria for Research and the DSM-IV-TR criteria are almost identical.

Finally, ICD-10 has a single category “depersonalization-derealization syndrome” for presentations characterized by either depersonalization or derealization. In contrast, the DSM-IV-TR category includes only depersonalization and mentions derealization as an associated feature. Furthermore, unlike DSM-IV-TR

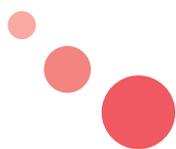

which includes this category in the dissociative disorders section, ICD-10 includes the category within the “other neurotic disorders” grouping.

## Conclusion

The dissociative disorders constitute a challenging and fascinating spectrum of psychiatric illnesses. The failure of integration of memory, identity, perception and consciousness seen in these disorders results in symptoms that illustrate fundamental problems in the organization of mental processes. Dissociative phenomena often occur during and after physical trauma but may also represent transient or chronic defensive patterns. Dissociative disorders are generally treatable and are a domain in which psychotherapy is a primary modality, although pharmacological treatment of comorbid conditions such as depression can be quite helpful. The dissociative disorders are ubiquitous around the world, although they take a variety of forms. They represent a fascinating diagnostic, therapeutic and investigative challenge.

A wide array of sexuality topics impact psychiatry. These topics range from those constituting a major social burden, such as teenage pregnancy, sex crimes and sexually transmitted diseases, to those involving ethical and moral values, such as abortion, extramarital affairs, commercial sex industries and crossing sexual boundaries with patients. They include those with a developmental or medical focus, such as sexual dysfunction or sexual dysfunction due to substance abuse or medical conditions, and those involving lifestyles, such as sexual minority status and drugs for sexual enhancement. There are also those that center on psychiatry's undisputed responsibility, such as psychotropic medication-induced sexual dysfunction and the sexual consequences of psychiatric illness. No discipline, no ideology, no religion and certainly no textbook chapter is sufficient fully to understand and encompass the myriad expressions of human sexuality.

Psychiatry has known for almost a century that child development lays the foundation for a wide variety of adult sexual outcomes (Freud, 1905). These are reflected in the variations of gender, orientation, intention and ease of sexual expression with chosen partners. Psychiatry has also been long aware that the conduct of adolescent and adult sexual life is laden with concern, and sometimes anguish, in every person. In the last generation, we have acquired greater convictions about the profound public health implications of several sexual patterns. First came awareness of the high incidence of childhood sexual abuse and its long-term consequences. Then came the data showing that some psychiatrists and other trusted professionals engaged in genital intimacies with patients. Psychiatry responded by unambiguously clarifying our ethical standards. At about the same time the AIDS epidemic led to a greater awareness of the lives of homosexual and bisexual men. In the 1990s when the Internet usage grew without regulation, addictions to at-home pornography appeared. As the use of SSRIs became widespread, psychiatrists learned about their negative sexual impact. In 1998 an effective pill for erectile dysfunction created an explosion of media interest across the world. The Viagra story reminded us that sexual function is really important to people.

Psychiatry prides itself about being the only field that can comprehend the biopsychosocial aspects of illness. We understand that all sexual expression is simultaneously constituted by biological, psychological and social forces. We also know that sexual disorders are a high prevalence, high incidence source of personal suffering, affecting almost every person at some time in the life-cycle. Sexual disorders often play a subtle role in the genesis of other psychiatric disorders as presented in Figure 57.1.

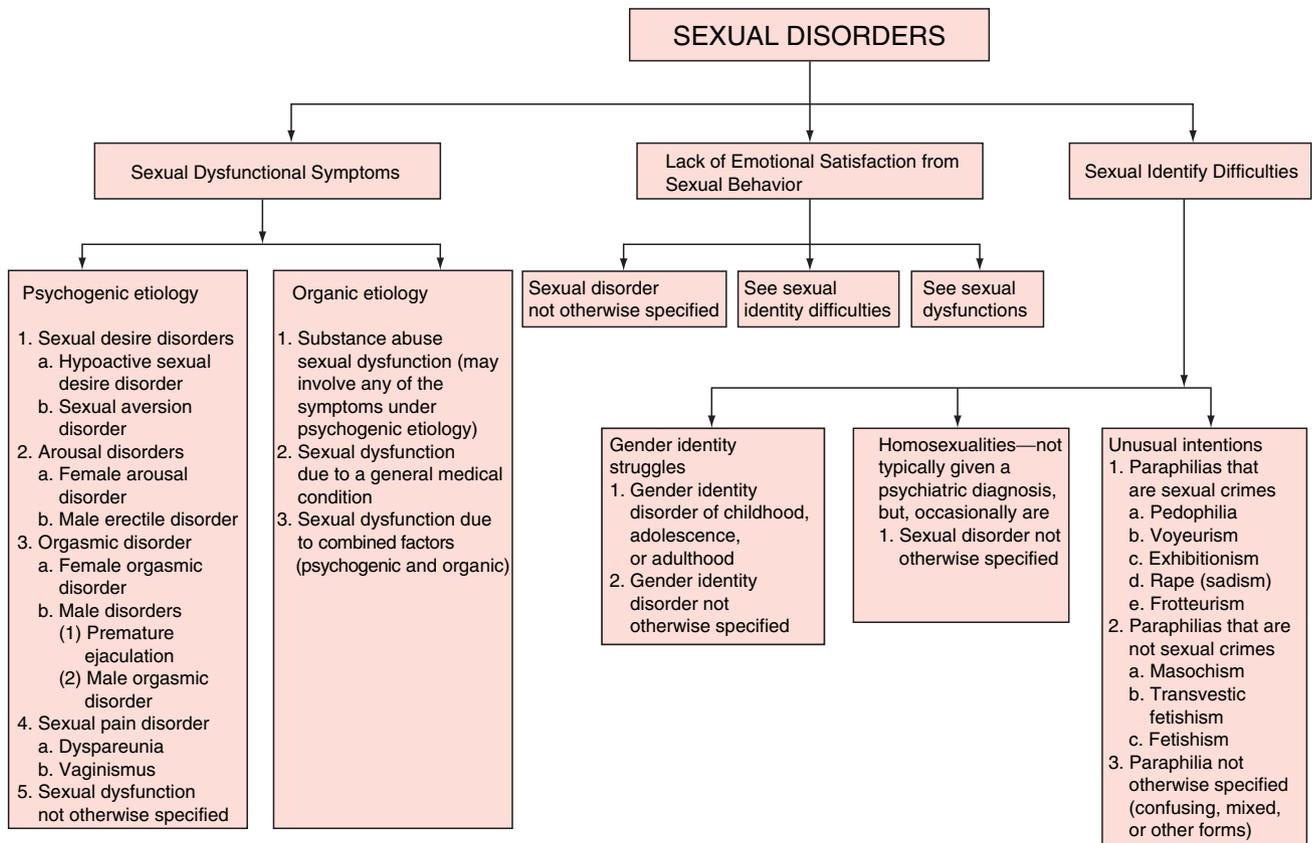

Patients assume their psychiatrists know about sexuality. Therapists can be helpful to many individuals and couples with these problems if they have an interest in the area, a comfort with the subject and a modest fund of knowledge. Sometimes the help can be given quite efficiently. The assistance is often based on knowledge of the diverse origins of these problems. To be able to treat a broad range of sexual disorders the psychiatrist needs to be diagnostically competent, skillful with medications and willing to engage in psychotherapeutic processes. This chapter provides background information for these three goals.

### The Components of Sexuality

An adult's sexuality has seven components – gender identity, orientation, intention (what one wants to do with a partner's body and have done with one's body during sexual behavior), desire, arousal, orgasm and emotional satisfaction. The first three components constitute our sexual identity. The second three comprise our sexual function. The seventh, emotional satisfaction, is based on our personal reflections on the first six (Table 57.1). The DSM-IV-TR designates impairments of five of these components as pathologies. Variations in orientation and the failure to find ordinary sexual experience emotionally satisfying, although problems for some, are not designated as “disorders”.

### Sexual Development Through the Life-cycle

While the psychological foundations for a healthy sexual life are laid down during childhood through parent–child relationships, each subsequent phase of life – adolescence, young adulthood, middle-life, and older age – has inherent developmental challenges and potentials. The normal tasks of sexual development at each phase provide the clinician with an understanding of age-related etiologies of sexual disorders. Adolescent sexual troubles often reflect difficulties consolidating a personally acceptable sexual identity. Young adult dysfunctions often indicate the presence of psychological obstacles to growing comfortable as a sexual pleasure-seeking, pleasure-giving person while integrating sex into the larger context of human attachment. Middle-life disorders often represent failures to maintain psychological intimacy and diplomatically to negotiate tensions within an increasingly complex interpersonal relationship. The dysfunctions of older persons often represent failures to preserve sexual function in the face of biological assaults of menopause, aging, illness, medications, radiation and surgery. Most etiologic factors can operate in another epoch as well. For instance, a young person's new indifference to sexual behavior may be due to an

**Figure 57.1** Diagnostic decision tree for sexual disorders.

SSRI or an older person’s new marriage may expose previously avoided personal discomfort with receiving and giving sexual pleasure.

## The Sexual Dysfunctions

### Significance of Sexual Dysfunction

While sex is widely thought of as recreation, psychiatrists recognize it as an important means of establishing and reaffirming emotional attachments. Sexual competence – the ability to desire a partner, become aroused and attain orgasm in a cooperative manner when together – is a valuable developmental accomplishment because it enables a person to experience the physical expressions and emotional complexities of love. Mutually pleasurable sexual behavior tends to recur far more often in couples than unilaterally satisfying behavior. Mutually pleasurable sexual behavior allows both partners to be comforted and stabilized by loving and feeling loved. The dysfunctions are symptomatic deficits in the quest for these widespread ideals: sexual competence, fun and stabilization of the self.

### DSM-IV Diagnoses

DSM-IV specifies three criteria for each sexual dysfunction (American Psychiatric Association, 1994). The first criterion describes the psychophysiological impairment – for example, absence of sexual desire, arousal, or orgasm. The second and third criteria are the same for each impairment: the dysfunction causes marked distress or interpersonal difficulty and the dysfunction is not better accounted for by another Axis I diagnosis or not due exclusively to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition. Table 57.2 lists the first criterion of each of the 12 sexual dysfunction diagnoses. DSM-IV gives the clinician additional latitude

**Table 57.1** Mechanisms of Sexual Equilibrium

#### Interplay I. of Each Person’s Seven Sexual Components

<i>Person A</i>		<i>Person B</i>
Gender identity	↔	Gender identity
Orientation	↔	Orientation
Intention	↔	Intention
Desire	↔	Desire
Arousal	↔	Arousal
Orgasm	↔	Orgasm
Emotional satisfaction	↔	Emotional satisfaction

#### Regard II. That Each Person Has for the Partner’s Component Characteristics

- Positive regard leads to:  
 Increased sensual abandon,  
 Positive attitudes toward self and partner, and  
 Frequent sexual behavior
- Negative regard leads to:  
 Increased personal inhibition,  
 Hostile critical attitudes toward self and partner, and  
 Limited motivation to engage in partner sexual behavior

**Table 57.2** Delineating Criteria of 12 Sexual Dysfunction Diagnoses

Sexual Desire Disorders	Sexual Arousal Disorders	Orgasmic Disorders	Sexual Pain Disorders
Hypoactive sexual desire disorder: persistently or recurrently deficient (or absent) sexual fantasies and desire for sexual activity	Female sexual arousal disorder: persistent or recurrent inability to attain, or to maintain until completion of the sexual activity, an adequate lubrication-swelling response of sexual excitement	Female orgasmic disorder: persistent or recurrent delay in, or absence of, orgasm after a normal sexual excitement phase	Dyspareunia: recurrent or persistent genital pain associated with sexual intercourse in either a male or a female
Sexual aversion disorder: persistent or recurrent extreme aversion to, and avoidance of, all (or almost all) genital sexual contact with a sexual partner	Male erectile disorder: persistent or recurrent inability to attain, or to maintain until completion of the sexual activity, an adequate erection	Male orgasmic disorder: persistent or recurrent delay in, or absence of, orgasm after a normal sexual excitement phase during sexual activity  Premature ejaculation: persistent or recurrent ejaculation with a minimal sexual stimulation before, on, or shortly after penetration and before the person wishes it	Vaginismus: recurrent or persistent involuntary spasm of the musculature of the outer third of the vagina that interferes with sexual intercourse
Sexual Dysfunction Due to a General Medical Condition	Substance-Induced Sexual Dysfunction	Sexual Dysfunction Not Otherwise Specified	
any of the above-mentioned diagnoses must be judged to be exclusively due to the direct physiological effects of a medical condition	a sexual dysfunction that is fully explained by substance use in that it develops within a month of substance intoxication	for problems that do not meet the categories just described	

for deciding when a person who meets the first criterion qualifies for a disorder. The doctor is asked to consider the effects of the individual's age, experience, ethnicity and cultural background, the degree of subjective distress, adequacy of sexual stimulation and symptom frequency. No instructions are provided about how to exercise this judgment. In this way DSM-IV makes it clear that understanding sexual life requires more than counting symptoms; it requires judgment.

## Epidemiology

Numerous attempts to describe the prevalence of sexual dysfunction have been made in the previous 25 years. These range from attempts to define the frequency of a particular dysfunction, for instance male erectile disorder, to attempts to estimate the prevalence of a series of separate dysfunction, for example, desire, arousal and orgasmic disorders of women. All such efforts quickly confront methodological influences of sampling, means of obtaining the information, definition of each dysfunction, purpose of the study and perspective of its authors. These data not surprisingly, therefore, demonstrate a range of prevalence depending on the problem studied. Gender identity disorders are relatively rare (<1–2%). Lifelong sexual desire disorders among women may involve 15% but are less

frequent among men. Acquired desire disorders among older individuals are probably three times as common. Perhaps more than half of women at age 55 years have recognized a deterioration in their sexual function. Perhaps 25% of women in their twenties have difficulty having orgasm and 33% of men less than age 40 claim to ejaculate too rapidly. The majority of men by age 70 years are likely to be having erection problems. The recent careful epidemiologic study, designed by sociologists, successfully generated a representative sample of the USA (Laumann *et al.*, 1994a). They interviewed men and women between age 18 and 59 years and found that sexual dysfunction is common, particularly among young women and older men. This is noteworthy for psychiatrists because our studies of sexual dysfunction caused by medications or acquired psychiatric disorders tend to assume that patients are generally functionally intact prior to becoming ill or taking medications. This assumption is not tenable based on a generation of epidemiologic studies.

## Sexual Equilibrium

Etiologic ideas about sexual dysfunction are a relatively simple conceptual challenge involving notions about the individual's psychology and his or her cultural expectations. In contrast,

for couples, they involve two individual psychologies, their interpersonal impact on one another and their cultures. The clinician must be wary when one coupled person is presented as having a sexual dysfunction and the partner is presented as “normal”. Sexual dysfunction in a couple is a two-person problem in terms of immediate effects and often in terms of cause as well (Table 57.1). How a partner regards the sexual characteristics of the other is a subtle ingredient of sexual comfort, competence and dysfunction. For instance, a young woman’s new inability to attain orgasm with her husband may be traced to her embarrassment at sharing her excitation with him because she perceives him to be generally critical of her. Similarly, the origin of a husband’s erectile dysfunction may be traced to the emergence of his wife’s negative regard for him, which stemmed from something other than his sexual behavior. This **ordinary** connectivity of a couple’s sexual function is referred to as the couple’s sexual equilibrium (Levine, 1998). The sexual equilibrium explains five observations:

1. Improvement and deterioration of sexual function can rapidly occur;
2. When a couple’s nonsexual relationship is good, their sexual life may not be;
3. Individual psychotherapy is often insufficient to help coupled patients improve their sexual life;
4. A negative attitude from the partner can block improvement in a couple’s sexual life regardless of the therapy format and therapist skill;
5. A conversation with a therapist who is attuned to the emotional meanings of a couple’s interaction can shift a dysfunctional equilibrium back to mutually satisfying sexual behavior.

### The Problems of Sexual Desire

Sexual desire manifestations are diverse: erotic fantasies, sexual dreams, initiation of sexual behavior, receptivity to partner-initiated sexual behavior, masturbation, genital sensations, heightened responsivity to erotic environmental cues and sincere statements about wanting to behave sexually. For most of the 20th century, these have been referred to as manifestations of libido. Psychiatrists spoke of libido as if it was a homogeneous instinctive force. Clinicians will find it far more useful to conceptualize that the diverse and changeable desire manifestations are produced by the intersection of three mental forces: drive (biology), motive (psychology) and wish (culture).

#### Drive

By only partially understood psychoneuroendocrine mechanisms, the preoptic area of the anterior-medial hypothalamus and the limbic system periodically produce sexual drive. **Drive** is recognized by genital tingling, heightened responsivity to erotic environmental cues, plans for self or partner sexual behavior, nocturnal orgasm and increased erotic preoccupations. These are often spontaneous. Although people can become aroused and attain orgasm without evident drive, it propels the entire sexual psychophysiological process. Without drive, the sexual response system is far less efficient and capable. While men as a group seem to have significant more drive than women as a group, in both sexes, drive requires the presence of a modest amount of testosterone. Drive is frequently dampened by medications that act within the central nervous system, substances of abuse, psychiatric illness, systemic physical illness, despair and aging. It is heightened by low doses of a few often-abused substances such

as alcohol or amphetamine, manic mechanisms, falling in love, joy, and some dopaminergic compounds such as those used to treat Parkinson’s disease.

#### Motive

The psychological aspect of desire is referred to as **motive** and is recognized by willingness to bring one’s body to the partner for sexual behavior either through initiation or receptivity. Motive often directly stems from the person’s perception of the context of the nonsexual and sexual relationship. Sexual desire diagnoses are often made in persons who have adequate drive manifestations. Most sexual desire problems in physically healthy adults are simply generated by one partner’s unwillingness to engage in sexual behavior. This is often a secret, however. Sexual motives are originally programmed by social and cultural experiences. Children and adolescents acquire values, beliefs, expectations and rules for sexual expression. Young people have to find a way to negotiate their way through the fact that their early motives to behave sexually frequently coexist with their motives **not** to engage in sexual behavior. Conflicted motives often persist throughout life but the reasons for the conflict evolve. A teenager possessed of considerable drive and motive to make love may inhibit all sexual activities because of moral considerations emanating from religious education or the sense that he or she is just not developmentally ready yet.

#### Wish

An 80-year-old man who had no drive manifestations and had avoided all sexual contact with his wife for a decade because he could not get an erection, passionately answered a doctor’s query about his sexual desire, “Of course, I have sexual desire! I am a red-blooded American male! Why do you think I am here?” In fact, he was only speaking about his wish to be sexually capable now that an effective treatment for erectile problems existed. The doctor asked an imprecise question. The doctor should have separately explored his drive manifestations, his sexual motivation to exchange sexual pleasure with his wife in recent years and his wish for sexual rejuvenation.

The appearance and disappearance of sexual desire is often enigmatic to a patient, but its ebb and flow result from the ever-changing intensities of its components, biological **drive**, psychological **motive** and socially acquired concepts, **wish** (Table 57.3) (Levine, 2002). In women, this interplay is generally more difficult to delineate because drive and motive are sometimes inseparable.

### Sexual Desire Diagnoses

Two official diagnoses are given to men and women whose desires for partner sexual behavior are deficient: hypoactive sexual desire disorder (HSDD) and sexual aversion disorder (SAD). The differences between the two revolve around the emotional intensity with which the patient avoids sexual behavior. When visceral anxiety, fear, or disgust is routinely felt as sexual behavior becomes a possibility, sexual aversion is diagnosed. HSDD is far more frequently encountered. It is present in at least twice as many women than men; female to male ratio for aversion is far higher. Like all sexual dysfunctions, the desire diagnoses may be lifelong or may have been acquired after a period of ordinary fluctuations of sexual desire. Acquired disorders may be partner specific (“situational”) or may occur with all subsequent partners (“generalized”).

**Table 57.3 Three Interactive Components of Sexual Desire**

<b>Sexual Drive = Biological Component</b>
Evolves over time, decreasing with increasing age Diminished by many psychotropic and antihypertensive medications Manifested by the internally stimulated genital sensations and thoughts of sexual behavior that occur within a person's privacy
<b>Sexual Motivation = Psychological Component</b>
Highly contextual in terms of relationship status The most socially and psychologically responsive of the three components Evolves over time but not predictably Manifested by a person's willingness to bring his or her body to a specific person for sexual behavior
<b>Sexual Wish = Social Component</b>
Expectations for sexual behavior based on membership in various subcultural groups such as family, religion, gender, region and nation These expectations begin as cognitions of what is right and wrong and what a person is entitled to sexually and are influenced by what people think others in their cohort are experiencing Often clinically difficult to distinguish from motivation, which wishes influence

When the psychiatrist concludes that the patient's acquired generalized HSDD is either due to a medical condition, a medication, or a substance of abuse, the diagnosis is further elaborated to sexual dysfunction due to general medical condition (for instance, HSDD due to multiple sclerosis). The frequency of the specific etiologies are heavily dependent on the clinical setting. In oncology settings, medical causes occur in high frequency; in drug rehabilitation programs, methadone maintenance will be a common cause. In marital therapy clinics, anger and loss of respect for the partner, hidden incompatibility of sexual identity between the self and the partner because of covert homosexuality or paraphilia, an affair, or childhood sexual abuse will commonly be the basis. In general psychiatry settings, medication side effects will often be the top layer of several causes. When a major depression disorder is diagnosed, for instance, the desire disorder is often assumed to be a symptom of the depression. This usually is incorrect. The desire disorder often preceded the decompensation into depression.

**From a Desire Diagnosis to Dynamics**

Those with **lifelong** deficiencies of sexual desire are often perceived to be struggling with either: 1) sexual identity issues involving gender identity, orientation, or a paraphilia; 2) having failed to grow comfortable as a sexual person due to extremely conservative cultural backgrounds, developmental misfortunes, or abuses. Occasionally the etiology is enigmatic, raising the important question whether it is possible to never have any sexual drive manifestations on a biological basis. (Theoretically, the answer is yes.) Both acquired and lifelong desire disorders are

often associated with past or chronic mood disorders. Disorders of desire are often listed as "of unknown etiology", but clinicians should be skeptical of this idea because:

1. The patient may not tell the doctor the truth early in the relationship;
2. The patient may have strong defenses against knowing the truth;
3. The patient may not be able to speak freely in front of the partner;
4. The patient may not know what is occurring in the partner's life, despite being influenced negatively by it;
5. The doctor may not realize the usual causes of the problem;
6. The doctor may not believe in developmental influences on the organization of adult sexual function.

Sexual aversion should strongly suggest three possibilities to the clinician:

1. that a remote traumatic experience is being relived by the partner's expression of interest in sexual behavior;
2. that without the symptom the patient feels powerless to say "no" to sexual advances;
3. the patient feels guilty about her own sexual behavior with another person.

The doctor's attention should focus on the patient's sexual development as a child, adolescent and young adult when the aversion is lifelong, whereas when it is **acquired**, the focus of the history should be on the period immediately prior to the onset of the symptom.

Desire disorders require the clinician to think both in terms of development and personal meanings of sex to their individual patients (Table 57.4). Because all explanations are speculative, they should at least make compelling sense of the patients' life experiences. Some explanations are based on the influence

**Table 57.4 Obstacles to Discovering the Psychological Contributors to a Sexual Desire Disorder**

<b>Obstacles That Reside in the Patient</b>
The patient may not tell the psychiatrist the truth about life circumstances The patient may have strong defenses against knowing the truth The patient may be unable to tell the truth in front of the partner The patient may not actually know what is occurring in the partner's life, although she or he is reactive to it
<b>Obstacles That Reside in the Psychiatrist</b>
The psychiatrist may not realize the psychological factors that usually cause these problems The psychiatrist may not believe that developmental influences can organize an adult sexual function such as sexual motivation The psychiatrist may not like to deal with the murky complexity of nonbiological developmental and interpersonal issues when thinking about etiology

of remote developmental processes. The term **madonna-whore complex** misleads us into thinking this is only a male pattern. The syndrome is manifested by normal sexual capacity with anyone but the fiancé or spouse. Freud interpreted this as a sign of incomplete resolution of the oedipal complex. The man was thought to be unable sexually to desire his beloved because he had unconsciously made her into his mother. He withdrew his sexual interest from her to protect himself from symbolic incest. Some women are comparably unable sexually to enjoy their partners because they unconsciously confuse their beloved with their father. Another form can be seen among patients whose parents were grossly inadequate caregivers. When these men and women find a reliable, kind, supportive person to marry, they quickly discover a strong motive to avoid sexual behavior with their fiancé. The patient makes the partner into a good-enough parent, experiences anxiety as an unconscious threat of incest associated with the possibility of sex, and becomes skillful at avoiding sexual opportunities.

Most sexual desire disorders are difficult to overcome quickly. Brief treatment generally should not be undertaken. Serious individual or couple issues frequently underlie these diagnoses. They have to be afforded time to emerge and to be worked through. However, clinicians need not be pessimistic about all of these conditions. For example, helping a couple resolve a marital dispute may return them to their usual normal sexual desire manifestations. For many individuals and couples, therapy assists the couple to accept more calmly the profound implications of continuing marital discord, infidelity, homosexuality, or other contributing factors. Some treatment failures lead to divorce and the creation of a relationship with a new partner. There is then no further sign of the desire problem. Problems rooted in early developmental experiences are particularly difficult to overcome. While DSM-IV asks the clinician to make many distinctions among the desire disorders, no follow-up study has been published in which either the subtypes (lifelong, acquired, situational, generalized) or etiologic organizers (relationship deterioration with and without extramarital affairs, sexual identity incompatibilities, parental, and medical) are separated into good and poor prognosis categories.

Developmental and identity matters are typically approached in long-term individual psychotherapy. In these sessions women often discuss the development of their femininity from adolescence to young womanhood, focusing on issues of body image, beauty, social worth to others, moral sensibilities, social awkwardness and whether they consider themselves deserving of personal physical pleasure. Men often discuss similar issues in terms of masculinity.

Anger, loss of respect, marital discord and extramarital affairs may be approached in either individual or conjoint formats. In either setting, patients often formulate the etiology as having fallen out of love with the partner. Those whose cultural backgrounds limit their ease in being a sexual person are often encouraged in educational and cultural experiences that might help them outgrow their earliest notions about what is proper sexual behavior.

### The Problems of Sexual Arousal

The emotion interchangeably referred to as sexual arousal or sexual excitement generates changes in respiration, pulse and muscular tension as well as an increased blood flow to the genitals. Genital vasocongestion creates vaginal lubrication, clitoral tumescence, labial color changes, and penile erection, testicu-

lar elevation and penile color changes. How arousal is centrally coordinated in either sex remains mysterious. During lovemaking, men and women do not necessarily maintain or progressively increase their arousal; rather often there is a fluctuating intensity of arousal which is reflected in variations in vaginal wetness and penile turgidity and nongenital signs of arousal.

### Female Sexual Arousal Disorder

The specificity and validity of this disorder is unclear. In women it is far more difficult to separate arousal and desire problems than in men. The perimenopausal period is now recognized as generating complaints about decreased drive, motivation, lubrication and arousal in at least 35 to 50% of women. However, it is unclear whether to label the problem as primarily of desire or arousal. It is assumed to be endocrine in origin even though estrogen, progesterone and testosterone replacement do not reliably reverse the pattern. Even in younger regularly menstruating women, however, diminished motivation and dampened drive makes it difficult to sustain arousal. Many have called into question the accepted notions that desire necessarily precedes arousal and that they are separate physiological processes. Female arousal disorder implies that drive and motivation are relatively intact although arousal is difficult. The disorder is usually an **acquired** diagnosis. Premenopausal women who have it focus on the lack of moisture in the vagina or their failure to be excited by the behaviors that previously reliably brought pleasure. They have drive and motive and wish, but enigmatically are unable to sustain arousal. Some mental factor arises to distract them from their excitement during lovemaking. Therapy is focused, therefore, on the meaning of what preoccupies them. This often involves the dynamics of their current individual or partnered life or the influence of their past relationships on their present. With therapy the diagnosis often is changed to a HSDD.

In peri- and postmenopausal women, arousal problems are more often focused on the body as a whole rather than just genital moisture deficiencies. Skin insensitivity, often a euphemism for decreased pleasure in response to oral and manual nipple, breast and vulvar stimulation, is often initially treated as a symptom of “estrogen” deficiency. Early in the menopause, a small minority of women have an increase in drive due to changing testosterone-estrogen ratios. Yet, they may still subjectively experience arousal as different than it used to be. Therapy often focuses on the women’s concerns about estrogen replacement and the consequences of menopause in terms of body image, attractiveness, fears of partner infidelity, loss of health and vigor, and aging.

Aging of the female arousal mechanisms, whether simply due to shifts in ovarian endocrine production or systemic aging mechanisms, occurs earlier than deterioration of orgasmic physiology. Women with decreasing arousal are often, therefore, still reliably orgasmic with the use of vaginal lubricants well into old age. Women who have been treated with chemotherapy for breast cancer are a particularly problematic group to offer assistance to for their new arousal problems. Fear of stimulating remaining cancerous cells makes systemic estrogen replacement contraindicated.

In 1999 a renewed interest in female arousal disorder, sometimes casually called female sexual dysfunction surfaced in response to the efficacy of Viagra for men’s arousal problems. It was reasoned that since the penis and clitoris are embryologic homologues with comparable adult histology, the drug would improve women’s arousal. Placebo-controlled trials concluded that the drug did not improve arousal any more than placebo (Basson *et al.*, 2002).

## Male Erectile Disorder

The mechanisms of erection – the sequestering and maintaining arterial blood within the corpora cavernosa – are being elucidated by urological research. Their research has led to a diminishing emphasis on “psychogenic impotence” diagnosis. Urologists may refer to male erectile disorders (ED) of a psychogenic origin as “adrenergic” ED, a reference to the preponderance of sympathetic tone on the corporal mechanisms that maintain flaccidity. Adrenergic dominance of the penile arterial tone is created by a mind that perceives the sexual context as a dangerous, frightening, or as unwanted.

The prevalence of ED rises dramatically in the sixth decade of life from less than 10 to 30%; it increases further during the seventh decade. Aging, medical conditions such as diabetes, prostatic cancer, hypertension and cardiovascular risk factors predict the most common pattern of ED due to a medical condition in this age group. While medication-induced, neurological, endocrine, metabolic, radiation and surgical causes of erectile dysfunction also exist, in population studies diabetes, hypertension, smoking, lipid abnormalities, obesity and lack of exercise are correlated with the progressive deterioration of erectile functioning in the sixth and seventh decades. These factors are thought to create a relative penile anoxemia which stimulates the conversion of corporal smooth muscle cells into fibrocytes. The gradual loss of elasticity of the corpora interferes with filling and sequestering of arterial blood. Erections at first become unreliable and finally impossible to obtain or sustain.

At every age, **selectivity** of erectile failure is the single most important diagnostic feature of primary erectile dysfunction. Clinicians should inquire about the relative firmness and duration of erections under each of these circumstances: masturbation, sex other than intercourse, sex with other female or male partners, upon stimulation with explicit media materials, in the middle of the night and upon awakening. If under some circumstances the erection is firm and lasting, the clinician can usually assume that the man’s neural, endocrine and vascular physiology is sufficiently normal and that the problem is psychogenic in origin. This is true even for men in their fifties and older. Clinicians often feel more certain about this diagnosis when no diseases thought to lead to erectile dysfunction are present.

Lifelong male ED typically is psychogenic and involves either a sexual identity dilemma: such as transvestism, gender identity disorder, a homoerotic orientation, a paraphilia, or another diagnosis that expresses the patient’s fear of being sexually close to a partner. Sexual identity problems are often initially denied unless the clinician is nonjudgmental and thorough during the inquiry. However, obsessive–compulsive disorder, schizoid personality, a psychotic disorder, or severe character disorders may be present. Occasionally, a reasonably normal young man with an unusually persistent fear of sexual intercourse seeks attention. These good prognosis cases are sometimes informally referred to as anxious beginners (Table 57.5). With that exception, men with lifelong male arousal disorder (MAD), when taken into individual therapy are usually perceived as having a strong motive to avoid sexual behavior and while dysfunctional with a partner during much of their therapy might equally be diagnosed as having HSDD with normal drive but a motive to avoid partner sex. The prognosis with older men with lifelong erectile dysfunction is poor even with modern erectogenic agents. Long-term therapy, even if it does not enable regular intercourse, may enable more emotional and sexual closeness to a partner. Some reasonably masculine appearing men with mild gender identity problems

**Table 57.5** What the Psychiatrist Should Expect to Encounter Among Men Who Have Never Been Able to Have Intercourse with a Woman

Unconventional Sexual Identity
Gender identity problem
Wish to be a woman
A history of cross-dressing in women’s clothing in public or private and/
Suspected by psychiatrist but information initially withheld
Homoeroticism
Without sexual behavior with men partner
With sexual behavior with men but not known to the female
With sexual behavior with men and known to the female partner
Paraphilia
One or more of a wide range of paraphilic patterns
Preference for prepubertal or young adolescents often initially denied unless thoroughly, systematically and nonjudgmentally questioned
Compulsivity with or without obvious paraphilia confined to masturbation with the help of pornographic images for stimulation
Serious Character Disorders (Men Have Strong Fear of Closeness to Women)
Obsessive–compulsive
Schizotypal
Schizoid
Avoidant
Past history of psychotic decompensation
Anxious Beginners
Psychiatrically normal young men with inordinate anxiety and shyness that quickly respond to psychiatrist’s encouragement and optimism and partner warmth and patience

can quickly become potent if they can reveal their need during sexual relationship to cross-dress (use a fetish article of clothing) to a partner who calmly accepts his requirement. However, most of these men have inordinate fears of sexually bonding to any woman and, in therapy, become preoccupied with basic developmental issues. Some of them marry and form companionate relationships that are rarely or never consummated.

In dramatic contrast, men with long-established good potency who have recently lost their erectile capacities with their partner – acquired psychogenic ED – have a far better prognosis (Table 57.6). They may be treated in individual or couples format, depending on the precipitants of the sexual problem and the status of their relationship with their partner. Many of these therapies become focused on resentments that have not been identified, discussed and worked through by the couple. Such distressed couples are most efficiently helped in a conjoint format. When extramarital affairs are part of the relationship deterioration and cannot be discussed, most clinicians simply work with one spouse. Potency is frequently lost following a separation or divorce. Impaired potency after a spouse’s death is either about unresolved grief or problems that exist prior to the wife’s terminal illness. Men are also often worried about their potency when their financial or

**Table 57.6** Apparent Precipitants of Recently Acquired Psychogenic Erectile Disorder and Their Associated Private Emotions\*

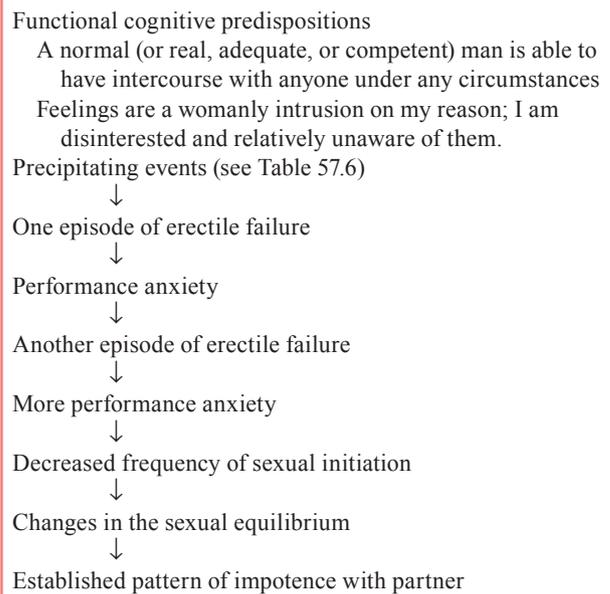

Deterioration of marital relationship: anger, guilt, disdain, sadness
Divorce: abandonment, anger, guilt, sadness, shame
Deterioration of personal or spousal health: sadness, anxiety, anger, shame
Death of spouse (“widower’s impotence”): sadness, longing, guilt
Threat of or actual unemployment: anxiety, worthlessness, guilt, anger, shame
Financial reversal: shame, guilt, anxiety
Surreptitious extramarital affair: guilt
Reunited marriage after extramarital affair: shame, anxiety

\*These short lists of simple emotions are a mere introduction to what transpires within the man’s mind as a result of the meanings that the sexual behavior has for him. Although incomplete and oversimplified, they are listed to remind the psychiatrist that what the man feels about his life competes with sexual arousal during sexual behavior to generate the psychogenic erectile dysfunction.

vocational lives crumble, when they have a serious new physical illness such as a myocardial infarction or stroke, or when their wives become seriously ill. The esthetics of lovemaking require a context of reasonable physical health; when one spouse becomes chronically ill or disfigured by illness or surgery, either one of the couple may lose their willingness to be sexual. This may be reflected in impaired erections or sexual avoidance.

Regardless of the precipitating factors, men with arousal disorders have performance anxiety. They anticipate erectile failure before sex begins and vigilantly monitor their state of tumescence during sex (Masters and Johnson, 1970). Performance anxiety is present in almost all impotent men. Performance anxiety is efficiently therapeutically addressed by identifying it to the patient and asking him to make love without trying intercourse on several occasions to demonstrate to himself how different lovemaking can feel for him when he is not risking failure. This enables many to relax, concentrate on sensation and return to previous states of sensual abandon during lovemaking. This technique is known as **sensate focus**.

The psychological treatment of acquired arousal disorders is often highly satisfying for the professional because many of the men are anxious for help. Motivation to behave sexually is often present, fear can be allayed and men can learn to appreciate the emotional complexity of their lives. They can be shown how their minds prevented intercourse until they could acknowledge what has been transpiring within and around them. Many recently separated men, for example, are grieving, angry, guilty, uncertain and worried about their finances. Yet, they may propel themselves into a new relationship. Two characteristics seem to predispose to erectile problems at key life transitions: 1) The pursuit of the masculine standard that men ought to be able to perform intercourse with anyone, anywhere, under any circumstances; 2) The inability to readily grasp the nature and significance of his inner experiences. “Yes, my schizophrenic daughter became homeless in another city, my wife was depressed and began drinking to excess in response, and I had a financially costly affair with my secretary. What do these have to do with my loss of potency?” (Table 57.7).

**Table 57.7** Pathogenesis Model for Acquired Erectile Dysfunction

Sildenafil revolutionized the treatment of erectile dysfunction in 1998. This phosphodiesterase type 5 inhibitor maintains corporal vasodilatation by preventing the degradation of cGMP. Sexual arousal leads to the corporal secretion of nitric oxide which is converted by an enzyme into cGMP. Sildenafil is increasingly effective as the dose is increased from 25 to 50 up to 100mg. The drug must not be used when any organic nitrate is being taken because it dangerously potentiates the hypotensive effect of the nitrates risking brain and myocardial infarction. Sildenafil is dramatically underutilized by psychiatrists.

Prior to sildenafil, urologists argued that most erectile dysfunction was organic in origin, but since the drug works at about the same rate regardless of the pretreatment etiology, most erectile dysfunction is now recognized to be of mixed – organic and psychosocial – origin. Three conditions have unique response profiles: after prostatectomy the response rate is approximately 34%, among diabetics it is approximately 43%, and among the spinal cord injured it is approximately 80%; the same rate seems to improve psychogenic ED. Other medical interventions are also effective in varying degrees for largely organic erectile dysfunction: vacuum pump, the intracavernosal injection of vasodilating substances, intraurethral apostadil, the surgical implantation of a penile prostheses and, outside the USA, sublingual apomorphine. Because sildenafil’s rate of improving erections is significantly higher than the restoration of a mutually satisfactory sexual equilibrium (approximately 44%), psychological ED that persists after medication should be treated by a mental health professional.

## Problems with Orgasm

### Female Orgasmic Disorder

The attainment of reasonably regular orgasms with a partner is a crucial personal developmental step for young women. This task of adult sexual development rests upon a subtle interplay of physiology, individual psychology and culture. Reliable orgasmic

attainment is usually highly valued by the woman and is often reflected in enhanced self-esteem, confidence in her femininity, relationship satisfaction and the motive to continue to behave sexually.

Orgasm is the reflexive culmination of arousal. It is manifested by rhythmic vaginal wall contractions and the release of muscular tension and pelvic vasocongestion, accompanied by varying degrees of pleasurable body sensations. Its accomplishment requires: 1) the physiologic apparatus to augment and sustain arousal; 2) the psychological willingness to be swept away by excitement; and 3) tenacious focus on the required physical work of augmenting arousal. The diagnosis of female orgasmic disorder (FOD) is made when the woman's psychology persistently interferes with her body's natural progression through arousal.

Estimates of prevalence of both lifelong and acquired psychological FOD range from 10 to 30% (Laumann *et al.*, 1994b). Some of this variability is due to the different definitions of anorgasmia. It remains a difficult scientific judgment, however, where to draw the line between dysfunction and normality, for example, is it normal to attain orgasms during one-third of partner sexual experiences? (Tiefer, 1998). Few women are always orgasmic.

During most of the 20th century, psychoanalysts thought that almost 90% of women were orgasmically dysfunctional. Prior to 1970, the accepted concept of normality required a woman to be brought to orgasm by penile thrusting. Orgasmic fulfillment through solitary masturbation or partner manual or oral stimulation was viewed as signifying the presence of a neurotic obstacle to mature femininity. This paternalistic idea has weakened considerably in the last generation.

The biologic potential for orgasmic attainment is an in-born endowment of nearly all physically healthy women. The cultural and psychological factors that influence orgasmic attainment are usually fundamental to the etiology of FOD. Centuries-old beliefs that sexual knowledge, behavior and sexual pleasure were not the prerogative of "good girls" powerfully affects some women's sexual adjustment. These beliefs cause young women to be uninformed about the location and role of their clitoris and ashamed of their erotic desires and sexual sensations. For women with FOD, modern concepts of equality of sexual expression are insufficient to overcome these traditional beliefs. These emotionally powerful beliefs often lay behind their classic dysfunctional pattern: the women can become aroused to a personal plateau beyond which they cannot progress; thereafter, their excitement dissipates. After numerous repetitions, they begin to lose motivation to participate in sex with their partner. They may eventually meet criteria for HSDD.

## Diagnosis

The doctor should know the answers to the following questions. Does the patient have orgasms under any of the following sexual circumstances: solitary masturbation, partner manual genital stimulation, oral-genital stimulation, vibratory stimulation, any other means? Does she have orgasms with a partner different from her significant other? How are they stimulated? Does a particular fantasy make orgasmic attainment easier or possible? Under what conditions has she ever been orgasmic? Has she had an orgasm during her sleep?

## Lifelong Varieties

The lifelong **generalized** variety of the disorder is recognized when a woman has never been able to attain orgasm alone or with a partner by any means, although she regularly is aroused. When a woman can only readily attain orgasm during masturbation,

she is diagnosed as having a lifelong **situational** type. Women with any form of lifelong FOD more clearly have conflicts about personal sexual expression due to fear, guilt, ignorance, or obedience to tradition than those with the acquired variety. Women who can masturbate to orgasm often feel fear and embarrassment about sharing their private arousal with any other person.

## Acquired Varieties

The acquired varieties of this disorder are more common and are characterized by both complete anorgasmia, too-infrequent orgasms and too-difficult orgasmic attainment. The most common cause of this problem are serotonergic compounds. Prospective studies of various antidepressants have demonstrated up to 70% incidence of this disorder among those treated with serotonergic antidepressants. Bupropion and nefazadone do not cause this problem. When medications are not the cause of an acquired FOD, the doctor needs carefully to assess the meaning of the changes in her life prior to the onset of the disorder. Some of these women are in the midst of making a transition to a new partner after many years in another relationship. Some seem to suffer from memories of earlier shame-ridden behaviors such as incest.

## Treatment

When a doctor applies a label of disorder to a relatively anorgasmic woman, the woman often privately interprets the diagnosis as meaning that she has a serious and difficult problem to overcome. Physicians need to be careful about this because some of these women are relatively easy to help. It must be realized that many women gradually undo the effects of their culture on their own and grow to be increasingly responsive sexually with time and growing trust of their partners. Clinicians can do many women a great service by offering education and reassurance. Giving an inhibited woman new-to-her information in an encouraging manner can subdue her anxiety and foster her optimism. On the other hand, some women with this disorder are profoundly entrenched in not being too excited and treatments fail. The ideal era to begin treatment is young adulthood.

Four formats are known to be of help. Individual therapy is the most commonly employed. In lifelong varieties of the disorder, therapy focuses on the cultural sources of sexual inhibition and how and when they impacted upon the patient. In the situational varieties, the therapist focuses on the meaning of the life changes that preceded the onset of the disorder. Group therapy is highly effective in helping women reliably to masturbate to orgasm and moderately effective in overcoming partner inhibition. It is typically done with college and graduate students in campus settings, not older women. Couple therapy may be useful to assist the couple with the subtleties of their sexual equilibrium. The personal and interpersonal dimensions of orgasmic attainment can be stressed. Often other issues then come to the fore that initially seemed to have little to do with orgasmic attainment. The most cost-effective treatment is bibliotherapy. Female orgasmic attainment has been widely written about in the popular press since the early 1970s. It is widely believed that these articles and books, which strongly encourage knowledge of her genital anatomy, masturbation and active pursuit of orgasm, have enabled many women to grow more comfortable and competent in sexual expression.

## Male Orgasmic Disorder

When a man can readily attain a lasting erection with a partner, yet is consistently unable to attain orgasm in the body of the

partner, he is diagnosed with male orgasmic disorder (MOD). The disorder has three levels of severity: 1) the most common form is characterized by the **ability** to attain orgasm with a partner outside of her or his body, either through oral, manual, or personal masturbation; 2) the more severe form is characterized by the man's inability to ejaculate in his partner's presence; and 3) the rarest form is characterized by the inability to ejaculate when awake. The disorder is usually lifelong and not partner specific. These men cannot allow themselves to be swept away in arousal by another person. They are sexually vigilant not to allow themselves to be controlled by the partner's power to convey them to orgasm. This power would provide the partner with personal pleasure and the man with this disorder, while initially appearing to be a sexual superman, ultimately disappoints the partner. Their psychological dysfunction represents a capacity to use a mental mechanism which other men would love to possess in smaller degrees. Both the partners and the therapists of these men tend to describe them as controlling, unemotional, untrusting, hostile, obsessive-compulsive, or paranoid. Some of these men improve with psychotherapy, others improve spontaneously with time and, for others, the dysfunction leads to the cessation of the aspiration for sex with a partner. One controlled study of patients with numerous sexual dysfunctions suggested that bupropion 300 to 450 mg/day may improve the capacity to ejaculate in a minority of patients.

### Premature Ejaculation

Premature ejaculation is a high prevalence (25–40% disorder seen primarily in heterosexuals characterized by an untameably low threshold for the reflex sequence of orgasm. The problem, a physiological **efficiency** of sperm delivery, causes social and psychological distress. In failing to develop a sense of control over the timing of his orgasm in the vagina, the man fails to meet his standards of being a satisfying sexual partner. However, if his partner does not explicitly or implicitly object, his rapidity is not likely to cause him to seek medical attention. The range of intravaginal containment times among self-diagnosed patients extends from immediately before or upon vaginal entry (rare), to less than a minute (usual), to less than the man and his partner desire (not infrequent). Time alone is a misleading indicator, however. The essence of the self-diagnosis is an emotionally unsatisfying sexual equilibrium apparently due to the man's inability to temper his arousal. Most men sometimes ejaculate before they wish to, but not persistently.

### Clinical Approach

The history should clarify the answers to following questions: Why is he seeking therapy now? Is the patient a sexual beginner or a beginner with a particular partner? Does he have inordinately high expectations for intravaginal containment time for a man his age and experience? Is he desperate about losing the partner because of the rapid ejaculation? Is the relationship in jeopardy for another reason? Does his partner have a sexual dysfunction? Does she have orgasms with him other than through intercourse? Is he requesting help in order to cover his infidelity? Is his partner now blaming the man's sexual inadequacy for her infidelity? Is his new symptom a reflection of his fear about having a serious physical problem during sex such as angina, a stroke, or another myocardial infarction? The answers will enable the doctor to classify the rapid ejaculation into an acquired or lifelong and specific or general pattern, to sense the larger

context in which his sexual behavior is conducted and to plan treatment.

Premature ejaculation reflects to the man's sense that his contribution to the sexual equilibrium is deficient. It implies that he considers that he is far behind most men in his vaginal containment time and that he wants to provide his partner with a better opportunity to be nurtured during lovemaking through prolonged intercourse. Typically, he aspires to "bring" his partner to orgasm during intercourse. If anxiety lowers the ejaculatory threshold and keeps it from its natural evolution to a higher level over time, then premature ejaculation is a self-perpetuating pattern. Premature ejaculation may last a lifetime.

### Therapy

There are three efficient approaches to this dysfunction. The first is simply to refuse to confirm the patient's self-diagnosis. Some anxious beginners, men with reasonable intravaginal containment times of two or more minutes, and those with exaggerated notions of sexual performance can be calmed down by a few visits. When they no longer think of themselves as dysfunctional their intravaginal containment times improve. The second is the use of serotonergic medications. In a study of 15 carefully selected stable couples, daily administration of clomipramine 25 and 50 mg increased intravaginal containment times on average of 249% and 517% over baseline observations (Althof *et al.*, 1995). At these dosage levels, there were few side effects. Numerous similar reports testify to the fact that various serotonergic reuptake inhibitors can significantly lengthen the duration of intercourse. Clinicians need to determine with each patient whether the medication can be taken within hours or days of anticipated intercourse. Improvement is not sustained after medication is stopped. Serotonergic medications are the most common treatment of rapid ejaculation because they are so quickly effective in over 90% of men. The third approach is behaviorally-oriented sex therapy that trains the man to focus his attention on his penile sensations during vaginal containment and to signal his partner to cease movement or to apply a firm squeeze of the glans/shaft area to interrupt the escalation of arousal. This requires an increase in communication and full cooperation of the partner which in themselves can go a long way in improving their sexual equilibrium.

Rapid ejaculation in some men reflects mere inexperience; for others it is stubborn physiological efficiency; for others it reflects fear of personal harm, which is either related to physical illness or to unresolved fears of closeness to a woman; and yet for others it reflects a partnership with a profoundly inhibited blaming partner. If the psychodynamic question is asked of men with persistent rapid ejaculation, "Why does this man want to finish intercourse so quickly?" the answers vary from, "It is not a relevant question!" to "I'm afraid of her!" to "I'm afraid of what will happen to me". For instance, a large percentage of men ejaculate quickly for the first months after a myocardial infarction.

The advantages of costlier couple psychotherapy are to allow the man and his partner to understand their lives better, to address both of their sexual anxieties, and to deal with other important nonsexual issues in their relationship. Effective psychotherapy allows the man to become positioned to continue the usual biological evolution that occurs during the life-cycle from rapid ejaculation, which is true for many young men, to occasional difficulty in ejaculating, which is true for many men in their sixties.

## Sexual Pain Disorders

The clinician needs to consider a series of questions when dealing with a woman who reports painful intercourse. Does she have a known gynecologic abnormality which is generally associated with pain? Is there anything about her complaint of pain that indicates a remarkably low pain threshold? Does she now have an aversion to sexual intercourse? At what level of physical discomfort did she develop the aversion? Does her private view of her current relationship affect her willingness to be sexual and her experience of pain? Does her partner's sexual style cause her physical or mental discomfort, for example, is he overly aggressive or does he stimulate memories of former abuse? What has been the partner's response to her pain? What role does her anticipation of pain play in her experience of pain?

These clinical questions are typical biopsychosocial ones. Sex-limiting pain often is the result of the subtle interplay of personal and relational, cognitive and affective, and fundamental biological processes that are inherent in other human sexual struggles that operate to produce these confusing disorders.

The DSM-IV presents dyspareunia and vaginismus as distinct entities. However, they have been viewed as inextricably connected in much of the modern sexuality literature: vaginismus is known to create dyspareunia and dyspareunia has been known to create vaginismus.

## Dyspareunia

### Terminology

Recurrent uncomfortable or painful intercourse in either gender is known as dyspareunia. Women's dyspareunia varies from discomfort at intromission, to severe unrelenting pain during penile thrusting, to vaginal irritation following intercourse. In both sexes, recurring coital pain leads to inhibited arousal and sexual avoidance. "Dyspareunia" is used as both a symptom and a diagnosis. When coital pain is caused solely by defined physical pathology, dyspareunia due to a medical condition is diagnosed. When coital pain is due to vaginismus, insufficient lubrication, or other presumably psychogenic factors, dyspareunia not due to a medical condition diagnosis is made. Psychogenic etiologies may include a CNS pain perception problem raising the question, "What do we mean by psychogenic?" This arena's nomenclature will undoubtedly change when a breakthrough in understanding the causes of coital pain occurs.

### Psychogenic Sources of Dyspareunia

Pain associated with intercourse may have purely subjective or psychological origin. Couple dynamics are often relevant, but the pain may be seen as a means of not allowing painful memories of childhood sexual abuse into clear focus. Fear of or helplessness about negotiating interpersonal conflicts may eventually lead to pain becoming a solution for avoiding unwanted sexual behaviors. While physicians tend to assume that pain has unconscious origins, sometimes it is merely faked; more often the patient is quite aware of its developmental origins but is too embarrassed quickly to communicate it to the doctor.

Personal psychological origins of painful intercourse pass through the common denominator of anxiety. Such anxiety may take the forms of dread of physical damage, worry about the psychological dependence that might result from physical union, fear of a first or another pregnancy, or a sexually transmitted disease. Intense anxiety, the psychological source of her pain, may lead

to involuntary contraction of vaginal muscles which is the mechanical source of her pain. Thus, dyspareunia and vaginismus reinforce each other. Both situational and acquired dyspareunia may reflect a woman's conscious or unconscious motivation to avoid sex with a particular partner; it may be her only means to express her despair about their nonsexual relationship. Lifelong dyspareunia draws the clinician's attention to developmental experiences.

### Differential Diagnosis

Because the **symptom** dyspareunia is produced by numerous organic conditions, the psychiatrist should be certain that the patient has had a pelvic examination by a person equipped to assess a broad range of regional pathology. Vulvovestibulitis is diagnosed by pain in response to cotton swab touching in a normal appearing vulvar vestibule. A fundamental question remains unanswered about this often devastating problem: "Is the disorder of local or central origin?" In these patients and some others, the pain can not be classified with certainty as a **symptom** or a **disorder**. Pain upon penile or digital insertion may be due to an intact hymen or remnants of the hymenal ring, vaginitis, cervicitis, episiotomy scars, endometriosis, fibroids, ovarian cysts, and so on. Postcoital dyspareunia often begins at orgasm when uterine contractions occur. Fibroids, endometriosis and pelvic inflammatory disease should be considered. Postmenopausal pain, particularly if the woman has had many years without intercourse, is often a result of thinning of the vaginal mucosa, loss of elasticity of the labia and vaginal outlet, and decreased lubrication. Normal menopause, however, is often associated with mild pain due to inadequate lubrication (in both partners).

Dyspareunia in men is usually due to a medical condition. Herpes, gonorrhea, prostatitis and Peyronie's disease cause pain during intercourse. Remote trauma to the penis may cause penile chordee or bowing which makes intercourse mechanically difficult and sometimes painful. Pain experienced upon ejaculation can be a side effect of trazodone.

### Vaginismus

Vaginismus is an involuntary spasm of the musculature of the outer third layer of the vagina which makes penile penetration difficult or impossible. The diagnosis is not made if an organic cause is known. Although a woman with vaginismus may wish to have intercourse, her symptom prevents the penis from entering her body. It is as though her vagina says, "No!" In lifelong vaginismus, the anticipation of pain at the first intercourse causes muscle spasm. Pain reinforces the fear and, on occasion, the partner's response gives her good reason to dread a second opportunity to have intercourse. Early episodic vaginismus may be common among women, but most of the cases that are brought to medical attention are chronic. Lifelong vaginismus is relatively rare. The clinician needs to focus attention on what may have made the idea of intercourse so overwhelming to her: parental intrusiveness, sexual trauma, childhood genital injury, illnesses whose therapy involved orifice penetration and surgery?

The woman with lifelong vaginismus not only has a history of unsuccessful attempts at penetration but displays an avoidance of finger and tampon penetration. The most dramatic aspect of her history, however, is her inability to endure a speculum examination of her vagina. Vaginismus is a phobia of vaginal entrance.

## Treatment of Dyspareunia and Vaginismus

While vaginismus has the reputation of being readily treatable by gynecologists by pairing relaxation techniques with progressively larger vaginal dilators, the mental health professional typically approaches the problem differently. The psychiatric approach to both vaginismus and dyspareunia is attuned to the role that her symptom plays in her life. The therapy, therefore, does not begin with a cavalier, optimistic attempt to remove the symptom, which only frightens some patients. Rather, it begins with a patient exploration of the developmental and interpersonal meanings of the need for the symptom. “I wonder how this problem originally got started? Can you tell me a bit more about your life?” In the course of assisting women with these problems a variety of techniques may be utilized including relaxation techniques, sensate focus, dilatation, marital therapy and medication. Short-term therapies should not be expected to have lasting good results because once the symptom is relieved, other problematic aspects of the patient’s sexual equilibrium and nonsexual relationship often come into focus. Clinicians have developed an impression that women with a diagnosis of dyspareunia are particularly difficult to help permanently. However, this is a largely unstudied topic.

## Sexual Dysfunction Not Otherwise Specified

This diagnosis is reserved for circumstances that leave the doctor uncertain as to how to diagnose the patient. This may occur when the patient has too many fluctuating dysfunctional symptoms without a clear pattern of prominence of any one of them. Sometimes the psychiatrist is unable to determine whether the dysfunction is the basic complaint or when the sexual complaints are secondary to marital dysfunction. At other times the etiology is the uncertain: psychogenic, due to a general medical condition, or substance-induced. When the patient does not emphasize the dysfunction as the problem but emphasizes instead the lack of emotional satisfaction from sex, the psychiatrist may temporarily provide this NOS diagnosis. It is usually possible to find a better dysfunction diagnosis after therapy begins.

## Gender Identity Disorders

The organization of a stable gender identity is the first component of sexual identity to emerge during childhood. The processes that enable this accomplishment are so subtle that when a daughter consistently acts as though she realizes that “I am a girl and that is all right”, or when a son’s behavior announces that “I am a boy and that is all right”, families rarely even remember their children’s confusion and behaviors to the contrary. Adolescent and adult gender problems are not rare. They are however commonly hidden from social view, sometimes long enough to developmentally evolve into other less dramatic forms of sexual identity.

## Early Forms

### Extremely Feminine Young Boys

Although occasionally the parents of a feminine son have a convincing anecdote about persistent feminine interests dating from early in the second year of life, boyhood femininity is more typically only apparent by the third year. By the fourth year playmate preferences become obvious. Same-sex playmate preference is a typical characteristic of young children. Cross-gender-identified children consistently demonstrate the opposite sex playmate preference. The avoidance of other boys has serious consequences in terms of social rejection and loneliness throughout the school years. The peer problems of feminine boys cause some of their

behavioral and emotional problems which are in evidence by middle-to-late childhood. However, psychometric studies support clinical impressions that feminine boys have emotional problems even before peer relationships become a factor, that is, something more basic about being cross-gender-identified creates problems. Young feminine boys have been shown to be depressed and have difficulties with separation anxiety.

Speculations about the origin of boyhood femininity generally suggest converging cumulative forces. Any child’s cross-gender identifications are likely to involve a host of factors: constitutional forces, problematic interactions with parents, problematic internal processing of life experiences and family misfortune: financial, reproductive, physical disease, emotional illness, or death of vital persons. These factors are sometimes restated as temperament, disturbed family functioning, separation-identification problems and trauma.

Temperament is a dual phenomenon being both the child’s predisposition to respond to the world in a certain way and the aspects of the child to which others respond. The common temperamental factors of feminine boys have been described as: a sense of body fragility and vulnerability that leads to the avoidance of rough-and-tumble play; timidity and fearfulness in the face of new situations; a vulnerability to separation and loss; an unusual capacity for positive emotional connection to others; an ability to imitate; sensitivities to sound, color, texture, odor, temperature and pain (Coates *et al.*, 1992).

The development of boyhood femininity may occur within the mind of the toddler in response to a loss of emotional availability of the nurturant mother. The child creates a maternal (feminine) self through imitation and fantasy in order to make up for the mother’s emotional unavailability. This occurs beyond the family’s awareness and is left in place by the family either ignoring what has transpired in the son or valuing it. The problem for the effeminate boy is that reality – the social expectations of other people – is unyielding on gender issues; the adaptive early life solution becomes progressively more maladaptive with time.

The answer to the question whether boyhood femininity is entirely constitutional, an adaptive solution, or due to a combination that includes some other process is not known. A few reports of femininity giving way to psychotherapeutic interventions with young boys and their families are of heuristic value but limited in follow-up duration.

Green prospectively studied a large well-matched group of feminine boys for over a decade and discovered that boyhood effeminacy was a frequent precursor of adolescent homoeroticism and homosexual behavior rather than gender identity disorders. He observed, as had others before, that without therapy feminine gender role behaviors give rise to more masculine behavioral styles as adolescence emerges (Green, 1987).

## Masculine Girls: Tomboys

The masculinity of girls may become apparent as early as age 2 years. The number of girls brought to clinical attention for cross-gendered behaviors, self-statements and aspirations is consistently less than boys by a factor of 1:5 at any age of childhood in Western countries (except Poland). It is not known whether this reflects a genuine difference in incidence of childhood gender disorders, cultural perceptions of femininity as a negative in boys versus the neutral-to-positive perception of boy-like behaviors in girls, the broader range of cross-gender expression permitted to girls but not to boys, or an intuitive understanding that cross-gender identity more accurately predicts homosexuality in boys than girls.

The distinction between tomboys and gender-disordered girls is often difficult to make. Tomboys are thought of as not as deeply unhappy about their femaleness, not as impossible occasionally to dress in stereotypic female clothing, and not thought to have a profound aversion to their girlish and future womanly physiologic transformations. Tomboys are able to enjoy some feminine activities along with their obvious pleasures in masculine-identified toys and games and the company of boys. Girls who are diagnosed as gender-disordered generally seem to have a relentless intensity about their masculine preoccupations and an insistence about their future. The onset of their cross-gendered identifications is early in life. Although most lesbians have a history of tomboyish behaviors, most tomboys develop a heterosexual orientation.

### The Subjectivity of a Well-developed Gender Disorder

Children, teenagers and adults exist who rue the day they were born to their biological sex and who long for the opportunity simply to live their lives in a manner befitting the other gender. They repudiate the possibility of finding happiness within the broad framework of roles given to members of their sex by their society. Their repudiation is not motivated by an intellectual attack on sexism, homophobia, or any other injustice imbedded in cultural mores. A gender-disordered person literally repudiates his or her body, repudiates the self in that body and rejects performing roles expected of people with that body. It is a subtle, usually self-contained rebellion against the need of others to designate them in terms of their biological sex.

The repudiation and rebellion may first occur as a subjective internal drama of fantasy, as behavioral expression in play, or a preference for the company of others. Regardless of when and how it is displayed, the drama of the gender-disordered involves the relentless feeling that “life would be better – easier, fuller, more enjoyable – if I and others could experience me as a member of the opposite sex”.

By mid-adolescence, the extremely gender-disordered have often envisioned the solution for their paralyzing self-consciousness: to live as a member of the opposite gender, to transform their bodies to the extent possible by modern medicine, and to be accepted by all others as the opposite sex. Most people with these cross-gender preoccupations, however, do not go beyond the fantasy or private cross-dressing. Those that do eventually come to psychiatric attention. When a clinician is called in, the family has one set of hopes, the patient another. The clinician has many tasks, one of which is to mediate between the ambitions of the gender-disordered person and society and see what can be done to help the patient. Negative countertransference may steer the clinician to deal with the opportunity expeditiously: “Obviously the patient is sick, maybe psychotic, and needs help. I don’t take care of people who do these things. Refer it out!” With a little supervisory encouragement to perform a thorough evaluation, therapists soon find that these patients possess many of the ordinary aspects of life and one unusual ambition: they often want to be the opposite sex so badly that they are willing to make it a priority over family, friends, vocation and material acquisition.

### Diagnostic Criteria of Gender Identity Disorder

Adults who permanently change their bodies to deal with their gender dilemmas represent the far end of the spectrum of adaptations to gender problems. Even the lives of those who reject bodily change, however, have considerable pain because the images

of a better gendered self may recur throughout life, becoming more powerful whenever life becomes strained or disappointing.

The diagnosis of the extreme end of the gender identity disorder spectrum is clinically obvious. The challenging diagnostic task for clinicians is to suspect a gender problem and inquire about gender identity and its evolution in those whose manner suggest a unisexed or cross-gendered appearance, those with dissociative gender identity disorder (GID), severe forms of character pathology and those who seem unusual in some undefinable manner.

DSM-IV provides the clinician with two Axis I gender diagnoses. To qualify for the first, a patient of any age must meet four criteria:

**Criterion 1: Strong, persistent cross-gender identification** Because young children may not verbalize enough about their inner experiences for the clinician to be certain that this criterion is met, at least four of five manifestations of cross-gender identification must be present: 1) repeatedly stated desire to be, or insistence that he or she is, the opposite sex; 2) in boys, preference for cross-dressing or simulating female attire; in girls, insistence on wearing stereotypical masculine clothing; 3) strong and persistent preferences for cross-gender roles in fantasy play or persistent fantasies of being the opposite sex; 4) intense desire to participate in the games and pastimes of the opposite sex; 5) strong preference for playmates of the opposite sex.

In adolescence and adulthood, this criterion is fulfilled when the patient states the desire to be the opposite sex, has frequent social forays into appearing as the opposite sex, desires to live or be treated as the opposite sex, or has the conviction that his or her feelings and reactions are those typical of the opposite sex.

**Criterion 2: Persistent discomfort with one’s gender or the sense of inappropriateness in a gender role** This criterion is fulfilled in boys who assert that their penis or testicles are disgusting or will disappear or that it would be better not to have these organs; or who demonstrate an aversion toward rough-and-tumble play and rejection of male stereotypical toys, games and activities. In girls, rejection of urinating in a sitting position or assertion that they do not want to grow breasts or menstruate, or marked aversion towards normative feminine clothing fulfill this criterion.

Among adolescents and adults, this criterion is fulfilled by the patients’ exhibiting the following characteristics: preoccupation with getting rid of primary and secondary sex characteristics; preoccupation with thoughts about hormones, surgery, or other alterations of the body to enhance the capacity to pass as a member of the opposite sex such as electrolysis for beard removal, cricoid cartilage shave to minimize the Adam’s apple, breast augmentation, or preoccupation with the belief that one was born into the wrong sex.

**Criterion 3: Not due to an intersex condition** In the vast majority of clinical circumstances the patient possesses normal genital anatomy and sexual physiology. When a patient with a gender identity disorder and an accompanying intersex condition such as congenital adrenal hyperplasia, an anomaly of the genitalia, or a chromosomal abnormality is encountered, the clinician will be uncertain whether the intersex condition is the cause of the GID. The clinician may either diagnose gender identity disorder not otherwise specified (GIDNOS) or classify the patient as having a GID and list the physical factor on Axis III as a comorbid condition. The relationship between GID and intersex conditions is controversial topic that may be clarified with further research being done in Germany.

**Criterion 4: Significant distress and impairment** It is likely that many children, adolescents and adults struggle for a while to consolidate their gender identity but eventually find an adaptation that does not impair their capacities to function socially, academically, or vocationally as a member of their sex. These persons do not qualify for GID nor do those who simply are not stereotypic in how they portray their gender roles. Mental health professionals occasionally encounter parents who are disturbed by their adolescent child's gender roles. Parental distress is not the point of criterion 4; this criterion refers to patient distress.

### Diagnostic Criteria of Gender Identity Disorder Not Otherwise Specified (GIDNOS)

If an accurate community-based study of the gender-impaired could be conducted, most cases would be diagnosed as GIDNOS. The diagnostician needs to understand that gender identity development is a dynamic evolutionary process and clinicians see people at crisis points in their lives. At any given time, although it is clear that the patient has some form of GID, it may not be that which is described in DSM-IV as GID. Here is one example: an adult female calls herself a "neuter". She wants her breasts removed because she hates to be perceived as a woman. For 2 years she has been exploring "neuterdom" and "I am definitely not interested in being a man!" If in 2 years, she evolves to meet criterion 1, her current GIDNOS diagnosis will change.

GIDNOS is a large category designed to be inclusive of those with unusual genders who do not clearly fit the criteria of GID. There is no implication that if a patient is labeled GIDNOS that his or her label cannot change in the future. GIDNOS would contain the many forms of transvestism: masculine-appearing boys and teenagers with persistent cross-dressing (former fetishistic transvestites) who are evolving toward GID, socially isolated men who want to become a woman shortly after their wives or mothers die (secondary transvestites) but express considerable ambivalence about the very matter they passionately desired at their last visit, extremely feminized homosexuals including those with careers as "drag queens" who seem to want to change their sex when depressed, and so on. GIDNOS would also capture men who want to be rid of their genitals without being feminized, unisexual females who imagine themselves as males but who are terrified of any social expression of their masculine gender identity, hypermasculine lesbians in periodic turmoil over their gender, and those women who strongly identify with both male and female who lately want mastectomies. In using gender identity diagnoses, clinicians need to remember that extremely masculine women or extremely feminine men are not to be dismissed as homosexual. "Lesbian" or "gay" is only a description of orientation. They are more aptly described as also cross-gendered.

### The Relationship of Gender Identity Disorders to Orientation

The usual clarity of distinctions between heterosexual, bisexual and homosexual orientations rests upon the assumption that the biological sex and psychological gender of the person and the partner are known. A woman who designates herself as a lesbian is understood to mean she is erotically attracted to other women. "Lesbian" loses its meaning if the woman says she feels she is a man and lives as one. She insists, "I am a heterosexual man; men are attracted to women as am I!" The baffled clinician may erroneously think, "You are a female therefore you are a lesbian!" DSM-IV suggests that adults with GIDs should be

subgrouped according to which sex the patient is currently sexually attracted: males, females, both, or neither. This makes sense for most gender patients because it is their gender identity that is most important to them. Some are rigid about the sex of those to whom they are attracted because it supports their idea about their gender, others are bierotic and are not too concerned with their orientation, still others have not had enough experiences to overcome their uncertainty about their orientation. A few gender patients find all partners too complicated and are only interested in themselves.

### Treatment Options for the Gender Identity Disorders

The treatment of these conditions, although not as well-based on scientific evidence as some psychiatric disorders, has been carefully scrutinized by multidisciplinary committees of specialists within the Harry Benjamin International Gender Dysphoria Association for over 20 years. For more details in managing an individual patient, please consult its "Standards of Care" (Meyer *et al.*, 2001). The treatment of any GID begins after a careful evaluation, including parents, other family members, spouses, psychometric testing, and occasionally physical and laboratory examination. The details will depend on age of the patient. It is possible, of course, to have a GID as well as mental retardation, a psychosis, dysthymia, severe character pathology, or any other psychiatric diagnosis (Table 57.8).

### Individual Psychotherapy

No one knows how to cure an adult's gender problem. People who have lived long with profound cross-gender identifications do not

**Table 57.8 Steps in Evaluation of the Profoundly Gender Disordered\***

<p>Formal evaluation and diagnosis—gender identity disorder or gender identity disorder NOS. Can the patient be referred to a gender program? Is another treatable psychiatric or physical disorder present?</p> <p>Individual psychotherapy within the gender program or with yes, interested professional. Do the diagnoses remain the same? If not, does the patient consistently want to discuss his (or her) situation but make no changes? Increase cross-dressing toward cross-living? Prepare the family for the real-life test? Obtain permission to proceed with hormones? Approval for hormones from a gender committee or on written recommendation from the psychiatrist to an endocrinologist. Individual or group psychotherapy should continue.</p> <p>Real-life test of living and working full time in the aspired-to gender role for at least 1 year. Does the patient want to continue to surgery?</p> <p>Gender committee approval for surgery. Many patients have cosmetic surgery other than that listed with only ordinary patient—surgeon consent. This most often involves breast augmentation but may include numerous other attempts to improve ability to pass as opposite sex and be attractive.</p> <p>Men—genital reconstruction</p> <p>Women—mastectomy, hysterectomy, genital reconstruction</p>
--

\*Most patients will not complete all of these steps.

get insight – either behaviorally modified or medicated – and find that they subsequently have a conventional gender identity. Psychotherapy is useful, nonetheless. If the patient is able to trust a therapist, there can be much to talk about: family relationships are often painful, barriers to relationship intimacy are profound, work poses many difficult issues, and the patient has to make monumental decisions. The central one is, “How am I going to live my life? Should I go through with cross-gender living, hormone therapy, mastectomy, or genital surgery?” The therapist can help the patient recognize the drawbacks and advantages of the various available options and to respect the initially unrecognized or unstated ambivalence. Completion of the gender transformation process usually takes longer than the patient desires, and the therapist can be an important source of support during and after these changes.

### Group Therapy

Group therapy for gender-disordered people has the advantages of allowing patients to know others with gender problems, of decreasing their social isolation, and of being among people who do not experience their cross-gender aspirations and their past behaviors as weird. Group members can provide help with grooming and more convincing public appearances. The success of these groups depends on the therapist’s skills in patient selection and using the group process. Groups are generally only available in a few specialized treatment programs.

### “Real-life Test”

Living in the aspired-to-gender role – working, relating, conducting the activities of daily living – is a vital process that enables one of three decisions: to abandon the quest, to simply live in this new role, or to proceed with breast or genital surgery (Peterson and Dickey, 1995). Some clinicians use the real-life test as a criterion for recommending hormones but this varies because some patients’ abilities to present themselves in a new way is definitely enhanced by prior administration of cross-sex hormones. The reason for the real-life test is to give the patient, who created a transsexual solution in fantasy, an opportunity to experience the solution in social reality. Passing the real-life test is expected to be associated with improved psychological function.

### Hormone Therapy

Ideally, hormones should be administered by endocrinologists who have a working relationship with a mental health team dealing with gender problems. The effects of administration of estrogen to a biological male are: breast development, testicular atrophy, decreased sexual drive, decreased semen volume and fertility, softening of skin, fat redistribution in a female pattern and decrease in spontaneous erections. Breast development is often the highest concern to the patient. Because hair growth is not affected by estrogens, electrolysis is often used to remove beard growth. Side effects within recommended doses are minimal but hypertension, hyperglycemia, lipid abnormalities, thrombophlebitis and hepatic dysfunction have been described. The most dramatic effect of hormones is on the sense of well-being. Patients report feeling calmer, happier knowing that their bodies are being demasculinized and feminized. All results derive from open-labeled studies.

The administration of androgen to females results in an increased sexual drive, clitoral tingling and growth, weight gain, and amenorrhea and hoarseness. An increase in muscle mass may be apparent if weight training is undertaken simultaneously. Hair

growth depends on the patient’s genetic potential. Androgens are administered intramuscularly 200 to 300 mg/month and are generally safe. It is prudent, however, periodically to monitor hepatic, lipid and thyroid functioning. Most patients are delighted with their bodily changes, although some are disappointed that they remain short, wide-hipped, relatively hairless men with breasts that do not significantly regress.

### Surgical Therapy

Surgical intervention is the final external step. It should not occur without mental health professional’s input, even when the patient provides a heart-felt convincing set of reasons to bypass the real-life test, hormones and therapeutic relationship. Genital surgery is expensive, time-consuming, at times painful, and has frequent anatomic complications and functional disappointments. Surgery can be expected to add further improvements in the lives of patients: more social activities with friends and family, more activity in sports, more partner sexual activity and improved vocational status.

**Males** Surgery consists of penectomy, orchiectomy, vaginoplasty and fashioning of a labia. The procedures used for the creation of a neovagina have evolved over the years. Postoperatively, the patient must maintain the patency of the neovagina by initially constantly wearing and then periodically using a vaginal dilator. Vaginal stenosis or shortening is a frequent complication. The quest for an unmistakable feminine shape leads many young adult patients to augmentation mammoplasty and the shaving of their cricoid cartilage.

**Females** The creation of a male-appearing chest through mastectomies and contouring of the chest wall requires only a brief hospital stay. Patients are usually immediately delighted with their new-found freedom, but their fantasies of going shirtless are often not fulfilled due to the presence of two noticeable horizontal chest scars. The creation of a neophallus that can become erect, contain a functional urethra throughout its length (enabling urination while standing), and pass as an unremarkable penis in a locker room has been a significant surgical challenge. It is far from perfected. The surgery is, however, the most time-consuming, technically difficult and expensive of all the sex reassignment procedures. Erection is made possible by a penile prosthesis. Many prudent patients consider themselves reassigned when they have a hysterectomy, oophorectomy and mastectomy. Some just have a mastectomy. They find a partner who understands the situation and supports the idea of living with, and loving with, female genitals.

### The Paraphilias

A paraphilia is a disorder of intention, the final component of sexual identity to develop in children and adolescents. Intention refers to what individuals want to do with a sexual partner and what they want the partner to do with them during sexual behavior. Normally, the images and the behaviors of intention fall within ranges of peaceable mutuality. The disorders of intention are recognized by unusual eroticism (images) and often socially destructive behaviors such as sex with children, rape, exhibitionism, voyeurism, masochism, obscene phone calling, or sexual touching of strangers. While 5% of the diagnoses of paraphilia are given to women, etiologic speculations refer to male sexual identity development gone awry. This raises the important question about what happens to girls who have the same

developmental misfortunes that are speculated to create male paraphilia. Accounts of paraphilic behaviors have been in the nonmedical literatures for centuries.

Now it is apparent that paraphilias occur among individuals of all orientations and among those with conventional and unconventional gender identities. A homosexual sadist is paraphilic only on the basis of sexual cruelty. A transsexual who desires to be beaten during arousal is paraphilic only on the basis of masochism.

### Three General Characteristics of the Paraphilias

#### A Longstanding, Unusual, Highly-arousing Erotic Preoccupation

Erotic intentions that are not longstanding, unusual, and highly arousing may be problematic in some way but they are not clearly paraphilic. The *sine qua non* of the diagnosis of paraphilia is unusual, often hostile, dehumanized eroticism which has preoccupied the patient for most of his adolescent and adult life. The paraphilic fantasy is often associated with this preoccupying arousal when it occurs in daydreams and masturbation reveries or is encountered in explicit films or magazines. The specific imagery varies from one paraphilic patient to the next, but both the imagined behavior and its implied relationship to the partner are unusual in that they are preoccupied with aggression. Images of rape, obscene phone calling, exhibitionism and touching of strangers, for example, are rehearsals of victimization. In masochistic images, the aggression is directed at the self, for instance, autoerotic strangulation, slavery, torture, spanking. In others, the aggression is well-disguised as **love** of children or teenagers. In some, such as simple clothing fetishism, the aggression may be absent. Aggression is so apparent in most paraphilic content, however, that when none seems to exist, the clinician needs to wonder whether it is actually absent or being hidden from the doctor. Paraphilic fantasies often rely heavily upon the image of a partner who does not possess “personhood”. Some imagery in fact has no pretense of a human partner at all; clothing, animals, or excretory products are the focus. Other themes such as preoccupation with feet or hair, combine both human and inanimate interests. Paraphilic images are usually devoid of any pretense of caring or human attachment. The hatred, anger, fear, vengeance, or worthlessness expressed in them require no familiarity with the partner. Paraphilic images are conscious – clearly known to the individual. They should not be confused with speculations about “unconscious” aggression or sadomasochism that some assume are part of all sexual behavior (Kernberg, 1991). Clinicians should expect occasionally to see paraphilic patients whose preoccupations are not hostile to others.

An individual’s paraphilic themes often change in intensity or seem to change in content from time to time. The stimuli for these changes often remain unclear. It is a moot point whether changes should be considered a shift to a different disorder, a new paraphilia, or a natural evolution of the basic problem. The shifts from imagining talking “dirty” on the phone in order to scare a woman to imagining raping can be considered an intensification of sadism. Switches between sadism and masochism or voyeurism and exhibitionism are common. Changes from voyeurism to pedophilia or from pedophilia to rape, however, raise the question whether a new disorder has developed. The most socially significant shifts are from erotic imagery to sexual behavior. In most instances, it is reasonable to consider that paraphilia is a basic developmental disorder in which particular erotic

and sexual manifestations are shaped by the individuality of the person’s history.

Most paraphilic adults can trace their fantasy themes to puberty and many can remember these images from earlier years. When adolescent rapists or incest offenders are evaluated, they often are able to report prepubertal aggressive erotic preoccupations. Men who report periodic paraphilic imagery interspersed with more usual eroticism have had their paraphilic themes from childhood or early adolescence. To make a diagnosis of paraphilia, the patient must evidence at least 6 months of the unusual erotic preoccupation. Duration is usually not in question, even among adolescents, however (Shaw, 1999).

#### Pressure to Act Out the Fantasy

To be paraphilic means that the erotic imagery exerts a pressure to play out the often imagined scene. In its milder forms, the pressure results merely in a preoccupation with a behavior. For instance, a man who prefers to be spoken to harshly and dominated by his wife during sex thinks about his masochistic images primarily around their sexual behaviors. He does not spend hours daydreaming of his erotic preferences. In its more intense forms, paraphilias create a **driveness** to act out the fantasy in sexual behavior – usually in masturbation. Frequent masturbation, often more than once daily, continues long after adolescence. In the most severe situations, the need to attend to the fantasy and masturbate is so overpowering that life’s ordinary activities cannot efficiently occur. Masturbation and sometimes partner-seeking behavior – such as finding a woman to shock through exhibiting an erection – is experienced as driven. The patient reports either that he cannot control his behavior or he controls it with such great effort that his work, study, parenting and relationships are disrupted. This pressure to behave sexually often leads the man to believe he has a high sex drive. Some severe paraphilics describe their masturbation-to-orgasm frequencies as 10/day. Even when the patient’s estimate of his frequency of orgasm strains credulity less, the return of sexual drive manifestations so soon after orgasm suggests that either something is wrong with the patients’ sexual drive generator, their satiety mechanisms, or that their existential anxiety overpowers their other defense mechanisms.

Paraphilic men often report collecting and viewing pornography, visiting sexual book stores to see explicit videos or peep shows, frequenting prostitutes for their special sexual behaviors, downloading explicit images from the Internet, or extensively using telephone sex services or strip clubs. Victimization of others, the public health problem, is the least common form of sexual acting out but it is by no means rare (Abel *et al.*, 1987). When the behavioral diagnosis of exhibitionism, pedophilia, or sadism is made, the clinician should assume that the numbers of victims far exceed the number stated in the criminal charges.

Two other conditions, compulsive sexual behavior and sexual addiction not part of the DSM-IV, are informally and synonymously used to refer to heterosexual and homosexual men and women who display an intense drivenness to behave sexually without paraphilic imagery. The personal, interpersonal and medical consequences of paraphilic and nonparaphilic sexual compulsivity seem indistinguishable as do their usual psychiatric comorbidities: depression, anxiety disorders, substance abuse and attention deficit disorders (Kafka and Prentky, 1998).

#### Partner Sexual Dysfunction

A severe sexual dysfunction involving desire, arousal, or orgasm with a partner, although not invariably, often is present

among paraphilics (Pawlak, 1991). The wives of paraphilics tell stories with these themes: “He is not interested in sex with me”. “He never initiates.” “He doesn’t seem to enjoy our sexual life together except when . . .” “He is usually not potent.” “Even when we do make love, he rarely ejaculates.” Some paraphilic men however are able to function well without paraphilic fantasies but others are either able primarily to function when their partners are willing to meet their special requirements for arousal or when they fantasize about their paraphilic script (Abel, 1989).

### Speculations About the Underlying Problem

Paraphilia has been considered in 15 somewhat different ways, depending on era, ideology and region: 1) an impairment in the bonding function of sexuality; 2) a courtship disorder; 3) the erotic form of hatred motivated by the need for revenge for childhood trauma; 4) a fixation to childhood misunderstandings that women had penises and that men could lose theirs during sex (castration anxiety); 5) the unsuccessful repair of early life passive, helpless experiences with a terrifying, malignant, malicious preoedipal mother; 6) a strategy to stabilize a conventional masculine or feminine gender identity; 7) a strategy to deny the differences between the sexes and the generations of child and parent; 8) an outcome of childhood sexual abuse; 9) a consequence of far less than ideal parent–child relationships; 10) a soft neurological sign of a neural wiring defect; 11) a released behavior due to cerebral pathology, for example, temporal lobe dysfunction, or substance abuse; 12) the sexual face of an addiction disorder; 13) an unusual manifestation of an affective disorder; 14) an obsessive–compulsive spectrum disorder; 15) a defective self-system requiring a patch – that is, a sexual preoccupation – to shore up the private, carefully-hidden-from-others sense of inadequate subjective masculinity.

Whatever its ultimate etiologies and nature, the paraphilias are sexual identity disorders that generally make normal erotic and sexual loving unattainable. Culture asks us to have some image of attachment, some ability to neutralize anger toward others, some ability to contain the anxiety over closeness, and some psychological motive simultaneously to enhance the self and the partner through sexual contact. Ordinary intentions aim for peaceable mutuality between real people; paraphilic ones aim at aggressive one-sidedness. This sexual identity disorder could be referred to as a disorder of self, specifically of that part of the self that maintains a sense of masculinity. Paraphilics often bear an enigmatic paradox between what they want to be and what they are. They often hunger for a behavior which feels uncontrollable or sick and which robs them of autonomy. This is why the behaviors are often thought of as addictions and are often associated with other forms of substance abuse, obsessive–compulsive phenomena and affective symptoms. Relative to the dynamic fluctuations of sexual dysfunctions, intention disorders are tenacious throughout life.

## The Specific Paraphilias

### Criminal Sex Offending Behaviors

#### Exhibitionism

Exhibitionism generally involves teenagers and men displaying their penises so that the witness will be shocked or (in the paraphilic’s fantasy) sexually interested. They may or may not

masturbate during or immediately following this act of victimization. This diagnosis is not usually made when a man is arrested for “public indecency” and his penile exposures are motivated to arrange homosexual contact in a public place generally unseen by heterosexuals. Penile display in parks is one way to make anonymous contact. The presence or absence of exhibitionistic imagery allows the clinician to make the distinction between paraphilia and homosexual courting.

#### Pedophilia

Pedophilia is the most widely and intensely socially repudiated of the paraphilias. Pedophiles are men who erotically and romantically prefer children or young adolescents. They are grouped into categories depending upon their erotic preferences for boys or girls and for infant, young, or pubertal children. Some pedophiles have highly age- and sex-specific tastes, others are less discriminating. Since the diagnosis of pedophilia requires that over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving sexual activity with a prepubescent child or children, the disorder should not be expected to be present in every person who is guilty of child molestation. Some intrafamilial child abuse occurs over a shorter time interval and results from combinations of deteriorated marriages, sexual deprivation, sociopathy and substance abuse. Child molestation, whether paraphilic or not, is a crime, however. Child molesters show several patterns of erectile responses to visual stimulation in the laboratory. Some have their largest arousal to children of a specific age and others respond to both children and adults (Barbaree and Marshall, 1989). Others respond with their greatest arousal to aggressive cues.

#### Voyeurism

Men whose sexual life consist of watching homosexual or heterosexual videos in sexual book stores occasionally come to psychiatric attention after being charged with a crime following a police raid. They may or may not qualify for this diagnosis. The voyeurs who are more problematic for society are those who watch women through windows or break into their dwellings for this purpose. Some of these crimes result in rape or nonsexual violence, but many are motivated by pure voyeuristic intent (which is subtly aggressive).

#### Sexual Sadism

While rape is an extreme variety of sadism, paraphilic sadism is present only in a minority of rapists. It is defined by the rapist’s prior use of erotic scripts that involve a partner’s fear, pain, humiliation and suffering. Rapists are highly dangerous men whose antisocial behaviors are generally thought to be unresponsive to ordinary psychiatric methods. Their violence potential often makes psychiatric therapy outside of institutions imprudent. Noncriminal paraphilic sadism, that is, arousal to images of harming another that has not crossed into the behavioral realm, can be treated in outpatient settings.

#### Frotteurism

Frotteurism, the need to touch and rub against nonconsenting persons, although delineated as a criminal act, is probably better understood as the most socially benign form of paraphilic sadism. Frotteurism often occurs in socially isolated men who become sexually driven to act out. They often are unaware of how frightening they can be.

## Stalking

Stalking is the latest erotic preoccupation to be criminalized. Forensic psychiatry has defined various motivations for arrested stalkers, including those who have made the transition from romantic to violent preoccupation with the victim. Stalking is particularly frightening because murder occasionally results. It is likely that stalking as a behavior is the product of further deterioration of an already compromised mind, although not necessarily a paraphilic one.

## Noncriminal Forms of Paraphilia

Because the individual manifestations of paraphilia depend on the particular individual life history of the affected, over 40 paraphilic categories have been identified although only a few are listed in the DSM-IV. Most of these are unusual means of attaining arousal during masturbation or consenting partner behaviors. Each of the themes identified below demonstrate a wide range of manifestations from the bizarre to the more “reasonable” and from the common to the unique. They often subtly combine elements of more than one paraphilia.

### Fetishism

Fetishism, the pairing of arousal with wearing or holding an article of clothing or inanimate object such as an inflatable doll, has a range of manifestations from infantilism in which a person dresses up in diapers to pretend he is a baby to the far more common use of a female undergarment for arousal purposes. Fetishism when confined to one garment for decades is classified as a paraphilia, but many cases involve more complex varieties of cross-dressing and overlap with gender identity disorders, usually GIDNOS. Fetishistic transvestism is the diagnosis used when it is apparent that the urges to use the clothing of the opposite sex is part of a larger mental preoccupation with that sex.

### Sexual Masochism

Sexual masochism is diagnosed over a range of behaviors from the sometimes fatal need to nearly asphyxiate oneself to the request to be spanked by the partner in order to be excited. Masochism may be the most commonly reported or acknowledged form of female paraphilia, although it is more common among men. Sadists and masochists sometimes find one another and work out arrangements to act out their fantasies and occasionally reverse roles.

### Paraphilia Not Otherwise Specified

Paraphilia not otherwise specified is a DSM-IV category for other endpoints of abnormal sexual development that lead to pre-occupations with amputated body parts, feces, urine, sexualized enemas and sex with animals.

## Treatment

Four general approaches are employed to treat the paraphilias. The treatments are not mutually exclusive, rather they are often multimodal in application.

### Evaluation Only

Evaluation only is often selected when the evaluator concludes that the paraphilia is benign in terms of society, the patient will be resistant to the other approaches, and does not suffer greatly in terms of social and vocational functioning in ways that might be improved. Often these are isolated men with private paraphilic sexual pleasures, such as telephone sex with a masochistic scenario.

## Psychotherapy

What constitutes psychotherapy for paraphilia heavily depends on the therapist training rather than strident declarations of treatment of choice. Little optimism exists that any form of therapy can permanently change the nature of a long established paraphilic erotic script, even among teenage sex offenders. Individual psychodynamic psychotherapy can be highly useful in diminishing paraphilic intensifications and gradually teaching the patient better management techniques of the situations that have triggered acting out. Well-described cognitive-behavioral interventions exist for interrupting paraphilic arousal via pairing masturbatory excitement with either aversive imagery or aversive stimuli. Comprehensive behavioral treatment involves social skills training, assertiveness training and confrontation with the rationalizations that are used to minimize awareness of the victims of sexual crimes, and marital therapy (Abel and Osborn, 1995). The self-help movement has created 12-step programs for sexual addictions to which many individuals now belong. Group psychotherapy is offered by trained therapists as well. When the lives of paraphilics are illuminated in various therapies, it becomes apparent that the emotional pain of the patients is thought to be great; the sexual acting out is often perceived as a defense against recurrent unpleasant emotions from any source. These often, however, involve self-esteem and primitive anxiety.

## Medications

In the early 1980s, depo-medroxy-progesterone (Provera) was first used to treat those who were constantly masturbating, seeking out personally dangerous sexual outlets, or committing sex crimes. The weekly 400 to 600 mg injections often led to the men being able to work, study, or participate in activities that were previously beyond them because of concentration or attention difficulties. In the late 1980s, the use of oral Provera, 20 to 120 mg/day led to similar results: the drug enabled these men to leave their former state in which their sexual needs took priority over other life demands, and they did not have depo-Provera's side-effect profile: weight gain, hypertension, muscle cramps and gynecomastia. Today, gonadotrophin-releasing blockers are occasionally used for this. The possible side effects are similar to oral Provera. Despite the fact that the clinical results are among the most powerful effected by any psychopharmacologic treatment, many psychiatrists cannot overcome their disinclination about giving a “female” hormone to a man or working with patients who victimize others sexually. Serotonergic agents are now more commonly used as a first line of treatment and their administration, of course, creates fewer countertransference obstacles. While these studies are not as methodologically sophisticated as they need to be, the SSRIs are in widespread use for compulsive sexual behaviors and sexual obsessions. Their efficacy is the source of the speculation that some of the paraphilias may be an obsessive-compulsive spectrum disorder.

## External Controls

Sexual advantage-taking, whether it be by a paraphilic physician with his patients, by a pedophilic mentally retarded man in the neighborhood, or of a grandfather who has abused several generations of his offspring, can often be stopped by making it **impossible** for these behaviors to be **unknown** to most people in his life. The doctor's staff can be told, the neighbors can know, the family can meet to discuss the current crisis and review who has been abused over the years and plan to never allow grandfather

alone with any child in or outside the family. The concept of external control is taken over by the judicial system when sex crimes are highly repugnant or heinous. The offender is removed from society for punishment and the protection of the public. Increasing pressure exists to criminalize sexual advantage-taking by physicians who are even more susceptible to losing their medical licenses at least for several years.

Psychiatrists need to be realistic about the limitations of various therapeutic ventures. Sexual acting out may readily continue during therapy beyond the awareness of the therapist. The more violent and destructive the paraphilic behavior to others, the less the therapist should risk ambulatory treatment. Since paraphilia occurs in patients with other psychiatric conditions, the psychiatrist needs to remain vigilant that the treatment program is comprehensive and does not lose sight of the paraphilia just because the depressive or compulsive symptoms are improved. Paraphilia may be improved by medications and psychotherapy but the clinician should expect that the intention disorder is the patient's lasting vulnerability.

### Sexual Disorder Not Otherwise Specified

If the clinician is uncertain about how to categorize a person's problem, it is more reasonable to use this diagnosis than one that does not encompass the range of the patient's suffering. Sexual disorder not otherwise specified can be used when the therapist perceives a dramatic interplay between issues of sexual identity and sexual dysfunction, or when "everything" seems to be amiss. DSM-IV-TR, however, encourages the clinician to make multiple sexual diagnoses involving, for instance, a gender identity disorder, a desire disorder, erectile and orgasmic disorder.

DSM-IV-TR provides two examples when it would be appropriate to use the diagnosis sexual disorder NOS: 1) nonparaphilic compulsive sexual behaviors, that is, relentless pursuit of masturbatory or heterosexual or homosexual partner experiences without evidence of paraphilic imagery; and 2) complicated or exaggerated struggles to manage homosexual urges. Despite the removal of homosexuality from the DSM in 1974 men (particularly) and women still generate symptoms in their struggle to balance the demands of their homoeroticism with their ambitions to participate in conventional family life. This ongoing struggle can generate a variety of anxiety, depressive, compulsive, substance abusing and suicidal states.

### Final Thoughts

A specific diagnosis like vaginismus or GIDNOS does not, per se, dictate the type and course of therapy. The clinician is called upon to weigh many factors in planning treatment. Accurate diagnosis is a vital first step but it quickly gives way to other, more artful considerations. "What factors set up this problem and what forces maintain it? What is the essence of this situation? What does this diagnosis mean in ordinary human terms? Can medication play a useful role? How am I to help? What am I to say? When and how should I say it?" These are essentially psychotherapy considerations. The sexual disorders challenge the doctor to integrate the advances of modern psychiatry with the traditions of less biologically-oriented psychiatry and the knowledge accumulating in forensic settings for the purpose of seeing if the patient's distress can be lastingly altered. In this challenge, clinical science inevitably gives way to clinical art. The art involves enabling the patient's distress to make sense so that the

underlying struggle – the developmental task – can be successfully negotiated.

For gender identity disorder, ICD-10 defines three separate disorders: "Gender Identity Disorder of Childhood", "Dual-role Transvestism" and "Transsexualism", all of which are included under the single DSM-IV-TR category Gender Identity Disorder.

### Comparison of DSM-IV/ICD-10 Diagnostic Criteria

For hypoactive sexual desire disorder, the ICD-10 Diagnostic Criteria for Research and the DSM-IV-TR criteria are essentially identical except that ICD-10 specifies a minimum duration of at least 6 months (DSM-IV-TR has no minimum duration).

The ICD-10 Diagnostic Criteria for Research for Sexual Aversion Disorder differs from the DSM-IV-TR criteria in several ways. In contrast to DSM-IV-TR which restricts the condition to the aversion to, and avoidance of, sexual genital contact, ICD-10 also includes presentations characterized by sexual activity resulting in "strong negative feelings and an inability to experience any pleasure". Furthermore, ICD-10 excludes cases in which the aversion is due to performance anxiety. Finally, ICD-10 specifies a minimum duration of at least 6 month whereas DSM-IV-TR does not specify any minimum duration.

For female sexual arousal disorder and male erectile disorder, the ICD-10 Diagnostic Criteria for Research and the DSM-IV-TR criteria are essentially equivalent except that ICD-10 specifies a minimum duration of at least 6 months. ICD-10 includes a single category ("Failure of Genital Response") with two separate criteria sets by gender. In contrast, DSM-IV-TR includes two separate categories.

For female and male orgasmic disorders, the ICD-10 Diagnostic Criteria for Research and the DSM-IV-TR criteria are essentially equivalent except that ICD-10 specifies a minimum duration of at least 6 months. In contrast to DSM-IV-TR which has male and female versions defined separately, ICD-10 has a single category that applies to both genders.

For premature ejaculation, the ICD-10 Diagnostic Criteria for Research and the DSM-IV-TR criteria are essentially equivalent except that ICD-10 specifies a minimum duration of at least 6 months. Similarly, the ICD-10 Diagnostic Criteria for Research and the DSM-IV-TR criteria for Dyspareunia and Vaginismus are essentially equivalent except that ICD-10 specifies a minimum duration of at least 6 months. Furthermore, these conditions are referred to in ICD-10 as "Nonorganic Dyspareunia" and "Nonorganic Vaginismus".

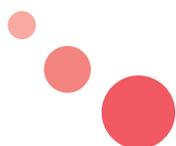

The definition of a paraphilia is essentially the same in DSM-IV-TR and ICD-10. However, ICD-10 does not include a separate category for Frotteurism and has a combined "Sadomasochism" category.

For gender identity disorder, ICD-10 defines three separate disorders: "Gender Identity Disorder of Childhood", "Dual-role Transvestism" and "Transsexualism", all of which are included under the single DSM-IV-TR category Gender Identity Disorder.

In the current psychiatric nomenclature of the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (DSM-IV-TR), the eating disorders consist of two clearly defined syndromes: anorexia nervosa and bulimia nervosa. Many individuals presenting for treatment of an eating disorder (Figure 58.1) fail to meet formal criteria for either anorexia nervosa or bulimia nervosa, which raises an important theoretical and practical question: What is an eating disorder? Although this topic has received surprisingly little attention, it has been suggested that a working definition of an eating disorder might be “a persistent disturbance of eating behavior or behavior intended to control weight, which significantly impairs physical health or psychosocial functioning” (Fairburn and Walsh, 2002). This definition clearly encompasses the recognized disorders, anorexia nervosa and bulimia nervosa. In addition, it provides a basis for viewing eating disorders as clinically significant problems that do not meet criteria for anorexia nervosa or bulimia nervosa. The term atypical eating disorder is often applied to such problems, even though the number of individuals suffering from them may well outnumber those with “typical” eating disorders. One example of an atypical eating disorder is that of women who are overly concerned about their weight, have dieted to a below-normal weight, but have not ceased menstruating and, therefore, do not meet full criteria for anorexia nervosa. Another is that of individuals who binge and vomit regularly, but at less than the twice-a-week frequency required for bulimia nervosa.

An additional example of a clinically important atypical eating disorder is the occurrence of frequent binge-eating that is not followed by the self-induced vomiting or other inappropriate attempts to compensate that are characteristic of bulimia nervosa. This disturbance, for which the name binge-eating disorder has been proposed (DSM-IV appendix B) is a common behavioral pattern among obese individuals who present for treatment at weight loss clinics.

At present, obesity is not considered an eating disorder. Obesity refers to an excess of body fat and is viewed as a general medical, not a psychiatric, condition. At this stage of our knowledge, obesity is conceived as an etiologically heterogeneous condition. Obese individuals are at increased risk for a number of serious medical problems and are subject to significant social stigmatization and its psychological sequelae. However, the widely held assumption that obesity is the result of a psychiatric disorder in which eating is used as a coping mechanism for depression or anxiety has not been substantiated by empirical research. Studies of obese and normal-weight subjects from the general (nonpatient) population have found no more psychiatric disturbance in those who are overweight than in those who are of normal weight. Therefore, it seems appropriate at present to describe as having an eating disorder only

those obese individuals who manifest a clear behavioral abnormality that impairs health or psychosocial functioning.

## Anorexia Nervosa

### Definition

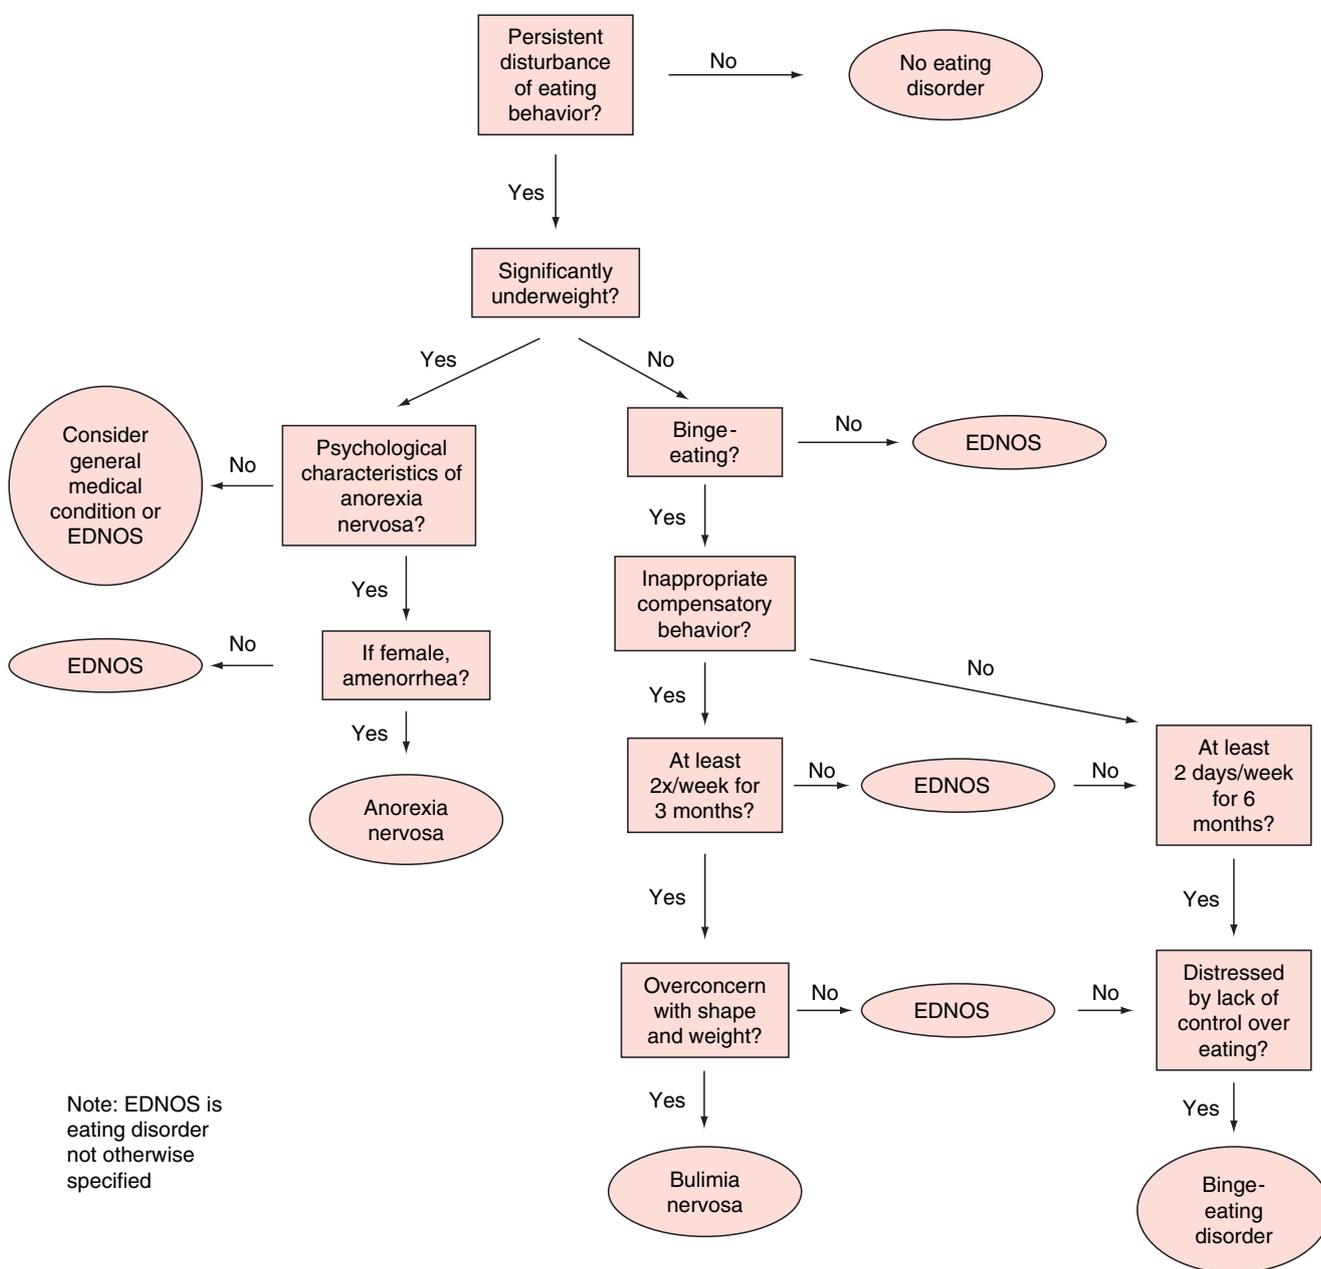

The DSM-IV-TR criteria require the individual to be significantly underweight for age and height. Although it is not possible to set a single weight loss standard that applies equally to all individuals, DSM-IV-TR provides a benchmark of 85% of the weight considered normal for age and height as a guideline. Despite being of an abnormally low body weight, individuals with anorexia nervosa are intensely afraid of gaining weight and becoming fat, and remarkably, this fear typically intensifies as the weight falls.

DSM-IV-TR criterion C requires a disturbance in the person's judgment about his or her weight or shape. For example, despite being underweight, individuals with anorexia nervosa often view themselves or a part of their body as being too heavy. Typically, they deny the grave medical risks engendered by their semistarvation and place enormous psychological importance on whether they have gained or lost weight. For example, someone with anorexia nervosa may feel intensely distressed if her or his weight increases by half a pound. Finally, criterion D requires that women with anorexia nervosa be amenorrheic.

The DSM-IV-TR criteria for anorexia nervosa are generally consistent with recent definitions and descriptions of this illness. In addition, in DSM-IV-TR, a new subtyping scheme was introduced. DSM-IV-TR suggests that individuals with anorexia nervosa be classed as having one of two variants, either the binge-eating/purging type or the restricting type. Individuals with the restricting type of anorexia nervosa do not engage regularly in either binge-eating or purging and, compared with individuals with the binge-eating/purging form of the disorder, are not as likely to abuse alcohol and other drugs, exhibit less mood lability and are less active sexually. There are also indications that the two subtypes may differ in their response to pharmacological intervention.

### Epidemiology

Anorexia nervosa is a relatively rare illness. Even among high-risk groups, such as adolescent girls and young women, the prevalence of strictly defined anorexia nervosa is only about 0.5%. The prevalence rates of partial syndromes are substantially higher. Despite the infrequent occurrence of anorexia nervosa, most studies suggest that its incidence has increased significantly during the last 50 years, a phenomenon usually attributed to changes in cultural norms regarding desirable body shape and weight.

**Figure 58.1** Algorithm for diagnosis of eating disorders.

Anorexia nervosa usually affects women; the ratio of men to women is approximately 1 : 10 to 1 : 20. Anorexia nervosa occurs primarily in industrialized and affluent countries and some data suggest that even within those countries, anorexia nervosa is more common among the higher socioeconomic classes. Some occupations, such as ballet dancing and fashion modeling, appear to confer a particularly high risk for the development of anorexia nervosa. Thus, anorexia nervosa appears more likely to develop in an environment in which food is readily available but in which, for women, being thin is somehow equated with higher or special achievement.

### Etiology

At present, the etiology of anorexia nervosa is fundamentally unknown. However, from several sources, such as the epidemiological data just reviewed, it is possible to identify risk factors

whose presence increases the likelihood of anorexia nervosa. It is also possible to describe the course and complications of the syndrome and to suggest interactions between features of the disorder, for example, between malnutrition and psychiatric illness. Thus, as indicated in Figure 58.2, the difficulties that lead to the development of anorexia nervosa may be distinct from the forces that intensify the symptoms and perpetuate the illness once it has begun.

### Genetic and Twin Studies

Anorexia nervosa occurs more frequently in biological relatives of patients who present with the disorder. The prevalence rate of anorexia nervosa among sisters of patients is estimated to be approximately 6%; the morbid risk among other relatives ranges from 2 to 4%. Some evidence for a genetic component in the etiology of anorexia nervosa comes from twin studies, which reported

## DSM-IV-TR Criteria 307.1

### Anorexia Nervosa

- A. weight at or above a minimally normal weight Refusal to maintain body for age and height (e.g., weight loss leading to maintenance of body weight less than 85% of that expected; or failure to make expected weight gain during period of growth, leading to body weight less than 85% of that expected).
- B. or becoming fat, Intense fear of gaining weight even though underweight.
- C. one's body Disturbance in the way in which weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight.
- D. In postmenarcheal females, amenorrhea, i.e., the absence of at least three consecutive menstrual cycles. (A woman is considered to have amenorrhea if her periods occur only following hormone, e.g., estrogen, administration.)

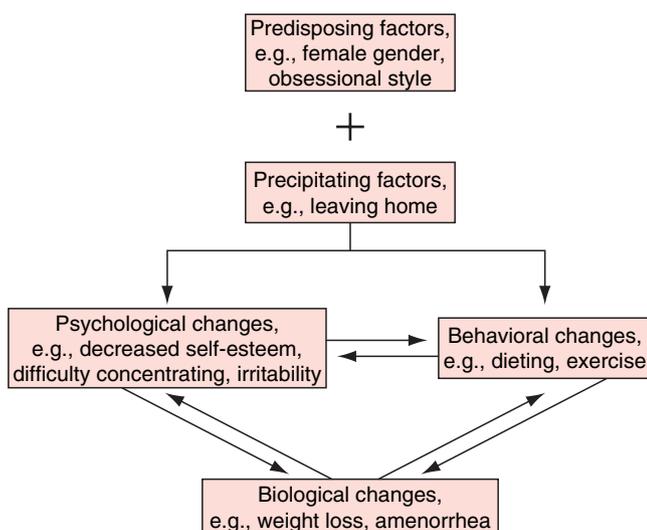

Specify type:

**Restricting type:** during the current episode of anorexia nervosa, the person has not regularly engaged in binge-eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas).

**Binge-eating/purging type:** during the current episode of anorexia nervosa, the person has regularly engaged in binge-eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas).

substantially higher concordance rates for monozygotic than for dizygotic twin pairs (Klump *et al.*, 2001). However, conclusive data for genetic transmission of the disorder are not yet available.

**Figure 58.2** Schematic diagram illustrating how an interplay of factors may lead to the initiation and persistence of anorexia nervosa.

## Family Studies

Individual psychiatric disorders in parents, dysfunctional family relationships and impaired family interaction patterns have been implicated in the etiology of anorexia nervosa. Mothers of individuals with anorexia nervosa are often described as over-protective, intrusive, perfectionistic and fearful of separation; fathers are described as withdrawn, passive, emotionally constricted, obsessional, moody and ineffectual. Family systems theorists have suggested that impaired family interactions such as pathological enmeshment, rigidity, overprotectiveness, and difficulties confronting and resolving conflicts are central features of anorexic pathology. However, few empirical studies have been conducted to date, particularly studies that also examine psychiatrically or medically ill comparison groups. Therefore, the precise role of the family in the development and course of anorexia nervosa, although undoubtedly important, has not been clearly delineated.

## Psychosocial Factors

The increased prevalence of anorexia nervosa has been connected to the current emphasis in contemporary Western society on an unrealistically thin appearance in women. There is substantial evidence that a desire to be slim is common among middle- and upper-class white women and that this emphasis on slimness has increased significantly during the past several decades. In the USA, anorexia nervosa develops much more frequently in white adolescents than in adolescents from other racial groups. It has been suggested that a variety of characteristics may protect African-American girls from having eating disorders, including more acceptance of being overweight, more satisfaction with their body image and less social pressure regarding weight.

It has also been suggested that the emphasis of contemporary Western society on achievement and performance in women, which is a shift from the more traditional emphasis on deference, compliance and unassertiveness, has left many young women vulnerable to the development of eating disorders such as anorexia nervosa. These multiple and contradictory role demands are embodied within the modern concept of a superwoman who performs all of the expected roles (e.g., is competent, ambitious and achieving, yet also feminine, nurturing and sexual) and, in addition, devotes considerable attention to her appearance (Gordon, 1990).

## Psychodynamic Factors

Various psychoanalytic theories have been postulated (e.g., defense against fantasies of oral impregnation; underlying deficits in the development of object relations; deficits in self-structure), but such hypotheses are difficult to verify. Bruch (1973, 1982) suggested that anorexia nervosa stems from failures in early attachment, attempts to cope with underlying feelings of ineffectiveness and inadequacy, and an inability to meet the demands of adolescence and young adulthood. These ideas, as well as her conceptualization that the single-minded focus on losing weight in anorexia nervosa is the concrete manifestation of a struggle to achieve a sense of identity, purpose, specialness and control, are compelling and clinically useful. Cognitive-behavioral theories emphasize the distortions and dysfunctional thoughts (e.g., dichotomous thinking) that may stem from various causal factors, all of which eventually focus on the belief that it is essential to be thin.

Although the existence of a specific predisposing personality style has not been conclusively documented, certain traits have commonly been reported among women with anorexia

nervosa. Women hospitalized for anorexia nervosa have greater self-discipline, conscientiousness and emotional caution than women hospitalized for bulimia nervosa and women with no eating disorders. In addition, even after they have recovered from their illness, women who have had anorexia nervosa tend to avoid risks and to exhibit high levels of caution in emotional expression and strong compliance with rules and moral standards.

### Developmental Factors

Because anorexia nervosa typically begins during adolescence, developmental issues are thought to play an important etiologic role. Critical challenges at this time of life include the need to establish independence, a well-defined personal identity, fulfilling relationships, and clear values and principles to govern one's life. Family struggles, conflicts regarding sexuality and pressures regarding increased heterosexual contact are also common. However, it is not clear that difficulties over these issues are more salient for individuals who will develop anorexia nervosa than for other adolescents. Depression has been implicated as a nonspecific risk factor, and higher levels of depressive symptoms as well as insecurity, anxiety and self-consciousness have been documented in adolescent girls in comparison with adolescent boys. Similarly, the progression of physical and sexual maturation and the concomitant increase in women's percentage of body fat may have a substantial impact on the self-image of adolescent girls, particularly because the relationship between self-esteem and satisfaction with physical appearance and body characteristics is stronger in women than in men.

### Pathophysiology

An impressive array of physical disturbances has been documented in anorexia nervosa and the physiological bases of many are understood (Table 58.1). Most of these physical disturbances appear to be secondary consequences of starvation, and it is not clear whether or how the physiological disturbances described here contribute to the development and maintenance of the psychological and behavioral abnormalities characteristic of anorexia nervosa. The remainder of this section briefly describes the major physical abnormalities of anorexia nervosa and what is understood about their etiology.

The central nervous system is clearly affected. Computed tomography has demonstrated that individuals with anorexia nervosa have enlarged ventricles, an abnormality that improves with weight gain. The cerebrospinal fluid concentrations of a variety of neurotransmitters and their metabolites are altered in underweight patients with anorexia nervosa and tend to normalize as weight is restored. An intriguing exception may be the serotonin metabolite 5-hydroxyindoleacetic acid, which has been reported to be elevated in the cerebrospinal fluid of patients with anorexia nervosa after they have achieved a normal or near-normal weight. Kaye (1997) has suggested that the elevated 5-hydroxyindoleacetic acid levels may reflect a serotonergic abnormality that is tied to the obsessional traits often observed in anorexia nervosa.

Some of the most striking physiological alterations in anorexia nervosa are those of the hypothalamic–pituitary–gonadal axis. In women, estrogen secretion from the ovaries is markedly reduced, accounting for the occurrence of amenorrhea. In analogous fashion, testosterone production is diminished in men with anorexia nervosa. The decrease in gonadal steroid production is due to a reduction in the pituitary's secretion of the gonadotropins luteinizing hormone and follicle-stimulating hormone, which in turn is secondary to diminished release of gonadotropin-releasing

**Table 58.1** Medical Problems Commonly Associated with Anorexia Nervosa

Skin
Lanugo
Cardiovascular system
Hypotension
Bradycardia
Arrhythmias
Hematopoietic system
Normochromic, normocytic anemia
Leukopenia
Diminished polymorphonuclear leukocytes
Fluid and electrolyte balance
Elevated blood urea nitrogen and creatinine concentrations
Hypokalemia
Hyponatremia
Hypochloremia
Alkalosis
Gastrointestinal system
Elevated serum concentration of liver enzymes
Delayed gastric emptying
Constipation
Endocrine system
Diminished thyroxine with normal thyroid-stimulating level hormone level
Elevated plasma cortisol level
Diminished secretion of luteinizing hormone, hormone, estrogen, or testosterone follicle-stimulating
Bone
Osteoporosis

hormone from the hypothalamus. Therefore, the amenorrhea of anorexia nervosa is properly viewed as a type of hypothalamic amenorrhea. It is of interest that in a significant minority amenorrhea begins before substantial weight loss has occurred, suggesting that factors other than malnutrition, such as psychological distress, contribute significantly to the disruption of the reproductive endocrine system.

In an adult with anorexia nervosa, the status of the hypothalamic–pituitary–gonadal axis resembles that of a pubertal or prepubertal child—the secretion of estrogen or testosterone, of luteinizing hormone and follicle-stimulating hormone and of gonadotropin-releasing hormone is reduced. This endocrinological picture may be contrasted with that of postmenopausal women who have a similar reduction in estrogen secretion but who, unlike women with anorexia nervosa, show increased pituitary gonadotropin secretion. Furthermore, even the circadian patterns of luteinizing hormone and follicle-stimulating hormone secretion in adult women with anorexia nervosa closely resemble the patterns normally seen in pubertal and prepubertal girls. Although similar abnormalities are also seen in other forms of hypothalamic amenorrhea and are therefore not specific to anorexia nervosa, it is nonetheless striking that this syndrome is accompanied by a physiological arrest or regression of the reproductive endocrine system.

The functioning of other hormonal systems is also disrupted in anorexia nervosa, although typically not as profoundly as is the reproductive axis. Presumably as part of the metabolic response to semistarvation, the activity of the thyroid gland is reduced.

Plasma thyroxine levels are somewhat diminished, but the plasma level of the pituitary hormone and thyroid-stimulating hormone is not elevated. The activity of the hypothalamic–pituitary–adrenal axis is increased, as indicated by elevated plasma levels of cortisol and by resistance to dexamethasone suppression. The regulation of vasopressin (antidiuretic hormone) secretion from the posterior pituitary is disturbed, contributing to the development of partial diabetes insipidus in some individuals.

Anorexia nervosa is often associated with the development of leukopenia and of a normochromic, normocytic anemia of mild to moderate severity. Surprisingly, leukopenia does not appear to result in a high vulnerability to infectious illnesses. Serum levels of liver enzymes are sometimes elevated, particularly during the early phases of refeeding, but the synthetic function of the liver is rarely seriously impaired so that the serum albumin concentration and the prothrombin time are usually within normal limits. Serum cholesterol levels are sometimes elevated in anorexia nervosa, although the basis of this abnormality remains obscure. In some patients, self-imposed fluid restriction and excessive exercise produce dehydration and elevations of serum creatinine and blood urea nitrogen. In others, water loading may lead to hyponatremia. The status of serum electrolytes is a reflection of the individual's salt and water intake and the nature and the severity of the purging behavior. A common pattern is hypokalemia, hypochloremia and mild alkalosis resulting from frequent and persistent self-induced vomiting.

It has become clear that individuals with anorexia nervosa have decreased bone density compared with age- and sex-matched peers and, as a result, are at increased risk for fractures. Low levels of estrogen, high levels of cortisol and poor nutrition have been cited as risk factors for the development of reduced bone density in anorexia nervosa. Theoretically, estrogen treatment might reduce the risk of osteoporosis in women who are chronically amenorrheic because of anorexia nervosa, but controlled studies indicate that this intervention is of limited, if any, benefit.

Abnormalities of cardiac function include bradycardia and hypotension, which are rarely symptomatic. The pump function of the heart is compromised, and congestive heart failure occasionally develops in individuals during overly rapid refeeding. The electrocardiogram shows sinus bradycardia and a number of nonspecific abnormalities. Arrhythmias may develop, often in association with fluid and electrolyte disturbances. It has been suggested that significant prolongation of the QT interval may be a harbinger of life-threatening arrhythmias in some individuals with anorexia nervosa, but this has not been conclusively demonstrated.

The motility of the gastrointestinal tract is diminished, leading to delayed gastric emptying and contributing to complaints of bloating and constipation. Rare cases of acute gastric dilatation or gastric rupture, which is often fatal, have been reported in individuals with anorexia nervosa who consumed large amounts of food when binge-eating.

As already noted, virtually all of the physiological abnormalities described in individuals with anorexia nervosa are also seen in other forms of starvation, and most improve or disappear as weight returns to normal. Therefore, weight restoration is essential for physiological recovery. More surprisingly, perhaps, weight restoration is believed to be essential for psychological recovery as well. Accounts of human starvation amply document the profound impact of starvation on mental health. Starving individuals lose their sense of humor, their interest in friends and family fades

and mood generally becomes depressed. They may develop peculiar behavior similar to that of patients with anorexia nervosa, such as hoarding food or concocting bizarre food combinations. If starvation disrupts psychological and behavioral functioning in normal individuals, it presumably does so as well in those with anorexia nervosa. Thus, correction of starvation is a prerequisite for the restoration of both physical and psychological health.

## Diagnosis and Differential Diagnosis

### Phenomenology

Anorexia nervosa often begins innocently. Typically, an adolescent girl or young woman who is of normal weight or, perhaps, a few pounds overweight decides to diet. This decision may be prompted by an important but not extraordinary life event, such as leaving home for camp, attending a new school, or a casual unflattering remark by a friend or family member. Initially, the dieting seems no different from that pursued by many young women, but as weight falls, the dieting intensifies. The restrictions become broader and more rigid; for example, desserts may first be eliminated, then meat, then any food that is thought to contain fat. The person becomes increasingly uncomfortable if she is seen eating and avoids meals with others. Food seems to assume a moral quality so that vegetables are viewed as “good” and anything with fat is “bad”. The individual has idiosyncratic rules about how much exercise she must do and when, where and how she can eat.

Food avoidance and weight loss are accompanied by a deep and reassuring sense of accomplishment, and weight gain is viewed as a failure and a sign of weakness. Physical activity, such as running or aerobic exercise, often increases as the dieting and weight loss develop. Inactivity and complaints of weakness usually occur only when emaciation has become extreme. The person becomes more serious and devotes little effort to anything but work, dieting and exercise. She may become depressed and emotionally labile, socially withdrawn and secretive and she may lie about her eating and her weight. Despite the profound disturbances in her view of her weight and of her calorie needs, reality testing in other spheres is intact, and the person may continue to function well in school or at work. Symptoms usually persist for months or years until, typically at the insistence of friends or family, the person reluctantly agrees to see a physician.

In general, anorexia nervosa is not difficult to recognize. Uncertainty surrounding the diagnosis sometimes occurs in young adolescents, who may not clearly describe a drive for thinness and the fear of becoming fat. Rather, they may acknowledge only a vague concern about consuming certain foods and an intense desire to exercise. It can also be difficult to elicit the distorted view of shape and weight (criterion C) from patients who have had anorexia nervosa for many years. Such individuals may state that they realize they are too thin and may make superficial efforts to gain weight, but they do not seem particularly concerned about the physical risks or deeply committed to increasing their calorie consumption.

## Assessment

### Special Issues in Psychiatric Examination and History

In assessing individuals who may have anorexia nervosa, it is important to obtain a weight history including the individual's highest and lowest weights and the weight he or she would

like to be now. For women, it is useful to know the weight at which menstruation last occurred, because it provides an indication of what weight is normal for that individual. The patient should be asked to describe a typical day's food intake and any food restrictions and dietary practices such as vegetarianism. The psychiatrist should ask whether the patient ever loses control over eating and engages in binge-eating and, if so, the amounts and types of food eaten during such episodes. The use of self-induced vomiting, laxatives, diuretics, enemas, diet pills, and syrup of ipecac to induce vomiting should also be queried.

Probably the greatest problem in the assessment of patients with anorexia nervosa is their denial of the illness and their reluctance to participate in an evaluation. A straightforward but supportive and nonconfrontational style is probably the most useful approach, but it is likely that the patient will not acknowledge significant difficulties in eating or with weight and will rationalize unusual eating or exercise habits. It is therefore helpful to obtain information from other sources such as the patient's family.

### Physical Examination and Laboratory Findings

The patient should be weighed, or a current weight should be obtained from the patient's general physician. Blood pressure, pulse and body temperature are often below the lower limit of normal. On physical examination, lanugo, a fine, downy hair normally seen in infants, may be present on the back or the face. The extremities are frequently cold and have a slight red–purple color (acrocyanosis). Edema is rarely observed at the initial presentation but may develop transiently during the initial stages of refeeding.

The basis for laboratory abnormalities is presented in the earlier section on pathophysiology. Common findings are a mild to moderate normochromic, normocytic anemia and leukopenia, with a deficit in polymorphonuclear leukocytes leading to a relative lymphocytosis. Elevations of blood urea nitrogen and serum creatinine concentrations may occur because of dehydration, which can also artificially elevate the hemoglobin and hematocrit. A variety of electrolyte abnormalities may be observed, reflecting the state of hydration and the history of vomiting and diuretic and laxative abuse. Serum levels of liver enzymes are usually normal but may transiently increase during refeeding. Cholesterol levels may be elevated.

The electrocardiogram typically shows sinus bradycardia and, occasionally, low QRS voltage and a prolonged QT interval; a variety of arrhythmias have also been described.

### Differences in Presentation
